Greenspan's Basic & Clinical Endocrinology

Ninth Edition

Edited by

David G. Gardner, MD, MS
Mount Zion Health Fund Distinguished Professor of Endocrinology and Medicine
Chief, Division of Endocrinology and Metabolism
Department of Medicine and Diabetes Center
University of California, San Francisco

Dolores Shoback, MD
Professor of Medicine
Department of Medicine
University of California, San Francisco
Staff Physician, Endocrine-Metabolism Section,
Department of Medicine
San Francisco Veterans Affairs Medical Center
Contents

1. Hormones & Hormone Action  
   David G. Gardner, MD, Mark Anderson, MD, PhD, & Robert A. Nissenson, PhD
   Relationship to the Nervous System  2
   Chemical Nature of Hormones  3
   Endocrine Glands & Target Organs  4
   Regulation of Hormone Levels in Plasma  4
   Hormone Action  5
   Receptors  5
   Neurotransmitter & Peptide Hormone Receptors  6
   G Protein–Coupled Receptors  7
   G Protein Transducers  8
   Effectors  9
   Disorders of G Proteins & G Protein–Coupled Receptors  11
   Growth Factor Receptors  13
   Cytokine Receptors  14
   Guanylyl Cyclase–Linked Receptors  16
   Nuclear Action of Peptide Hormones  18
   Nuclear Receptors  18
   Steroid Receptor Family  18
   Thyroid Receptor Family  21
   Nongenomic Effects of the Steroid Hormones  25
   Steroid & Thyroid Hormone Receptor Resistance Syndromes  25

2. Endocrine Autoimmunity  
   Juan Carlos Jaume, MD
   Immune Recognition & Response  28
   Tolerance  31
   T-Cell Tolerance  31
   B-Cell Tolerance  35
   Autoimmunity is Multifactorial  35
   Genetic Factors in Autoimmunity  36
   Environmental Factors in Autoimmunity  36
   Single-Gland Autoimmune Syndromes  37
   Autoimmune Aspects of Thyroid Disease  37
       Genes & Environment  37
       Autoimmune Response  37
       Animal Models of Autoimmune Thyroid Disease  38
   Autoimmune Aspects of Type 1 Diabetes  38
       Genes & Environment  39
       Autoimmune Response  39
       Animal Models of Autoimmune Diabetes Mellitus  40
   Autoimmune Aspects of Other Endocrinopathies  40
       Autoimmune Adrenal Failure  40
       Autoimmune Oophoritis & Orchitis  41
       Autoimmune Hypophysitis  41
       Autoimmune Hypoparathyroidism  41
   Autoimmune Polyglandular Syndromes  42
   Autoimmune Polyglandular Syndrome I (APS-I)  42
   Autoimmune Polyglandular Syndrome II (APS-II)  43
   Management of Autoimmune Polyglandular Syndromes  44
   Immunodeficiency, Polyendocrinopathy, & Enteropathy, X-Linked Syndrome  44
   POEMS Syndrome (Osteosclerotic Myeloma)  44

3. Evidence-Based Endocrinology & Clinical Epidemiology  
   David C. Aron, MD, MS
   Diagnostic Testing: Test Characteristics  47
       Sensitivity & Specificity  48
       Receiver-Operating Characteristic Curves  50
       Predictive Values, Likelihood Ratios, & Diagnostic Accuracy  51
   An Approach to Diagnosis in Practice  52
   Clinical Epidemiologic Principles Applied to Treatment Decisions  54
   Decision Analysis  55
       Determine the Probability of Each Chance Event  57
       Deciding on a Strategy: Averaging Out & Folding Back the Tree  58
       Discounting Future Events  58
       Sensitivity Analysis  58
       Cost-Effectiveness Analysis Using Decision Analysis  58
       Other Aspects of Clinical Epidemiology  58
   Evidence-Based Endocrinology  58
       Step One: Translation of the Clinical Problem into Answerable Questions  61
       Step Two: Finding the Best Evidence  61
       Step Three: Appraising the Evidence for Its Validity & Usefulness  61
       Steps Four & Five: Applying the Results in Practice & Evaluating Performance  62

4. Hypothalamus & Pituitary Gland  
   Bradley R. Javorsky, MD, David C. Aron, MD, MS, James W. Findling, MD, & J. Blake Tyrrell, MD
   Anatomy & Embryology  66
   Blood Supply  68
   Pituitary Development & Histology  68
   Hypothalamic Hormones  70
       Hypophysiotropic Hormones  70
       Neuroendocrinology: The Hypothalamus as Part of a Larger System  73
5. The Posterior Pituitary (Neurohypophysis) 115

Alan G. Robinson, MD

- Physiology of Hormone Function 115
- Anatomy of Hormone Synthesis & Release 117
- Pathophysiology 117
- Diagnostic Tests of Diabetes Insipidus 120
- Treatment of Diabetes Insipidus 121
- Treatment of Hyponatremia in SIADH 125
- Summary 126

6. Growth 129

Dennis Styne, MD

- Normal Growth 129
- Intrauterine Growth 129
- The Placenta 130
- Classic Hormones of Growth & Fetal Growth 130
- Growth Factors & Oncogenes in Fetal Growth 130
- Insulin-like Growth Factors, Receptors, & Binding Proteins 130
- Insulin 131
- Epidermal Growth Factor 131
- Fetal Origins of Adult Disease 132
- Postnatal Growth 132
- Measurement of Growth 139
- Skeletal (Bone) Age 142
- Disorders of Growth 142
- Short Stature due to Nonendocrine Causes 142
- Short Stature due to Endocrine Disorders 146

7. The Thyroid Gland 163

David S. Cooper, MD &
Paul W. Ladenson, MA (Oxon.), MD

- Embryology, Anatomy, & Histology 163
- Physiology 163
  - Structure & Synthesis of Thyroid Hormones 163
- Iodine Metabolism 164
  - Thyroid Hormone Synthesis & Secretion 164
- Abnormalities in Thyroid Hormone Synthesis & Release 168
- Thyroid Hormone Transport 169
- Metabolism of Thyroid Hormones 171
- Control of Thyroid Function & Hormone Action 173
- Physiologic Changes in Thyroid Function 181
- Thyroid Autoimmunity 183
- Tests of Thyroid Function 184
  - Tests of Thyroid Hormones in Blood 184
  - Assessment of Thyroid Iodine Metabolism & Biosynthetic Activity 187
- Thyroid Imaging 188
- Thyroid Ultrasonography & Other Imaging Techniques 189
- Thyroid Biopsy 189
- Test of Peripheral Thyroid Hormone Actions 190
- Measurement of Thyroid Autoantibodies 190
- Disorders of the Thyroid 190
  - Hypothyroidism 191
  - Hyperthyroidism & Thyrotoxicosis 198
  - Nontoxic Goiter 209
  - Thyroiditis 211
  - Effects of Ionizing Radiation on the Thyroid Gland 214
- Thyroid Nodules & Thyroid Cancer 214

8. Metabolic Bone Disease 227

Dolores Shoback, MD, Deborah Sellmeyer, MD, &
Daniel D. Bikle, MD, PhD

- Cellular & Extracellular Calcium Metabolism 227
- Parathyroid Hormone 228
- Vitamin D 234
- How Vitamin D & PTH Control Mineral Homeostasis 241
- Medullary Carcinoma of the Thyroid 241
- Hypercalcemia 242
- Disorders Causing Hypercalcemia 244
- Treatment of Hypercalcemia 252
- Hypocalcemia 252
- Causes of Hypocalcemia 254
- Treatment of Hypocalcemia 258
- Bone Anatomy & Remodeling 258
- Functions of Bone 258
- Structure of Bone 259
- Bone Remodeling 261
- Osteoporosis 262
- Treatment of Osteoporosis 266
- Glucocorticoid-Induced Osteoporosis 270
- Osteomalacia & Rickets 271
Nephrotic Syndrome 273
Hepatic Osteodystrophy 274
Drug-Induced Osteomalacia 274
Hypophosphatemic Disorders 274
Calcium Deficiency 276
Primary Disorders of the Bone Matrix 276
Osteogenesis Imperfecta 276
Inhibitors of Mineralization 277
Paget Disease of Bone (Osteitis Deformans) 277
Etiology 277
Renal Osteodystrophy 280
Hereditary Forms of Hyperphosphatemia 281

9. Glucocorticoids & Adrenal Androgens 285
Ty B. Carroll, MD, David C. Aron, MD, MS, James W. Findling, MD, & J. Blake Tyrrell, MD
Embryology & Anatomy 285
Biosynthesis of Cortisol & Adrenal Androgens 287
Circulation of Cortisol & Adrenal Androgens 292
Metabolism of Cortisol & Adrenal Androgens 292
Biologic Effects of Adrenal Steroids 294
Adrenal Androgens 299
Laboratory Evaluation 299
Disorders of Adrenocortical Insufficiency 303
Primary Adrenocortical Insufficiency (Addison Disease) 303
Secondary Adrenocortical Insufficiency 308
Diagnosis of Adrenocortical Insufficiency 308
Treatment of Adrenocortical Insufficiency 310
Prognosis of Adrenocortical Insufficiency 312
Cushing Syndrome 312
Hirsutism & Virilism 323
Incidental Adrenal Mass 323
Glucocorticoid Therapy for Nonendocrine Disorders 324

10. Endocrine Hypertension 329
William F. Young, Jr, MD, MSc
Renin-Angiotensin-Aldosterone System 329
Renin & Angiotensin 329
Aldosterone 331
Primary Aldosteronism 332
Other Forms of Mineralocorticoid Excess or Effect 340
Hyperdeoxy corticalinism 340
Apparent Mineralocorticoid Excess Syndrome 340
Liddle Syndrome—Abnormal Renal Tubular Ionic Transport 341
Hypertension Exacerbated by Pregnancy 341
Other Endocrine Disorders Associated with Hypertension 341
Cushing Syndrome 341
Thyroid Dysfunction 342
Acromegaly 342

11. Adrenal Medulla & Paraganglia 345
Paul A. Fitzgerald, MD
Anatomy 346
Hormones of the Adrenal Medulla & Paraganglia 347
Catecholamines 347
Catecholamine (Adrenergic) Receptors 352
Disorders of the Adrenal Medulla & Paraganglia 357
Epinephrine & Norepinephrine Deficiency 357
Pheochromocytoma & Paraganglioma 358
Incidentally Discovered Adrenal Masses 381

12. Testes 395
Glenn D. Braunstein, MD
Anatomy & Structure-Function Relationships 395
Testes 395
Physiology of The Male Reproductive System 397
Accessory Structures 397
Gonadal Steroids 397
Control of Testicular Function 399
Evaluation of Male Gonadal Function 400
Clinical Evaluation 400
Laboratory Tests of Testicular Function 401
Pharmacology of Drugs used to Treat Male Gonadal Disorders 403
Androgens 403
Gonadotropins 405
Gonadotropin-Releasing Hormone 405
Clinical Male Gonadal Disorders 405
Klinefelter Syndrome (XY Seminiferous Tubule Dysgenesis) 405
Bilateral Anorchia (Vanishing Testes Syndrome) 407
Leydig Cell Aplasia 408
Cryptorchidism 409
Noonan Syndrome (Male Turner Syndrome) 410
Myotonic Dystrophy 411
Adult Seminiferous Tubule Failure 411
Adult Leydig Cell Failure (Andropause) 412
Male Infertility 413
Erectile Dysfunction 415
Gynecomastia 417
Testicular Tumors 420

13. Female Reproductive Endocrinology & Infertility 423
Mitchell P. Rosen, MD & Marcelle I. Cedars, MD
Embryology & Anatomy 424
Ovarian Steroidogenesis 426
Physiology of Folliculogenesis & the Menstrual Cycle 427
Amenorrhea 436
Hypothalamic Amenorrhea 437
Pituitary Amenorrhea 440
Ovarian Amenorrhea 442
Anovulation 445
Obesity 452
Outflow Tract Disorders 454
Menopause 455
Oocyte Depletion 455
Endocrine System Changes with Aging 456
Menopausal Consequences 458
Infertility 461
Diagnosis of Infertility 461
Management of the Infertile Couple 463
Contraception 464
Oral Contraceptives 464
Contraception: Long-Acting Contraceptives 470
Emergency Contraception 475

14. Disorders of Sex Determination & Differentiation 479
Felix A. Conte, MD, & Melvin M. Grumbach, MD

Human Sex Differentiation 480
Testicular & Ovarian Differentiation 485
Psychosexual Differentiation 489
Classification & Nomenclature of Disorders of Sex Determination (& Differentiation) 489
Klinefelter Syndrome & Its Variants: Seminiferous Tubule Dysgenesis—Sex Chromosome DSD 493
Syndrome of Gonadal Dysgenesis: Turner Syndrome & Its Variants 495
Ovotesticular DSD (Individuals with Both Ovarian & Testicular Tissue) 500
46,XY DSD Androgen Induced (Female Pseudohermaphroditism) 502
P450 Aromatase Deficiency 509
Maternal Source Androgens & Progestogens 509
Unclassified Forms of Abnormal Sexual Development in Males 517
Unclassified Forms of Abnormal Sexual Development in Females 519
Management of Patients with DSD 519

15. Puberty 527
Dennis Styne, MD

Physiology of Puberty 527
Physical Changes Associated with Puberty 527
Endocrine Changes from Fetal Life to Puberty 531
Ovulation & Menarche 534
Adrenarche 534
Miscellaneous Metabolic Changes 535
Delayed Puberty or Absent Puberty (Sexual Infantilism) 535
Constitutional Delay in Growth & Adolescence 535
Hypogonadotropic Hypogonadism 535
Hypergonadotropic Hypogonadism 540
Differential Diagnosis of Delayed Puberty 542
Treatment of Delayed Puberty 543
Precocious Puberty (Sexual Precocity) 545
Central (Complete or True) Precocious Puberty 545

16. The Endocrinology of Pregnancy 553
Robert N. Taylor, MD, PhD & Martina L. Badell, MD

Conception & Implantation 553
Fertilization 553
Implantation & hCG Production 554
Ovarian Hormones of Pregnancy 555
Symptoms & Signs of Pregnancy 555
Fetal-Placental-Decidual Unit 555
Polypeptide Hormones 555
Human Chorionic Gonadotropin 555
Human Placental Lactogen 555
Other Chorionic Peptide Hormones & Growth Factors 558
Steroid Hormones 558
Progesterone 558
Estrogens 558
Maternal Adaptation to Pregnancy 559
Maternal Pituitary Gland 559
Maternal Thyroid Gland 559
Maternal Parathyroid Gland 559
Maternal Pancreas 559
Maternal Adrenal Cortex 561
Fetal Endocrinology 562
Fetal Pituitary Hormones 562
Fetal Thyroid Gland 562
Fetal Adrenal Cortex 562
Fetal Gonads 562
Endocrine Control of Parturition 563
Sex Steroids 563
Oxytocin 563
Prostaglandins 563
Preterm Labor/Birth 563
Maternal/Fetal Stress 564
Pathologic Uterine Distention 564
Infection/Inflammation 564
Decidual Hemorrhage & Coagulation 564
Postterm Pregnancy 565
Management of Postterm Pregnancy 565
Endocrinology of the Puerperium 566
Physiologic & Anatomic Changes 566
Uterine Changes 566
Endocrine Changes 566
Lactation 566
Endocrine Disorders & Pregnancy 567
Hyperthyroidism in Pregnancy 567
Hypothyroidism in Pregnancy 567
Pituitary Disorders in Pregnancy 567
Obesity & Pregnancy 568
Parathyroid Disease & Pregnancy 569
Preeclampsia/Eclampsia 569
17. Pancreatic Hormones & Diabetes Mellitus

Umesh Masharani, MB, BS, MRCP (UK) & Michael S. German, MD

The Endocrine Pancreas 574
Anatomy & Histology 574
Hormones of the Endocrine Pancreas 575
Diabetes Mellitus 587
Classification 587
Type 1 Diabetes Mellitus 587
Type 2 Diabetes 590
Other Specific Types of Diabetes 593
Clinical Features of Diabetes Mellitus 599
Treatment of Diabetes Mellitus 609
Agents for the Treatment of Hyperglycemia 610
Sulfonylureas 612
Steps in the Management of the Diabetic Patient 622
Immunopathology of Insulin Therapy 625
Acute Complications of Diabetes Mellitus 626
Transition to Subcutaneous Insulin Regimen 631
Chronic Complications of Diabetes Mellitus 634
Specific Chronic Complications of Diabetes Mellitus 636
Management of Diabetes in the Hospitalized Patient 642
Diabetes Mellitus & Pregnancy 644

18. Hypoglycemic Disorders

Umesh Masharani, MB, BS, MRCP (UK) & Stephen E. Gitelman, MD

Pathophysiology of the Counterregulatory Response to Neuroglycopenia 658
Counterregulatory Response to Hypoglycemia 659
Maintenance of Euglycemia in the Postabsorptive State 660
Classification of Hypoglycemic Disorders 661
Diabetes 661
Factitious Hypoglycemia 662
Drugs 662
Autoimmune Hypoglycemia 663
Pancreatic ß Cell Tumors 663
Congenital Hyperinsulinism 670

19. Disorders of Lipoprotein Metabolism

Mary J. Malloy, MD & John P. Kane, MD, PhD

Atherosclerosis 675
Overview of Lipid Transport 676
Differentiation of Disorders of Lipoprotein Metabolism 680
Clinical Descriptions of Primary & Secondary Disorders of Lipoprotein Metabolism 681
The Hypertriglycerideremias 681
Primary Hypertriglyceridermia 683
Secondary Hypertriglyceridermia 685

CONTENTS vii

The Primary Hypercholesterolemias 687
Familial Hypercholesterolemia 687
Familial Combined Hyperlipidemia 687
Lp(a) Hyperlipoproteinemia 688
Familial Ligand-Defective Apo B-100 688
Cholesterol 7a-Hydroxylase Deficiency 688
Hypothyroidism 688
Nephrosis 688
Immunglobulin Disorders 688
Anorexia Nervosa 688
Cholestasis 689
The Primary Hypolipidemias 689
Primary Hypolipidemia due to Deficiency of High-Density Lipoproteins 689
Primary Hypolipidemia due to Deficiency of Apo B–Containing Lipoproteins 690
Secondary Hypolipidemia 691
Other Disorders of Lipoprotein Metabolism 691
The Lipodystrophies 691
Rare Disorders 692
Treatment of Hyperlipidemia 692
Dietary Factors in the Management of Lipoprotein Disorders 693
Drugs Used in Treatment of Hyperlipoproteinemia 694
Bile Acid Sequestrants 694
Niacin (Nicotinic Acid) 695
Fibric Acid Derivatives 695
HMG-CoA Reductase Inhibitors 696
Cholesterol Absorption Inhibitors 697
Combined Drug Therapy 697

20. Obesity

Alka M. Kanaya, MD & Christian Vaisse, MD, PhD

Definition & Epidemiology 699
Definition 699
Prevalence & Projections 699
Possible Explanations for the Increased Obesity Rates 700
Pathophysiology & Genetics of Obesity 700
Regulation of Food Intake & Energy Expenditure 700
Informing the Brain of the Energy Status: Leptin & Short-Term Gastrointestinal Signals 700
Central Integration of Energy Homeostasis Signals 701
Leptin Resistance in Obesity 702
Genetics of Obesity 702
Health Consequences of Obesity 703
Mechanism Underlying Obesity Complications: Adipose Tissue as an Endocrine Organ 703
Metabolic Complications of Obesity: Insulin Resistance & Type 2 Diabetes 704
Dyslipidemia 705
The Metabolic Syndrome 705
Cardiovascular Complications 705
Pulmonary Complications 705
Gastrointestinal Complications 706
Reproduction & Gynecologic Complications 706
Cancer 706
Management of the Obese Patient 706
Screening & Prevention of Complications 706
Therapeutic Approaches for Weight Loss 706
21. Humoral Manifestations of Malignancy  711
Dolores Shoback, MD, & Janet L. Funk, MD

Ectopic Hormone & Receptor Syndromes  711
APUD Concept of Neuroendocrine Cell Tumors  712
Hypercalcemia of Malignancy  712
Pathogenesis  712
Humoral Mediators  712
Solid Tumors Associated with Hypercalcemia of Malignancy  713
Hematologic Malignancies Associated with Hypercalcemia of Malignancy  714
Diagnosis  715
Treatment  715
Ectopic Cushing Syndrome  715
Differential Diagnosis  715
Clinical Features  717
Syndrome of Inappropriate Antidiuretic Hormone Secretion  717
Etiology & Pathogenesis  718
Clinical & Laboratory Features  718
Non-Islet Cell Tumor-Induced Hypoglycemia  718
Other Hormones Secreted by Tumors  719
Oncogenic Osteomalacia  720
Etiology & Clinical Features  720
Pathology & Pathogenesis  720
Gut Hormones  721

22. Multiple Endocrine Neoplasia  723
David G. Gardner, MD

Multiple Endocrine Neoplasia Type 1  723
Pathogenesis  725
Treatment  726
Screening  727
Multiple Endocrine Neoplasia Type 2  729
Pathogenesis  730
Treatment  732
Screening  732
Other Disorders Characterized by Multiple Endocrine Organ Involvement  733
Carney Complex  733
McCune-Albright Syndrome  734
Neurofibromatosis Type 1  734
Von Hippel-Lindau Disease  734
MEN X  734

23. Geriatric Endocrinology  737
Susan L. Greenspan, MD, Mary Korykowski, MD, & Neil M. Resnick, MD

Thyroid Function & Disease  738
Disorders of the Thyroid Gland  738
Hyperthyroidism  739
Hypothyroidism  741
Multinodular Goiter  742
Thyroid Nodules & Cancer  743
Carbohydrate Intolerance & Diabetes Mellitus  743
Osteoporosis  750

Hyperparathyroidism  757
Changes in Water Balance  757
Hypernatremia  758
Hyponatremia  758
Hyporeninemic Hypoaldosteronism  758
Glucocorticoids & Stress  758
Disorders of the Hypothalamic-Pituitary-Adrenal Axis  759
Changes in Reproductive Function in Men  760

24. Endocrine Emergencies  763
David G. Gardner, MD

Myxedema Coma  763
Thyroid Storm  765
Thyrotoxic Periodic Paralysis  766
Amiodarone-Induced Thyrotoxicosis  767
Acute Adrenal Insufficiency  768
Pituitary Apoplexy  769
Diabetic Ketoacidosis  769
Nonketotic Hyperosmolar Coma  773
Hypercalcemic Crisis  775
Acute Hypocalcemia  777
Hyponatremia  779
Diabetes Insipidus  782

25. AIDS Endocrinopathies  787
Carl Grunfeld, MD, PhD & Grace Lee, MD

Thyroid Disorders  787
Adrenal Disorders  789
Bone & Mineral Disorders  791
Gonadal Disorders  792
Pituitary Disorders  794
AIDS Wasting Syndrome  794
Abnormalities of Fat Distribution Associated with HIV  795
Disorders of Glucose & Lipid Metabolism  796
Conclusion  801

26. Endocrine Surgery  803
Geeta Lal, MD & Orlo H. Clark, MD

The Thyroid Gland  803
Embryology & Anatomy  803
Developmental Thyroid Abnormalities  804
Hyperthyroidism  804
Thyroiditis  805
Goiter (Nontoxic)  805
Thyroid Nodules  805
Thyroid Cancer  806
Conduct of Thyroidectomy  809
The Parathyroid Gland  811
Embryology & Anatomy  811
Primary Hyperparathyroidism  811
Secondary Hyperparathyroidism  814
Primary Hyperparathyroidism  814
Secondary Hyperparathyroidism  814
Special Consideration: Familial Hyperparathyroidism  815
Complications of Parathyroid Surgery  815
The Adrenal (Suprarenal) Gland  815

Preface

This represents the ninth edition of *Greenspan's Basic & Clinical Endocrinology*—the first in an all-color format, which we hope will add to the value of the text for our readers. Each of the individual chapters has been revised and updated to contain the most current information in the field. We have introduced two entirely new chapters on Endocrine Hypertension (Chapter 10) and Obesity (Chapter 20) and added five new authors to our existing chapters.

Once again, we hope that you will find this text useful in dealing with the expanding world of basic and clinical endocrinology, and we trust that you will find it a valuable tool for education of trainees and the treatment of endocrine patients.

</table>
Hormones are signaling molecules that traffic information from one cell to another, typically through a soluble medium like the extracellular fluid. Hormones fall into one of a number of different hormonal classes (e.g., steroids, monoamines, peptides, proteins, eicosanoids) and signal through a variety of general (e.g., nuclear vs cell surface) and specific (e.g., tyrosine kinase vs phosphoinositide turnover) mechanisms in target cells.

Hormones produced in one tissue may promote activity in a target tissue at some distance from the point of secretion. In this case the hormone travels through the bloodstream, often bound to a plasma protein, to access the target tissue. In addition, hormones may act locally following secretion; either on a neighboring cell (paracrine effect), on the secretory cell itself (autocrine effect), or without actually being released from the secretory cell (intracrine effect) (Figure 1–1).

Identification of a tissue as a target for a particular hormone requires the presence of receptors for the hormone in cells of the target tissue. These receptors, in turn, are linked to effector mechanisms that lead to the physiological effects associated with the hormone.

**RELATIONSHIP TO THE NERVOUS SYSTEM**

Many features of the endocrine system, for example, the use of ligands and receptors to establish communication between cells, are shared by the nervous system. In fact, from a functional standpoint, the two systems are probably related from an evolutionary standpoint. However, there are some important differences between the two systems. While the nervous system uses a highly compartmentalized, closed system of cables to connect cells at some distance from one another, the endocrine system relies on circulating plasma to carry newly released hormone to its targets in the periphery. As a result, the time constants for signal delivery are quite different between the two—virtually instantaneous for the nervous system but delayed, by virtue of circulation times, for the endocrine system. Thus, while neural responses are typically measured in seconds, endocrine responses are measured in minutes to hours—thereby accommodating different needs in the organism. A second difference relates to the nature of the ligand–receptor interaction. In the nervous system, the affinity of receptor for ligand is relatively low. This allows for rapid dissociation of ligand from receptor and, if that ligand is degraded locally, a rapid cessation of biological effect. Despite this rapid dissociation, the secretory neuron is able to maintain receptor occupancy by keeping concentrations of the ligand high around the target neuron. It does this through pulsatile release of secretory granules into an incredibly small volume (i.e., that determined by the volume in the synaptic cleft). The endocrine system, on the other hand, has a very large volume of distribution for many of its ligands (e.g., circulating blood
FIGURE 1-1 Actions of hormones and neurotransmitters. Endocrine and neurotransmitter cells synthesize hormones and release them by specialized secretory pathways or by diffusion. Hormones can act at the site of production either following release (autocrine) or without release (intracrine) from the producer cell. They can also act on neighboring target cells, including neurotransmitter-producing cells, without entering the circulation (paracrine). Finally, they can access target cells through the circulation (hormonal). Neurotransmitters that access the extracellular compartment, including circulating plasma, can act as paracrine or hormonal regulators of target cell activity (H, hormone; N, neurotransmitter; R, receptor).

CHEMICAL NATURE OF HORMONES

Hormones vary widely in terms of their chemical composition. Specific examples include proteins (e.g., adrenocorticotropic hormone), peptides (e.g., vasopressin), monoamines (e.g., norepinephrine), amino acid derivatives (e.g., triiodothyronine), steroids (e.g., cortisol), and lipids (e.g., prostaglandins). Proteins can be glycosylated (e.g., thyroid-stimulating hormone) and/or dimerized (e.g., follicle-stimulating hormone) to generate full biological activity. In general, protein, peptide, monoamine, and lipophilic hormones tend to exert their effects primarily through protein receptors at the cell membrane, while thyroid hormone and steroids tend to operate in the cell nucleus. However, there are increasing numbers of exceptions to these rules (e.g., triiodothyronine activates classic thyroid hormone receptors in the nuclear compartment, and the trace amine receptor [TAR1] on the cell surface and estradiol appears to activate both nuclear
and plasma membrane receptors). It is likely that the biological “effect” of a given hormone reflects a composite of receptor activity located in several different cellular compartments.

**ENDOCRINE GLANDS AND TARGET ORGANS**

Endocrine glands are traditionally defined as the ductless glandular structures that release their hormonal secretions into the extracellular space where they eventually access circulating plasma. Classic endocrine glands include organs like the pituitary gland, thyroid gland, parathyroid glands, pancreatic islets, adrenal glands, ovaries, and testes. It is now clear that hormones can be secreted from nontraditional endocrine organs and play critical roles in the regulation of physiological homeostasis. Examples of the latter include the heart (natriuretic peptides), kidney (erythropoietin and renin), adipose tissue (leptin and adiponectin), and gut (cholecystokinin and incretins). Once in the circulation, hormones bind to receptors on target tissues to elicit their biological effects. Target tissues for some hormones (eg, glucocorticoids) are numerous reflecting the ubiquitous distribution of glucocorticoid receptors, while those for other tissues have a more limited distribution (eg, androgens).

**REGULATION OF HORMONE LEVELS IN PLASMA**

Hormone levels in plasma determine the effective ligand concentration at the level of the hormone receptors in peripheral target cells. Thus, regulation of hormone levels plays an important role in the control of the biological effects that the hormone exerts.

**Hormone Biosynthesis**

New hormone synthesis is one of the principal mechanisms used to raise hormone levels in circulating plasma. In the case of protein or peptide hormones this usually reflects increased expression of the gene encoding the hormone (ie, increased production of the mRNA encoding the hormone) with subsequent increase in hormone synthesis. In the case of steroid or thyroid hormones it reflects increased sequestration of precursors for hormone synthesis (eg, cholesterol for steroid hormones or iodide for thyroid hormone) as well as increased activity of those enzymatic proteins responsible for executing the individual catalytic events required for hormone production—typically the latter may involve a rate-limiting step in the synthetic cascade (eg, 1-alpha hydroxylase activity in the synthesis of 1,25-dihydroxyvitamin D).

**Precursor Processing**

Processing of hormone precursors participates to varying degrees in controlling circulating hormone levels. Most peptide and protein hormones require some degree of processing to generate the mature hormonal product (eg, conversion of proinsulin to insulin) and impairment in the processing activity can alter the ratio of precursor to product in plasma. In other cases, critical processing events are part of the secretory process itself (eg, cleavage of thyroxine from thyroglobulin) and impaired processing can result in a dramatic reduction in immunoreactivity as well as bioactivity of the mature hormone. In addition, protein hormones may require posttranslational modification (eg, glycosylation) or assembly (eg, heterodimerization) prior to secretion in order to optimize biological activity.

**Hormone Release**

Many hormones (eg, peptides, proteins, and monoamines) are stored in secretory granules in endocrine cells. Release of these granules is promoted by signaling events triggered by exogenous regulators termed secretagogues. This often requires activation of a second messenger system (see discussion under “Receptors”) like cyclic AMP generation or intracellular calcium mobilization in the endocrine cell. Steroid hormones, on the other hand, are not stored to a significant degree in the hormone-producing cells. In this case synthesis rather than hormone release appears to play the dominant role in controlling hormone levels in circulating plasma.

**Hormone Binding in Plasma**

Hormones in plasma can circulate either in a free form, uncomplexed with other molecules, or bound to other molecules like plasma proteins. It is the uncomplexed or free form of the hormone that represents the biologically active fraction of hormone in the plasma compartment, and it is this fraction which homeostatic regulatory mechanisms work to preserve. However, binding of hormone to plasma proteins does play an important role in endocrine physiology. First, it provides a reservoir of hormone that exchanges with the free hormone fraction according to the laws of mass action (see under “Receptors”). This makes plasma hormone concentrations less dependent on hormone synthesis and release, effectively stabilizing those concentrations over extended periods of time. This also serves to guarantee a uniform distribution of hormone concentration in capillary beds perfusing target tissues (Figure 1–2). Second, it slows the metabolism or turnover of the hormone by sequestering it away from degradative enzymes or filtration by the kidney.

**Hormone Metabolism**

Metabolism of hormones also plays an important role in regulating hormone concentrations. In some cases metabolism is responsible for converting precursors with less hormonal activity to products with greater activity (eg, conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D and conversion of androstenedione to testosterone). In other cases, metabolism leads to degradation and inactivation of the hormone with a cessation of hormone activity. This type of degradation is often specific to the hormonal class under examination. Steroids, for example, are catalytically converted to inactive metabolites and/or sulfated to promote excretion. Thyroid hormones are subjected
to deiodination which strips them of their biological activity. Protein and peptide hormones are internalized by target, as well as nontarget, cells and degraded in intracellular lysosomes. In general, the more avid the degradative mechanisms, the shorter the plasma half-life of the hormone.

**Regulation of Hormone Levels**

Hormone levels can be modulated through regulatory factors affecting any of the steps listed earlier; however, the bulk of the acute “fine-tuning” of hormone levels occurs at the level of hormone secretion and synthesis. Many, if not most, hormone levels are controlled either directly or indirectly by the biological activity that they serve to control. For example, parathyroid hormone (PTH) secretion which responds to low extracellular calcium levels, mobilizes calcium out of bone which, in turn, signals back to the parathyroid gland to turn off PTH secretion. This negative feedback inhibition is a hallmark of endocrine regulation. The end product or negative regulator can either be an inorganic ion or metabolite (eg, calcium for PTH) or a hormonal product in the endocrine cascade (eg, thyroid hormone for TSH). Not all feedback is negative in nature and positive feedback loops (eg, mid-cycle estradiol-induced luteinizing hormone secretion) also play important roles in governing physiological homeostasis.

**HORMONE ACTION**

Hormones produce their biologic effects through interaction with high-affinity receptors that are, in turn, linked to one or more effector systems within the cell. These effectors involve many different components of the cell’s metabolic machinery, ranging from ion transport at the cell surface to stimulation of the nuclear transcriptional apparatus. Steroids and thyroid hormones exert their effects in the cell nucleus, although regulatory activity in the extranuclear compartment has also been documented. Peptide hormones and neurotransmitters, on the other hand, trigger a plethora of signaling activity in the cytoplasmic and membrane compartments while at the same time exerting parallel effects on the transcriptional apparatus. The discussion that follows will focus on the primary signaling systems employed by selected hormonal agonists and attempt to identify examples where aberrant signaling results in human disease.

**RECEPTORS**

The biologic activity of individual hormones is dependent on their interactions with specific high-affinity receptors on the surfaces or in the cytoplasm or nuclei of target cells. The receptors, in turn, are linked to signaling effector systems responsible for generating the observed biologic response. Receptors, therefore, convey not only specificity of the response (ie, cells lacking receptors lack responsiveness to the hormone) but also the means for activating the effector mechanism. In general, receptors for the peptide hormones and neurotransmitters are aligned on the cell surface and those for the steroid hormones, thyroid hormone, and vitamin D are found in the cytoplasmic or nuclear compartments.

Interactions between the hormone ligand and its receptor are governed by the laws of mass action:

\[
[H] + [R] \xrightarrow{k_{+1}} [HR] \quad \text{or} \quad K_D = \frac{k_{-1}}{k_{+1}}
\]

where \([H]\) is the hormone concentration, \([R]\) is the receptor concentration, \([HR]\) is the concentration of the hormone–receptor complex, and \(k_{+1}\) and \(k_{-1}\) are the rate constants for \([HR]\) formation and dissociation, respectively. Thus, at equilibrium,

\[
K_{+1}[H][R] = K_{-1}[HR]
\]

where \(K_D\) is the equilibrium dissociation constant that defines the affinity of the hormone–receptor interaction (ie, lower the dissociation constant, higher the affinity). Assuming that total receptor concentration \(R_0 = [HR] + [R]\), this equation can be rearranged to give
agonist, they antagonize the functional activity of the latter. Partial agonists bind to the receptor but possess limited ability to activate the effector mechanisms. In different circumstances, partial agonists demonstrate variable biologic activity. For example, when used alone, they may display weak activating activity, whereas their use together with a full agonist may lead to inhibition of function because the latter is displaced from the receptor molecule by a ligand with lower intrinsic activity.

In some systems, receptors are available in a surplus, which is several-fold higher than that required to elicit a maximal biologic response. Such spare receptor systems, although they superficially appear redundant, are designed to rectify a mismatch between low circulating ligand levels and a relatively low-affinity ligand–receptor interaction. Thus, by increasing the number of available receptors, the system is guaranteed a sufficient number of liganded receptor units to activate downstream effector systems fully, despite operating at subsaturating levels of ligand.

**NEUROTRANSMITTER AND PEPTIDE HORMONE RECEPTORS**

As mentioned above, neurotransmitter and peptide hormones interact predominantly with receptors expressed on the plasma membrane at the cell surface. The $K_D$ of a neurotransmitter for its receptor is typically higher than that of a hormone for its receptor, reflecting a higher $k_{off}$ rate constant (see earlier). Neurotransmitter receptor occupancy is driven by the extraordinarily high concentrations of ligand that can be achieved in the synaptic cleft, and occupancy of the hormone receptor is driven by its high affinity for ligand. The high $k_{off}$ of the neurotransmitter–receptor interaction guarantees that the effect is rapid in onset but of short duration, whereas the lower $k_{off}$ of the hormone–receptor interaction guarantees that the effect is slow in onset but difficult to extinguish, kinetics that are more appropriate for the hormonal functions of these ligands.

The neurotransmitter and peptide receptors can be divided into several major groups (Table 1-1 and Figure 1-4). The first includes the so-called serpentine or “seven-transmembrane-domain” receptors. These receptors each contain an amino terminal extracellular domain followed by seven hydrophobic amino acid segments, each of which is believed to span the membrane bilayer (Figure 1-4). The seventh of these, in turn, is followed by a hydrophilic carboxyl terminal domain that resides within the cytoplasmic compartment. As a group, they share a dependence on the $G$ protein transducers (see discussed later) to execute many of their biologic effects. A second group includes the single-transmembrane-domain receptors that harbor intrinsic tyrosine kinase activity. This includes the insulin, insulin-like growth factor (IGF), and epidermal growth factor (EGF) receptors. A third group, which is functionally similar to the second group, is characterized by a large, extracellular binding domain followed by a single membrane-spanning segment and a cytoplasmic tail. These receptors do not possess intrinsic tyrosine kinase activity but appear to function through interaction with soluble transducer molecules which do possess such activity. Prolactin and growth

G PROTEIN–COUPLED RECEPTORS

G protein–coupled receptors constitute a large superfamily of molecules capable of responding to ligands of remarkable structural diversity—ranging from photons to large polypeptide hormones. These receptors share overall structural features, most notably seven membrane-spanning regions connected by intracellular and extracellular loops (see Figure 1–4). The receptors are oriented such that the amino terminal domain is extracellular, whereas the carboxyl terminal tail is cytoplasmic. The membrane-spanning segments interact with one another, forming an irregular cylindrical bundle around a central cavity within the molecule. G protein–coupled receptors can assume at least two conformations with differing orientations of the membrane-spanning segments relative to one another. One orientation is favored in the absence of an agonist ligand, and in this orientation the receptor does not activate a G protein (inactive conformation). The second orientation is stabilized by the binding of an appropriate agonist ligand, and in this conformation the receptor activates a cognate G protein (active conformation). All G protein–coupled receptors are thought to undergo a similar conformational switch on agonist binding, producing a structural change in the cytoplasmic domain that promotes G protein activation. Some small agonists, such as catecholamines, are able to enter the cavity formed by the transmembrane segments, thereby directly stabilizing the active receptor conformation. Other agonists, such as large polypeptide hormones are included in this group. Another group are the transforming growth factor beta (TGF-β) family members which signal through serine/threonine kinase domains in their cytoplasmic tails. A fifth group, which includes the natriuretic peptide receptors, operates through activation of a particulate guanylyl cyclase and synthesis of cGMP. The cyclase is covalently attached at the carboxyl terminal portion of the ligand-binding domain and thus represents an intrinsic part of the receptor molecule.
hormones, bind primarily to the extracellular domain of their G protein–coupled receptors. This indirectly results in movement of the transmembrane region of the receptor and stabilization of the active receptor conformation.

Until recently, it was thought that G protein–coupled receptors function exclusively as monomers. Many G protein–coupled receptors are now known to dimerize either with themselves (homodimerization) or with other G protein–coupled receptors (heterodimerization). In some cases, dimerization is important for efficient receptor biosynthesis and membrane localization. In other cases, dimerization is important for optimal ligand affinity, specificity, or receptor signaling.

Heritable mutations in a variety of G protein–coupled receptors are known to be associated with disease. Loss-of-function phenotypes result from mutations that eliminate one or both receptor alleles, or that result in the synthesis of signaling-defective receptors. Gain-of-function phenotypes generally result from point mutations that produce constitutively active receptors (i.e., stably assume the active receptor conformation even in the absence of an agonist ligand). Examples of such G protein–coupled receptor disorders relevant to endocrinology are described below and discussed in greater detail elsewhere in this book.

**G PROTEIN TRANSDUCERS**

G protein–coupled receptors initiate intracellular signaling by activating one (or in some cases multiple) G proteins. G proteins are a family of heterotrimeric proteins that regulate the activity of effector molecules (e.g., enzymes, ion channels) (Table 1–2), resulting ultimately in biological responses. The identity of a G protein is defined by the nature of its α subunit, which is largely responsible for effector activation. The major G proteins involved in hormone action (and their actions on effectors) are Gα (stimulation of adenylyl cyclase), Gδ (inhibition of adenylyl cyclase; regulation of calcium and potassium channels), and Gq/11 (stimulation of phospholipase C [PLC] β). The β and γ subunits of G proteins are tightly associated with one another and function as a dimer. In some cases, the βγ subunit dimer also regulates effector function.

G proteins are noncovalently tethered to the plasma membrane and are thus proximate to their cognate receptors and to their effector targets. The basis for specificity in receptor–G protein interactions has not been fully defined. It is likely that specific structural determinants presented by the cytoplasmic loops of the G protein–coupled receptor determine the identity of the G proteins that are activated. It is the nature of the α subunit of the G protein that is critical for receptor recognition. There are about a dozen different G protein α subunits and hundreds of distinct G protein–coupled receptors. Thus, it is clear that a particular G protein is activated by a large number of different receptors. For example, Gα is activated by receptors for ligands as diverse as β-adrenergic catecholamines and large polypeptide hormones such as luteinizing hormone (LH). LH is thereby able to stimulate adenylyl cyclase and raise intracellular levels of cAMP in cells that express LH receptors (e.g., Leydig cells of the testis).

Figure 1–5 is a schematic representation of the molecular events associated with activation of G proteins by G protein–coupled receptors. In the basal, inactive state, the G protein is an intact heterotrimer with guanosine diphosphate (GDP) bound to the G subunit. Agonist binding to a G protein–coupled receptor promotes the physical interaction between the receptor and its cognate G protein. This produces a conformational change in the G protein, resulting in the dissociation of GDP.

**FIGURE 1–5** G protein–mediated signal transduction. α and β/γ subunits of a representative G protein are depicted (see text for details) (E, effector; H, hormonal ligand; R, hormone receptor).
This in turn allows the binding of GTP (which is present at a much higher concentration in cells than is GDP) to the α subunit. Dissociation of the GTP-bound α subunit from the βγ dimer then occurs, allowing these subunits to activate their effector targets. Dissociation of the hormone–receptor complex also occurs. The duration of activation is determined by the intrinsic GTPase activity of the G protein α subunit. Hydrolysis of GTP to GDP terminates the activity and promotes reassociation of the αβγ trimer, returning the system to the basal state. The GTPase activity of G protein α subunits can be increased by the action of proteins termed “regulators of G protein signaling” (RGS proteins).

**EFFECTORS**

Numerous effectors have been linked to the G protein–coupled receptors. A number of these are presented in Table 1-2. A great many other G proteins—not dealt with here—are coupled to physical or biochemical stimuli but have very limited involvement in hormone action. As discussed, adenylyl cyclase, perhaps the best-studied of the group, is activated by Gs (Figure 1-6). This activation results in a transient increase in intracellular cAMP levels. The cAMP binds to the inhibitory regulatory subunit of inactive protein kinase A (PKA) and promotes its dissociation from the complex, thereby permitting enhanced activity of the catalytic subunit. The latter phosphorylates a variety of cellular substrates, among them the hepatic phosphorylase kinase that initiates the enzymatic cascade which results in enhanced glycogenolysis. It also phosphorylates and activates the cAMP response element–binding protein (CREB), which mediates many of the known transcriptional responses to cAMP (and to some extent calcium) in the nuclear compartment. Other transcription factors are also known to be phosphorylated by PKA.

PLC beta (PLCβ) is a second effector system that has been studied extensively. The enzyme is activated through Gq-mediated transduction of signals generated by a wide array of hormone–receptor complexes, including those for angiotensin II, α-adrenergic agonists, and endothelin. Activation of the enzyme leads to

---

**FIGURE 1-6** β-Adrenergic receptor signaling in the cytoplasmic and nuclear compartments. The cAMP response element–binding protein (CREB) is depicted bound to a consensus CRE in the basal state. Phosphorylation of this protein leads to activation of the juxtaposed core transcriptional machinery.
cleavage of phosphoinositol 4,5-bisphosphate in the plasma membrane to generate inositol 1,4,5-trisphosphate (IP$_3$) and diacylglycerol (DAG) (Figure 1–7). The former interacts with a specific receptor present on the endoplasmic reticulum membrane to promote release of Ca$^{2+}$ into the cytoplasmic compartment. The increased calcium, in turn, may activate protein kinases, promote secretion, or foster contractile activity. Depletion of intracellular calcium pools by IP$_3$ results in enhanced uptake of calcium across the plasma membrane (perhaps through generation of IP$_4$, [1,3,4,5-tetrakisphosphate]), thereby activating a second, albeit indirect, signaling mechanism that serves to increase intracellular calcium levels even further. DAG functions as an activator of several protein kinase C (PKC) isoforms within cells. Several different isoforms of PKC (eg, α, β, γ) exist in a given cell type. A number of these are calcium dependent, a property which, given the IP$_3$ activity mentioned above, provides the opportunity for a synergistic interaction of the two signaling pathways driven by PLC$\beta$ activity. However, not all PKC activity derives from the breakdown of PIP$_2$ substrate. Metabolism of phosphatidylcholine by PLC$_{PC}$ (phosphatidyl choline-selective phospholipase) leads to the generation of phosphocholine and DAG. This latter pathway is believed to be responsible for the more protracted elevations in PKC activity seen following exposure to agonist.

Other phospholipases may also be important in hormone-dependent signaling. Phospholipase D employs phosphatidylcholine as a substrate to generate choline and phosphatidic acid. The latter may serve as a precursor for subsequent DAG formation. As with PLC$_{PC}$ above, no IP$_3$ is generated as a consequence of this reaction. Phospholipase A$_2$ triggers release of arachidonic acid, a precursor of prostaglandins, leukotrienes, endoperoxides, and thromboxanes, all signaling molecules in their own right. The relative contribution of these other phospholipases to hormone-mediated signal transduction and the role of the specific lipid breakdown products (eg, phosphocholine, phosphatidic acid) in conveying regulatory information remains an area of active research.

Activation of effectors by G protein–coupled receptors is subject to regulatory mechanisms that prevent overstimulation of cells by an agonist ligand. At the level of the receptor, two regulatory events are known to occur. One is desensitization, wherein initial
stimulation of a receptor by its agonists leads to a loss of the ability of the receptor to subsequently elicit G protein activation. This is shown schematically in Figure 1–8 for the β-adrenergic receptor. A similar regulatory mechanism exists for many G protein-coupled receptors. Agonist binding to the receptor produces G protein activation and results also in activation of a kinase (termed G protein-coupled receptor kinase, GRK) that phosphorylates the cytoplasmic domain of the receptor. By virtue of this phosphorylation, the receptor acquires high affinity for a member of the arrestin family of proteins. The name “arrestin” derives from the observation that the receptor is no longer capable of interacting with a G protein when arrestin is bound. Thus, the phosphorylated receptor becomes uncoupled from its G protein, preventing signaling to the effector. The receptor remains inactive until a phosphatase acts to restore the receptor to its unphosphorylated state.

Many G protein-coupled receptors are also susceptible to agonist-induced downregulation, resulting in a reduced level of cell surface receptors following exposure of cells to an agonist. This can result from agonist-induced internalization of receptors, followed by trafficking of receptors to lysosomes where degradation occurs. In addition, chronic exposure of cells to an agonist may result in signaling events that suppress the biosynthesis of new receptors, thereby lowering steady-state receptor levels. Together, these regulatory events ensure that the cell is protected from excessive stimulation in the presence of sustained high levels of an agonist.

Recently, it has become clear that these events that serve to dampen G protein signaling can also have important positive roles in promoting cell signaling. For example, arrestin association with G protein–coupled receptors can produce activation of specific pathways such as the MAP kinase pathway, and this occurs independently of G protein signaling. In addition, internalized G protein-coupled receptors can in some cases retain the ability to signal, and the effects may differ from those produced when activation occurs at the plasma membrane.

**DISORDERS OF G PROTEINS AND G PROTEIN–COUPLED RECEPTORS**

Two bacterial toxins are capable of covalently modifying specific G protein α subunits, thereby altering their functional activity. Cholera toxin is a protein that binds to receptors present on all cells, resulting in the internalization of the enzymatic subunit of the toxin. The toxin enzyme is an ADP-ribosyl transferase that transfers ADP-ribose from NAD to an acceptor site (Arg201) on the α subunit of Gs. This covalent modification greatly inhibits the GTPase activity of αs, enhancing the activation of adenylyl cyclase by extending the duration of the active GTP-bound form of the G protein. Even in the absence of an active G protein–coupled receptor, GDP dissociates (albeit very slowly) from the G protein. Thus, cholera toxin will eventually activate adenylyl cyclase activity even without agonist binding to a G protein–coupled receptor. The result is a large and sustained activation of adenylyl cyclase. When this occurs in intestinal epithelial cells, the massive increase in cAMP results in the increased water and salt secretion characteristic of cholera.
Pertussis toxin is also an ADP-ribosyl transferase. However, in this case, the substrates are \( \alpha \) subunits of different G proteins, most notably \( \mathrm{G}_{12} \) and \( \mathrm{G}_{13} \). The ADP-ribosyl moiety is transferred to a cysteine residue near the carboxyl terminus of the \( \alpha \) subunit, a region required for interaction with activated G protein–coupled receptors. Once ADP-ribosylated by pertussis toxin, these G proteins are no longer able to interact with activated receptors and are thus stuck in an inactive (GDP-bound) conformation. Inhibition of receptor-mediated activation of \( \mathrm{G}_{12} \) and \( \mathrm{G}_{13} \) accounts for many of the clinical manifestations of pertussis infection.

Genetic mutations in G protein \( \alpha \) subunits are seen in a number of human diseases. Activated activating mutations in \( \alpha_{i} \) can produce a variety of phenotypes depending on the site of expression of the mutant protein. In McCune-Albright syndrome, the mutation occurs in a subset of neural crest cells during embryogenesis. All of the descendants of these cells, including certain osteoblasts, melanocytes, and ovarian or testicular cells, express the mutant protein. The result is a form of genetic mosaicism in which the consequence of unregulated production of cAMP in particular tissues is evident (ie, the progressive bone disorder polyostotic fibrous dysplasia, the abnormal skin pigmentation referred to as café au lait spots, gonadotropin-independent precocious puberty). In cells where cAMP is linked to cell proliferation (eg, thyrotropes, somatotropes), a subset of patients with benign tumors has been shown to have acquired activating mutations in \( \alpha_{i} \). Activating mutations in one of the \( \mathrm{G}_{i} \) proteins that is coupled to cell proliferation, \( \alpha_{2} \), have been reported in a subset of adrenal and ovarian tumors.

Loss-of-function mutations in \( \alpha_{i} \) are associated with the hereditary disorder pseudohypoparathyroidism type 1 (PHP-1a). This disorder, first described by Fuller Albright, is the first documented example of a human disease attributable to target cell resistance to a hormone. Affected patients display biochemical features of hypoparathyroidism (eg, hypocalcemia, hyperphosphatemia) but have markedly increased circulating levels of parathyroid hormone (PTH) and display target cell resistance to PTH. Many hormone receptors couple to adenylyl cyclase via \( \mathrm{G}_{i} \), yet patients with PHP-1a generally display only subtle defects in responsiveness to other hormones (eg, TSH, LH). The explanation for this lies in the fascinating genetics of this disorder. In brief, affected patients have one normal and one mutated \( \alpha_{i} \) allele. The mutated allele fails to produce an active form of the protein. Tissues in these patients are expected to express about 50% of the normal level of \( \alpha_{i} \), a level sufficient to support signaling to adenylyl cyclase. However, in certain tissues, the \( \alpha_{i} \) gene is subject to genetic imprinting such that the paternal allele is expressed poorly or not at all. In individuals harboring inactivating mutations, if the paternal allele has the mutation, all cells express about 50% of the normal level of \( \alpha_{i} \) (derived from the normal maternal allele). However, if the maternal allele has the mutation, then the cells in which paternal imprinting occurs express low levels or no \( \alpha_{i} \). One of the major sites of this paternal imprinting is in the proximal renal tubule, an important target tissue for the physiologic actions of PTH. This accounts for the clinical resistance to PTH seen in PHP-1a and accounts also for the fact that only a subset of patients with haploinsufficiency of \( \alpha_{i} \) are resistant to PTH. Interestingly, essentially all patients with haploinsufficiency of \( \alpha_{i} \) display Albright hereditary osteodystrophy, a developmental disorder with phenotypic manifestations affecting a variety of tissues. This indicates that even a partial loss of adenylyl cyclase signaling is incompatible with normal development.

Mutations in the genes encoding G protein–coupled receptors are being increasingly recognized as important in the pathogenesis of endocrine disorders. Loss-of-function mutations generally need to be homozygous (or compound heterozygous) in order to result in a significant disease phenotype. This is probably due to the fact that most cells have a complement of receptors which exceeds what is needed for maximal cellular response (spare receptors). Thus, a 50% reduction in the amount of a cell surface receptor may have little influence on the ability of a target cell to respond. However, in some situations, haploinsufficiency of a G protein–coupled receptor can produce a clinical phenotype. For instance, heterozygous loss-of-function mutations in the G protein–coupled calcium-sensing receptor result in the autosomal dominant disorder familial hypocalciuric hypercalcemia due to mild dysregulation of PTH secretion and renal calcium handling. Homozygous loss-of-function of the calcium-sensing receptor results in severe neonatal hyperparathyroidism due to the loss of the ability of plasma calcium to suppress PTH secretion and promote renal calcium clearance. Syndromes of hormone resistance have also been reported in patients lacking expression of functional G protein–coupled receptors for vasopressin, ACTH, and TSH. Loss of functional expression of the PTH receptor results in Blomstrand chondrodysplasia, a disorder that is lethal due to the inability of PTH-related protein (a PTH receptor agonist) to promote normal cartilage development.

Mutations that render G protein–coupled receptors constitutively active (in the absence of an agonist ligand) are seen in a number of endocrine disorders. Generally speaking, such mutations produce a disease phenotype resembling that seen with excessive levels of the corresponding hormone agonist. Thus, activating mutations in the TSH receptor produce neonatal thyrotoxicosis, and activating mutations in the LH receptor result in pseudoprecocious puberty or testotoxicosis. Activating mutations in the PTH receptor result in Jansen type metaphyseal chondrodysplasia; a disorder characterized by hypercalcemia and increased bone resorption (mimicking the effects of excess PTH on bone) and delayed cartilage differentiation (mimicking the effects of excess PTH–related protein on cartilage). A theoretical approach to treating disorders resulting from constitutively active G protein–coupled receptors would be administration of "inverse agonists," agents that stabilize receptors in their inactive conformation. Although inverse agonists have been identified for a number of G protein–coupled receptors, they have yet to be successfully employed as therapeutics. Molecular analysis of G protein–coupled receptors has revealed that point mutations, in addition to producing constitutive activity, can alter the specificity of ligand binding or the ability of the receptor to become desensitized. It is almost certain that such mutations will be found to provide the basis for some perhaps more subtle endocrinopathies.
The growth factor receptors differ from those described earlier both structurally and functionally. Unlike the G protein–associated receptors, these proteins span the membrane only once and acquire their signaling ability, at least in part, through activation of tyrosine kinase activity, which is intrinsic to the individual receptor molecules. The insulin and IGF receptors fall within this group as do those for the autocrine or paracrine regulators platelet-derived growth factor (PDGF), fibroblast growth factor (FGF), and EGF. Signaling is initiated by the association of ligand (eg, insulin) with the receptor’s extracellular domain (Figure 1–9) and subsequent receptor dimerization. This results in phosphorylation of tyrosines both on the receptor itself as well as on nonreceptor substrates. It is assumed that phosphorylation of these substrates results in a cascade of activation events, similar to those described for the G protein–coupled systems, which contribute to perturbations in intracellular pathways. The autophosphorylation of the receptor molecules themselves has been studied extensively and provided some intriguing insights into the mechanisms that underlie signal transduction by this group of proteins.

Tyrosine phosphorylation takes place at specific locations in the receptor molecule. Once phosphorylated, these sites associate, in highly specific fashion, with a variety of accessory proteins that possess independent signaling capability. These include PLCγ, phosphoinositide (PI) 3′ kinase, GTPase-activating protein (GAP), growth factor receptor–bound protein-2 (GRB2), and the Src family nonreceptor tyrosine kinases. These interactions are fostered by the presence of highly conserved type 2 src homology (based on sequence homology to the src proto-oncogene) domains (SH2) in each of the accessory molecules. Each individual SH2 domain displays specificity for the contextual amino acids surrounding the phosphotyrosine residues in the receptor molecule. In the PDGF receptor, for example, the SH2 domain of PLCγ associates selectively with Tyr\(^{977}\) and Tyr\(^{989}\), whereas that of PI 3′ kinase associates with Tyr\(^{970}\) and Tyr\(^{710}\). Thus, diversity of response is controlled by contextual sequences around individual phosphotyrosine residues that determine the types of accessory proteins brought into the signaling complex. These protein–protein interactions may provide a means of directly activating the signaling molecule in question, perhaps through a change in steric conformation. Alternatively, they may facilitate the sequestration of these accessory proteins in or near the plasma membrane compartment, in close proximity to key substrates (eg, membrane lipids in the case of PLCγ) or other important regulatory proteins.

Some of these associations trigger immediate signaling events, but others (eg, GRB2) may act largely to provide the scaffolding needed to construct a more complex signaling apparatus (Figure 1–10). In the case of GRB2, another accessory protein (son-of-sevenless; SOS) associates with the receptor–GRB2 complex through a type 3 src homology (SH3) domain present in the latter. This domain recognizes a sequence of proline-rich amino acids present in the SOS protein. SOS, in turn, facilitates assembly of the Ras–Raf complex, which permits activation of downstream effectors such as mitogen-activated protein kinase (MAPK) kinase (MEK). This latter kinase, which possesses both serine-threonine and tyrosine kinase activity, activates the p42 and p44 MAPKs (also called extracellular signal–regulated kinases; ERKs). ERK acts on a variety of substrates within the cell, including the RSK kinases, which, in turn, phosphorylate the ribosomal S\(_6\) protein and thereby stimulates protein synthesis. These phosphorylation reactions (and their amplification in those instances where the MAPK substrate is a kinase itself) often lead to protean changes in the phenotype of the target cells.

The liganded growth factor receptors, including the insulin receptor, may also signal through the phosphoinoside 3-OH kinase (PI-3K). SH2 domains of the p85 regulatory subunit of PI-3K associate with the growth factor receptor through specific
phosphotyrosine residues (Tyr$^{740}$ and Tyr$^{751}$ in the PDGF receptor) in a manner similar to that described above for GRB2 (see Figure 1–10). This leads to activation of the p110 catalytic subunit of PI-3K and increased production of phosphatidylinositol-3,4,5-trisphosphate (PIP$_3$) and phosphatidylinositol-3,4-bisphosphate (PI[3,4]P$_2$). These latter molecules sequester protein kinase B (also known as Akt) at the cell membrane through association with the plekstrin homology domains in the amino terminal of the kinase molecule. This in turn leads to phosphorylation of PKB at two separate sites (Thr$^{308}$ and Ser$^{473}$ in the active kinase domain and Thr$^{308}$ in the carboxyl terminal tail) by PI3K-dependent kinases (PDK1 and PDK2). These phosphorylations result in activation of PKB. In the case of insulin-sensitive target cells, downstream targets of activated PKB (eg, following insulin stimulation) include 6-phosphofructo-2-kinase (increased activity), glycogen synthase kinase-3 (GSK3) (decreased activity), the insulin-responsive glucose transporter GLUT4 (translocation and increased activity), and p70 S6 kinase (increased activity). This leads to increased glycolysis, increased glycogen synthesis, increased glucose transport, and increased protein synthesis, respectively. There is also a growing body of evidence suggesting that PKB may protect cells from programmed cell death through phosphorylation of key proteins in the apoptotic pathway.

It has been reported that G protein–coupled receptors may also activate the Raf-MEK-ERK cascade, although in this case the signal traffic through a nonreceptor protein tyrosine kinase (NRPTK such as Src and Fyn) rather than the traditional growth factor receptor–linked tyrosine kinases. The details of the mechanism are incompletely understood, but it appears to require the participation of β-arrestin (discussed earlier) as an adaptor molecule linking the G protein receptor to the NRPTK. Interestingly, this implies that β-arrestin, which terminates coupling between the receptor and G protein, actually promotes coupling between the desensitized receptor and downstream effectors traditionally associated with growth factor–dependent activation.

**CYTOKINE RECEPTORS**

These include the receptors for a variety of cytokines, erythropoietin, colony-stimulating factor, GH, and prolactin. These cell membrane receptors have a single internal hydrophobic stretch of amino acids, suggesting that they span the membrane but once (see Figure 1–4). They can be composed of monomers or heterodimers of different molecules.

**Growth Hormone and Prolactin Receptors**

Receptors for GH and prolactin are prototypical cytokine receptors (Figure 1–11). Interestingly, alternative splicing of the GH receptor gene primary transcript results in a foreshortened “receptor” that lacks the membrane anchor and carboxyl terminal domain of the protein. This “receptor” is secreted and serves to bind GH in the extracellular space (eg, circulating plasma). Unlike the growth factor receptors described above, GH receptors lack a
FIGURE 1-11 Signaling by the growth hormone receptor (GHR). Different portions of a single growth hormone molecule associate with homologous regions of two independent GHR molecules. This is believed to lead to the recruitment of Janus kinase 2 (JAK2), which phosphorylates the GHR, providing a docking site for STAT. The latter is phosphorylated, dissociates from the liganded receptor complex, and migrates to the nucleus, where it associates with binding elements of target genes and regulates transcription.

Tyrosine kinase domain. Different domains of a single GH molecule associate with homologous regions of two independent GH receptors, promoting dimerization of the receptors and subsequent association with and activation of Janus kinase (JAK) 2. JAK2 undergoes autophosphorylation and concurrently tyrosine phosphorylates the GH receptors. The latter provide a docking site for the signal transducer and activator of transcription (STAT) factors; STAT 5a and 5b appear to be particularly relevant to GH and prolactin action. The STATs are phosphorylated, dissociate from the GH receptor, migrate to the nucleus, and bind to specific STAT-binding DNA regulatory elements (SIE/ISRE/GAS) responsible for transcriptional control of GH target genes such as IGF-1. There are a number of different STAT family members, and there is specificity of certain cytokine receptors for certain STAT family members. This helps direct the specificity of signaling by each type of receptor. STAT signaling is also regulated by a family of inhibitors referred to as suppressor of cytokine signaling (SOCS) proteins. SOCS proteins bind to JAK and STAT proteins and target them for degradation. SOCS proteins are induced after cytokine/hormone binding and help to autoregulate signaling in this pathway.

TGF-β Receptors

These receptors bind a variety of ligands that include the cytokine transforming growth factor beta (TGF-β) and the hormones inhibin, activin, and anti-müllerian hormone (AMH). The ligands for these receptors are typically homo- or heterodimers of subunits that have a highly conserved, cysteine-dependent structure. TGF-β family receptors bind to ligands through a heterodimeric receptor consisting of two transmembrane subunits known as type I and type II receptors (Figure 1-12). There are a number of different type I and type II receptor subunits in this family and type I/type II pairs can form between several different family members. Both type I and type II receptors have an intracellular serine/threonine kinase domain. The type II receptor is constitutively phosphorylated and active, while the type I receptor is not. The ligands in this family initially bind the type II receptor. The type I receptor is recruited to the complex where the type II receptor kinase phosphorylates and activates the type I receptor, which then further propagates the signal. Downstream in the signaling pathway are a group of phosphorylation targets called the Smad proteins. These proteins, upon phosphorylation, can migrate to the nucleus to activate and/or repress transcription of target genes.

TNF-Receptors

The tumor necrosis factor (TNF) family of receptors is a large group of cytokine receptors that bind to both soluble and cell-membrane-associated ligands. One important member of this family is the receptor activator of nuclear factor kappa B (RANK) which plays a critical function in the regulation of bone physiology (see Chapter 8). These receptors consist of a trimeric complex of three single transmembrane receptors that bind to ligand. The cytoplasmic tail of many TNF-receptors
Chapter 1 Hormones and Hormone Action

Figure 1-12 Signaling by the TGF-β receptors. TGF-β ligand first docks with the type II receptor which has an intracellular serine/threonine kinase domain that is constitutively active. After ligand binding, the type I receptor is then recruited to the complex and the type II receptor can phosphorylate the intracellular serine/threonine kinase domain of the type I receptor. This then propagates the signal downstream leading to the phosphorylation and activation of Smad proteins which can migrate to the nucleus and activate or repress gene transcription.

Guanylyl cyclase-linked receptors

Activation of guanylyl cyclase-dependent signaling cascades can occur through two independent mechanisms. The first involves activation of the soluble guanylyl cyclase, a heme-containing enzyme that is activated by the gas nitric oxide (NO) generated in the same or neighboring cells. NO is produced by the enzyme nitric oxide synthase. NO synthase exists as three different isozymes in selected body tissues. Constitutive forms of NO synthase (NOS) are produced in endothelial (NOS-3) and neuronal (NOS-1) cells. The endothelial enzyme possesses binding sites for FAD and FMN as well as calcium and appears to require calcium for optimal activity. Agents such as bradykinin and acetylcholine, which interact with receptors on the surface of endothelial cells

and increase intracellular calcium levels, trigger an increase in constitutive NO synthase activity with consequent generation of NO and activation of soluble guanylyl cyclase activity in neighboring vascular smooth muscle cells (Figure 1-14). Thus, in this instance, the cGMP-dependent vasodilatory activity of acetylcholine requires sequential waves of signaling activity in two different cell types to realize the ultimate physiologic effect.

Figure 1-13 TNF receptor signaling. TNF binds to a trimolecular cell surface receptor which transmits a downstream signal that leads to the phosphorylation and activation of the I-κB kinase (IKK). IKK phosphorylates the inhibitor of NF-κB (I-κB) which is then tagged for degradation through the ubiquitin-dependent proteasomal pathway. This allows NF-κB to migrate to the nucleus where it can carry out activation or repression of gene transcription.
FIGURE 1-14 Signaling through the endothelial (e) and inducible (i) nitric oxide synthases (NOS) in the vascular wall. Activation of eNOS in the endothelial cell or iNOS in the vascular smooth muscle cell leads to an increase in NO and stimulation of soluble guanylyl cyclase (GC) activity. Subsequent elevations in cGMP activate cGMP-dependent protein kinase (PKG) and promote vasorelaxation.

The inducible (i) form of NO synthase (NOS-2) is found predominantly in inflammatory cells of the immune system, although it has also been reported to be present in smooth muscle cells of the vascular wall. Unlike the endothelial form of NO synthase, expression of iNOS synthase is low in the basal state. Treatment of cells with a variety of cytokines triggers an increase in new iNOS synthase synthesis (hence, the inducible component of iNOS synthase activity), probably through activation of specific cis elements in the iNOS synthase promoter. Thus, hormones, cytokines, or growth factors with the capacity for induction of iNOS synthase activity may direct at least a portion of their signaling activity through a cGMP-dependent pathway.

A third mechanism for increasing cGMP levels within target cells involves the activation of particulate guanylyl cyclases (Figure 1-15). From an endocrine standpoint, this involves predominantly the natriuretic peptide receptors (NPR). NPR-A is a single-transmembrane-domain receptor (about 130 kDa) with a large extracellular domain that provides ligand recognition and binding. This is followed by a hydrophobic transmembrane domain and a large intracellular domain that harbors the signaling function. The amino terminal portion of this intracellular region contains an ATP-binding kinase homology domain (KHD) that is involved in regulating cyclase activity, whereas the carboxyl terminal domain contains the catalytic core of the particulate guanylyl cyclase. It is believed that association of ligand with the extracellular domain leads to a conformational change in the receptor that arrests the tonic inhibitory control of the kinase-like domain and permits activation of guanylyl cyclase activity. Recent studies suggest that the small GTPase Rac can directly activate the catalytic domain through its effector kinase PAK (p21-activated kinase).

NPR-B, the product of a separate gene, has a similar topology and a relatively high level of sequence homology to the NPR-A gene product; however, while NPR-A responds predominantly to the cardiac atrial natriuretic peptide (ANP) and brain natriuretic peptide (BNP), NPR-B is activated by the C-type NP (CNP), a peptide found in the central nervous system, endothelium, and reproductive tissues but not in the heart. Thus, segregated expression of the ligand and its cognate receptor convey a high level of response specificity to these two systems despite the fact that they share a common final effector mechanism. Noteworthy, both NPR-A and NPR-B require a high degree of phosphorylation in the kinase homology domain to retain sensitivity to agonist. Dephosphorylation, perhaps through agonist-triggered exposure of the phosphoserine residues to regulatory phosphatase activity in the target cell, results in receptor desensitization. In humans, homozygous mutation of the NPR-B genes results in acromesomelic dysplasia, Maroteaux type (AMDM), a rare form of autosomal recessive, short-limbed dwarfism.
Although the initial targets of peptide hormone receptor signaling appear to be confined to the cytoplasm, it is clear that these receptors can also have profound effects on nuclear transcriptional activity. They accomplish this through the same mechanisms they use to regulate enzymatic activity in the cytoplasmic compartment (eg, through activation of kinases and phosphatases). In this case, however, the ultimate targets are transcription factors that govern the expression of target genes. Examples include hormonal activation of c-Jun and c-Fos nuclear transcription factors that make up the heterodimeric AP-1 complex. This complex has been shown to alter the expression of a wide variety of eukaryotic genes through association with a specific recognition element, termed the phorbol ester (TPA) response element (TRE), present within the DNA sequence of their respective promoters. Other growth factor receptors that use the MAPK-dependent signaling mechanism appear to target the serum response factor (SRF) and its associated ternary complex proteins. Posttranslational modification of these transcription factors is believed to amplify the signal that traffics from this complex, when associated with the cognate serum response element (SRE), to the core transcriptional apparatus. The cAMP-dependent activation of protein kinase A results in the phosphorylation of a nuclear protein CREB (cAMP response element–binding protein) at Ser119, an event that results in enhanced transcriptional activity of closely positioned promoters. The latter requires the participation of an intermediate CREB-binding protein (CBP). CBP is a coactivator molecule that functionally tethers CREB to proteins of the core transcriptional machinery. Interestingly, CBP may also play a similar role in nuclear receptor (NR) signaling (see “Nuclear Receptors”). GH is known to induce the phosphorylation of an 84-kDa and a 97-kDa protein in target cells. These proteins have been shown to associate with the sis-inducible element (SIE) in the c-fos promoter and to play a role in signaling cytokine activity that traffics through this element. It remains to be demonstrated that these proteins play a similar functional role in mediating GH-dependent effects. Several recent studies have provided evidence suggesting that a number of peptide hormones and growth factors may bind to high-affinity receptors in the cell nucleus. The role these receptors play—if any—in contributing to the signaling profile of these peptides remains undefined.

NUCLEAR RECEPTORS

The NRs, which include those for the glucocorticoids, mineralocorticoids, androgens, progesterone, estrogens, thyroid hormone, and vitamin D, differ from the receptors of the surface membrane described above in that they are soluble receptors with a proclivity for using transcriptional regulation as a means of promoting their biologic effects. Thus, although some receptors are compartmentalized in the cytoplasm (eg, glucocorticoid receptor), whereas others are confined to the nucleus (eg, thyroid hormone receptor), they all operate within the nuclear chromatin to initiate the signaling cascade. These receptors can be grouped into two major subtypes based on shared structural and functional properties. The first, the steroid receptor family, includes the prototypical glucocorticoid receptor (GR) and the receptors for mineralocorticoids (MR), androgens (AR), and progesterone (PR). The second, the thyroid receptor family, includes the thyroid hormone receptor (TR) and the receptors for estrogen (ER), retinoic acid (RAR and RXR), and vitamin D (VDR) as well as the peroxisome proliferator–activated receptor (PPAR). There are also so-called orphan receptors that bear structural homology to members of the extended NR family. For most of these, the “ligand” is unknown, and their functional roles in the regulation of gene expression have yet to be determined. In total, there are 48 nuclear receptors and orphan receptors in humans.

STEROID RECEPTOR FAMILY

Steroid receptors (ie, GR, MR, AR, and PR), under basal conditions, exist as cytoplasmic, multimeric complexes that include the heat shock proteins (HSP) 90, 70, and 56. ER, although
demonstrating similar association with HSP, is largely confined to the nuclear compartment. Association of the steroid ligand with the receptor results in dissociation of the HSP. This in turn exposes a nuclear translocation signal previously buried in the receptor structure and initiates transport of the receptor to the nucleus, where it associates with the hormone response element (Figure 1–16).

Each of the family members has been cloned and sequenced, and crystallographic structures have been obtained for many of them. Consequently, we know a great deal about their structure and function (Figure 1–17). Each has an extended amino terminal domain of varying length and limited sequence homology to other family members. In at least some receptors, this region, which has been termed AF-1, is believed to participate in the transactivation function through which the individual receptors promote increased gene transcription. Significant variability in the length of the amino terminal regions of the different receptors suggests potential differences in their respective mechanisms for transcriptional

![Figure 1-16](image)

**FIGURE 1–16** Signaling through the steroid receptor complex. Similar mechanisms are employed by members of the TR gene family, though most of the latter are concentrated in the nuclear compartment and are not associated with the heat shock protein complex (HSP) prior to binding ligand (\(m\text{G}\), methyl guanosine).

![Figure 1-17](image)

**FIGURE 1–17** Structural schematic of a representative steroid receptor molecule. Separate designations are given to the amino terminal (NH\(_2\)), DNA-binding (DBD), and ligand-binding (LBD) domains. Functional activity associated with each of these individual domains, as determined by mutagenesis studies, is indicated below each individual domain.
regulation. The amino terminal is followed by a basic region that has a high degree of sequence homology in both the steroid and thyroid receptor gene families. This basic region encodes two zinc finger motifs (Figure 1–18) that have been shown to establish contacts in the major groove of the cognate DNA recognition element (see the discussion later). Based on crystallographic data collected for the DNA-binding region of the GR, we know that the amino acid sequence lying between the first and second fingers (ie, recognition helix) is responsible for establishing specific contacts with the DNA. The second finger provides the stabilizing contacts that increase the affinity of the receptor for DNA. The DNA-binding region also harbors amino acid residues that contribute to the dimerization of monomers contiguously arrayed on the DNA recognition element. Following the basic region is the carboxyl terminal domain of the protein. This domain is responsible for binding of the relevant ligand, receptor dimerization or heterodimerization, and association with the heat shock proteins. It also contributes to the ligand-dependent transactivation function (incorporated in a subdomain termed AF-2) that drives transcriptional activity. Interestingly, in selected cases, nonligands have been shown to be capable of activating steroid receptors. Dopamine activates the progesterone receptor and increases PR-dependent transcriptional activity, probably through a phosphorylation event, which elicits a conformational change similar to that produced by the association of the receptor with progesterone.

The DNA-binding regions of these receptors contact DNA through a canonical HRE, which is described in Table 1–3. Interestingly, each receptor in the individual subfamily binds to the same recognition element with high affinity. Thus, specificity of hormone action must be established either by contextual DNA sequence lying outside the recognition element or by other, non-receptor DNA-protein interactions positioned in close proximity to the element. Interestingly, the GR, as well as some other NRs (eg, ER), are capable of binding to DNA sequence lacking the classic HRE. Originally described in the mouse proliferin gene promoter, these composite elements associate with heterologous

**FIGURE 1–18** Schema of the two zinc fingers, together with coordinated zinc ion, which make up the DNA-binding domain of the glucocorticoid receptor (amino acids are numbered relative to the full-length receptor). Shaded regions denote two alpha helical structures which are oriented perpendicularly to one another in the receptor molecule. The first of these, the recognition helix, makes contact with bases in the major groove of the DNA. Red arrows identify amino acids which contact specific bases in the glucocorticoid response element (GRE). Black arrows identify amino acids that confer specificity for the GRE; selective substitutions at these positions can shift receptor specificity to other response elements. Dots identify amino acids making specific contacts with the phosphate backbone of DNA. (Modified from Luisi BF et al. Reprinted, with permission, from *Nature*. 1991;352:498. \(^a\)Elements represent consensus sequences selected to emphasize the modular nature of the half-sites and their capacity for palindrome generation. Sequences read in the 5' to 3' direction. N denotes a spacer nucleoside (either A, G, C, or T). Half-sites are identified by the overlying arrows. The TRE is arrayed as a direct repeat but may also exist as a palindrome or an inverted palindrome. A variable number of spacer nucleotides are positioned between the two direct repeats, depending on the type of hormone receptor. Three, four, and five nucleotides (ie, n = 3, 4, or 5) are preferred for binding of the VDR, TR, or RAR, respectively.
complexes containing GR, as well as with components of the AP-1 transcription factor complex (ie, c-Jun and c-Fos). They display unique regulatory activity at the level of contiguously positioned promoters. One such composite element, for example, directs very specific transcriptional effects depending on whether the GR or the MR is included in the complex.

Several steroids, particularly the glucocorticoids and estrogens, have been reported to have independent effects on the stability of target gene transcripts. At this point, it is unclear what role the hormone receptors play in this process and whether transcript stabilization is tied mechanistically to the enhancement of transcriptional activity.

**THYROID RECEPTOR FAMILY**

Included in this group are the TR, RAR, RXR, ER, PPAR, and VDR. They share a high degree of homology to the proto-oncogene c-erbA and high affinity for a common DNA recognition site (Table 1–3). With the exception of the ER, they do not associate with the HSPs, and they are constitutively bound to chromatin in the cell nucleus. Specificity of binding for each of the individual receptors is, once again, probably conferred by a contextual sequence surrounding this element, the orientation of the elements (eg, direct repeats or inverted repeats or palindromes), the polarity (ie, 5' in contrast to 3' position on two successive repeats), and the number and nature of the spacing nucleotides separating the repeats.

The ER binds to its RE as a homodimer, whereas the VDR, RAR, RXR, and TR prefer binding as heterodimers. The nature of the heterodimeric partners has provided some intriguing insights into the biology of these receptors. The most prevalent TR-associated partners appear to be the retinoid X receptors. These latter receptors, which as homodimers form high-affinity associations with 9-cis-retinoic acid, also form heterodimeric complexes in the unliganded state with VDR and RXR. In the individual cases in which it has been examined, heterodimerization with RXR amplifies both the DNA binding and the functional activity of these other receptors. Thus, the ability to form such heterodimeric complexes may add significantly to the flexibility and potency of these hormone receptor systems in regulating gene expression. Interestingly, the positioning (5' vs 3') of the participant proteins on the RE is important in determining the functional outcome of the association. In most of those situations linked to transcriptional activation, RXR seems to prefer the upstream (5') position in the dimeric complex. Thus, diversity of response is engendered by the selection of recognition elements (eg, monomeric vs dimeric vs oligomeric sites) and by the choice and positioning of the dimeric partner (eg, homodimer vs heterodimer) where applicable.

The crystallographic structures of the ligand-binding domains (LBDs) of several members of the TR family have been described. These include the dimeric unliganded RXRα, monomeric liganded RARγ, monomeric liganded TRα, dimeric agonist (ie, estradiol)—and antagonist (ie, raloxifene)—liganded ERα, liganded VDR, and liganded PPARγ. A composite LBD displays a common folding pattern with 12 alpha helices (numbered by convention H1-H12) and a conserved beta turn. Some variability exists in that there is no H2 in RARγ and a short H2' helix is present in PPARγ, but the overall structural configuration is preserved. The dimeric interface is formed through interaction of amino acids located in helices 7 to 10, with the strongest influence exerted by H10. These interactions appear to be important for both homodimeric as well as heterodimeric interactions. Binding of ligand has been shown to occur through what has been termed a "mousetrap" mechanism. In the unliganded state, H12, which contains the carboxyl terminal activation domain AF-2, is displaced away from the ligand-binding pocket (Figure 1–19). Association of agonist ligand (eg, estradiol in the case of the ER) with the hydrophobic core of the receptor leads to a repositioning of H12 over the ligand-binding cavity, where it stabilizes receptor–ligand interactions and closes the "mousetrap." Binding of an antagonist ligand such as raloxifene, which because of its structure engenders steric hindrance in the ligand-binding pocket, prevents closure of H12 into the normal agonist position. Instead, H12 folds into an alternative location between H4 and H3, a conformation that suppresses the activation function of the receptor (discussed later). Crystal structure of a full-length nuclear receptor pair (in this case PPAR gamma and RXR alpha) shows that the PPAR gamma protein dominates its heterodimeric partner, dictating the overall structure of the complex.

The mechanistic underpinnings of transcriptional regulation by the NRs have been partially elucidated (Figure 1–20). In the unliganded state, the receptor dimers are associated with a macromolecular complex containing the repressor proteins N-CoR or SMRT, a transcriptional corepressor Sin3, and a histone deacetylase RPD3. N-CoR and SMRT each use two independent receptor interaction domains (IDs) to associate with the NRs (one repressor; two receptors). Each ID contains an amino acid sequence (LIIXXI/VI, where I = isoleucine, L = leucine, V = valine, X = any amino acid), which interacts with helices 4, 5, and 6 of the NR LBD. Histone acetylation is typically associated with activation of gene transcription (presumably reflecting decompaction of chromatin surrounding the transcriptional unit), so the presence of histone deacetylase activity in the complex is thought to promote a transcriptionally quiescent state. Addition of ligand leads to a change in receptor conformation that no longer favors interaction with the coressor (a shift in position of helix 12 in the LBD prevents corepressor interaction and promotes coactivator assembly into the complex) and promotes both ATP-dependent chromatin remodeling and assembly of an activator complex containing p160 coactivator proteins (eg, SRC-1, GRIP-1, or P/CIP) and, secondarily, the CREB-binding protein (CBP) and the histone acetylase P/CAF. The net accrual of histone acetylase activity (CBP and P/CIP as well as P/CAF possess acetylase activity) leads to acetylation of chromatin proteins (eg, histones) as well as components of the core transcriptional machinery, resulting in chromatin decompaction and a net increase in transcriptional activity. Interaction of the NRs with the coactivators in this complex takes place through LXXLL motifs (where L = leucine and X = any amino acid) present in the coactivator proteins. Each coactivator
FIGURE 1-19 Three-dimensional structures for the agonist- and antagonist-occupied ERα LBD. (A) Orthogonal views of the agonist diethylstilbestrol-ERα LBD-NR Box II peptide complex. Coactivator peptide and LBD are presented as ribbon diagrams. Peptide is colored medium orange, helix (H) 12 (ERα residues 538-546) is colored dark orange. Helices 3, 4, and 5 are colored light pink. Diethylstilbestrol is depicted in red in a space-filling format. (B) Orthogonal views of the antagonist 4-hydroxytamoxifen-ERα LBD complex. Color scheme is the same as in panel A. 4-Hydroxytamoxifen is shown in green in a space-filling format. Note that NR Box II is absent in this structure. (C) Schematic representation of the mechanism underlying agonist-dependent activation of nuclear hormone receptor. In the presence of agonist, helix 12 (the terminal helix in the LBD) folds across the ligand-binding pocket, stabilizing ligand–receptor interaction and promoting a conformation conducive for coactivator association. In the presence of antagonist, steric hindrance precludes folding of helix 12 across the ligand-binding pocket. Instead, it positions itself in the region typically occupied by the coactivator, thereby blocking the activation function of the receptor. may have several of these motifs, which preferentially associate with different NRs, other transcription factors, or other coactivators. This allows for a degree of selectivity in terms of which regulatory proteins are incorporated in the complex. Notably, a recent structural analysis showed that a 13-amino-acid peptide, containing an LXXLL motif from the GRIP-1 protein, interacts with TRβ through a hydrophobic cleft generated by helices 3, 4, and 12 (including AF-2) in the receptor protein. This is the same cleft that is occupied by helix 12, which harbors an LXXLL motif, in the raloxifene-bound ERα. This suggests that the antagonist in the latter instance acquires its activation-blocking properties by repositioning helix 12 in a manner that leads to displacement of the coactivator protein from this groove (see discussion earlier). It also appears that the antagonist-bound receptor may preferentially associate with the coactivator molecules NCoR and SMRT. SRC also interacts with the AF-1 domain, suggesting a potential mechanism for maximizing synergistic activity between AF-1 and AF-2 domains in the receptors. The importance of SRC1 in thyroid hormone action is underscored by the finding that SRC1 knockout mice display significant thyroid hormone resistance in peripheral tissues.

CBP is thought to function as a pivotal component of the NR regulatory complex. While the p160 class of coactivators interact directly with the NRs (primary coactivator), CBP associates primarily with the p160 coactivators, thereby establishing an indirect link to the receptors (secondary coactivator). CBP also has the ability to establish weaker, primary associations with the receptor proteins. As noted above, CBP functions as a central integrator of transcriptional regulatory signals from multiple pathways, including the cAMP-dependent activation of the transcription factor CREB. Recent evidence suggests that an additional level of regulatory control may be involved in selectively amplifying NR-dependent transcriptional activity. An enzyme called coactivator-associated arginine methyltransferase 1 (CARM1) associates with CBP and methylates the protein. This results in a reduction in CREB-dependent gene activation and, secondarily, an increase in NR-dependent gene transcription. This switching mechanism effectively refocuses the transcriptional machinery on expression of NR-dependent gene expression. CARM1 also interacts with all three members of the SRC family. It binds to the AD2 domain at the carboxy terminus of the p160 coactivators (by contrast, CBP associates with the AD1 domain located in the midregion of the molecule). CARM1 in this context promotes methylation of the p160 coactivator and dissociation of the CARM1-SRC complex from NR-associated DNA, effectively clearing the promoter of the transcriptional regulatory complex.

More recently, another family of coactivator complexes has been identified as playing an important role in NR signaling. The human TR-associated protein (TRAP) and vitamin D receptor–interacting protein (DRIP) complexes are the best characterized to date. These complexes, which contain in the neighborhood of 25 individual proteins, are thought to serve as a functional bridge between the liganded NR bound to DNA and the general transcription factors (GTFs) (eg, TBP, TFIIIB, RNA polymerase II, and TAFs) involved in formation of the preinitiation complex, a function previously assigned to the Mediator complex in yeast. The TRAP220 subunit appears to establish the relevant contacts, through LXXLL motifs, with the NRs in promoting this assembly. Their role is clear in the p160 coactivators alluded to earlier remains undefined; however, it has been suggested that they proceed the p160 coactivator complex in binding with liganded NRs positioned on target gene promoters, establish the requisite structural and functional connections with the core transcriptional machinery, and initiate mRNA synthesis. It has also been suggested that acetylation of one of the key NR-binding motifs (LXXLL) on the SRC coactivator by CBP leads to dissociation of SRC from the nuclear receptors, thereby allowing access for assembly of the TRAP/DRIP complex (Figure 1-20).

Nuclear receptors can be posttranslationally modified through acetylation, ubiquitination, and phosphorylation. Phosphorylation, which is the most extensively studied of these modifications, can affect virtually all nuclear receptors. Phosphorylation by kinases associated with the general transcriptional machinery (eg, cyclin-dependent kinase 7) or major intracellular signaling pathways (eg, Akt) may serve to recruit coactivators into the complex, thereby facilitating transcriptional regulation. Coactivator molecules or other factors recruited into the multisubunit transcription complexes may possess kinase, ubiquitin ligase, ATPase, methyltransferase, or acetylase activity which can target either nuclear receptors or other coregulators. Thus, in addition to their ability to provide the scaffolding for transcription complex assembly, they also possess the enzymatic capacity to fine-tune the transcriptional activity of the complex. In addition to their effects on transcription, coactivators have been suggested to be involved in transcript elongation, RNA splicing, and mRNA transport.

Recent studies have shown that a significant portion of ER DNA-binding sites in MCF7 lines (breast cancer cell line) are topographically linked to, or in some cases directly overlap with, those for the forkhead box transcription factor A1 (FOX A1). FOX A1 has been referred to as a pioneer factor that aids in positioning ER (or AR) at specific sites on DNA. FOX A1 is recruited to specific epigenetic markers in chromatin; in the case of MCF7 cells this is a lysine 4 methylation on histone 3. This, in turn, directs ER binding to nearby regions on the DNA. Similar findings have been reported with the AR, albeit with different epigenetic chromatin markers.

Although the glucocorticoid receptor is encoded by a single gene, TR is encoded by two genes (α and β). TR α1 and TR β1 appear to be the dominant forms of TR in the body. Although considerable overlap exists in their tissue distribution, TR α1 is enriched in skeletal muscle, brown fat, and the central nervous system, and TR β1 is found in the liver, kidney, and central nervous system. They are believed to signal most of the developmental and thermogenic effects of thyroid hormone in the whole animal. TR β2, a splice variant of the TR β gene, is found in the rodent pituitary gland, where it may subserve a specific regulatory function (eg, control of TSH secretion). TR α2, an alternatively spliced product of the TR α gene, lacks the hormone-binding domain at the carboxyl terminal of the molecule and thus is not a true thyroid hormone receptor. Under certain experimental conditions, TR α2 can block the activity of
other members of the TR family, but its physiologic role, if one exists, remains undefined.

Similar heterogeneity exists in the retinoid receptor family. There are three isoforms for both the RXR and RAR. Collectively, these receptors are thought to play an important role in morphogenesis, but the function of the individual isoforms remains only partially understood. There are two ER isoforms. ERα appears to signal the bulk of traditional estrogenic activity. ERβ is found in a variety of different tissues and possesses antiproliferative activity that may serve to dampen the effects of liganded ER.

NONGENOMIC EFFECTS OF THE STEROID HORMONES

Although steroids exert most of their biologic activity through direct genomic effects, there are several lines of evidence suggesting that this does not provide a complete picture of steroid hormone action. There are several examples that, for kinetic or experimental reasons, do not fit the classic paradigm associated with a transcriptional regulatory mechanism. Included within this group are the rapid suppression of ACTH secretion following steroid administration, the modulation of oocyte maturation and neuronal excitability by progesterone, the stimulation of endothelial nitric oxide synthase (through interaction of ERα with the p85 subunit of PI-3K) by estrogen, the inhibition of type II deiodinase and stimulation of mitochondrial oxygen consumption by thyroid hormone, and regulation of calcium channel function by 1,25-(OH)₂ vitamin D. Recent studies have demonstrated the presence of conventional estrogen receptors on the plasma membrane of target cells. The relationship of these receptors to their nuclear counterparts and their role in signaling estrogen-dependent activity (genomic vs nongenomic) is being actively investigated. The PR displays a novel ability to interact with the SH3 domains of the Src family tyrosine kinases, thereby accessing the Ras/Raf/MEK-1/ERK signaling pathway (discussed earlier). Although we still do not completely understand the mechanisms underlying these nongenomic effects, their potential importance in mediating steroid or thyroid hormone action may, in selected instances, approach that of their more conventional genomic counterparts.

Neurosteroids represent another class of nontraditional hormonal agonists with unique biologic activity. Some of these are native steroids (eg, progesterone), whereas others are conjugated derivatives or metabolites of the native steroids (eg, dihydropregesterone). These agonists have been identified in the central nervous system and in some instances shown to have potent biologic activity. It is believed that they operate through interaction with the receptor for γ-aminobutyric acid, a molecule that increases neuronal membrane conductance to chloride ion. This has the net effect of hyperpolarizing the cellular membrane and suppressing neuronal excitability. Interactions that promote receptor activity would be predicted to produce sedative-hypnotic effects in the whole animal, whereas inhibitory interactions would be expected to lead to a state of central nervous system excitation.

STEROID AND THYROID HORMONE RECEPTOR RESISTANCE SYNDROMES

Heritable defects in these receptors have been linked to the pathophysiology of a number of hormone-resistant syndromes. These syndromes are characterized by a clinical phenotype suggesting hormone deficiency, by elevated levels of the circulating hormone ligand, and increased (or inappropriately detectable) levels of the relevant trophic regulatory hormone (eg, ACTH, TSH, FSH, or LH). Point mutations in the zinc fingers of the DNA-binding domain as well the ligand-binding domain of the vitamin D receptor lead to a form of vitamin D–dependent rickets (type II) characterized by typical rachitic bone lesions, secondary hyperparathyroidism, and alopecia. It is inherited as an autosomal recessive disorder. Molecular defects scattered along the full length of the androgen receptor, although concentrated in the ligand-binding domain, have been linked to syndromes characterized by varying degrees of androgen resistance ranging from infertility to the full-blown testicular feminization syndrome. Clinical severity, in this case, is thought to be related to the severity of the functional impairment that the mutation imposes on the receptor. Because the androgen receptor is located on the X chromosome, these disorders are inherited in an X-linked fashion. Defects in the glucocorticoid receptor are less common, perhaps reflecting the life-threatening nature of derangements in this system. However, mutations have been identified that impact negatively on receptor function. Clinical presentations in these cases have been dominated by signs and symptoms referable to glucocorticoid deficiency (eg, fatigue, asthenia) and adrenal androgen (eg, hirsutism) and sexual precocity and mineralocorticoid (low renin hypertension) overproduction. This presumably results from defective steroid-mediated suppression of ACTH secretion and adrenal hyperplasia as the former rises in a futile attempt to restore glucocorticoid activity at the periphery. Resistance to thyroid hormone has been linked to a large number of mutations scattered along the full length of the β form of the receptor, although, once again, there is a concentration of mutations in the ligand-binding domain, particularly along the rim of the coactivator-binding pocket. No mutations in the α form of the receptor have been linked to a hormone-resistant phenotype. The clinical presentation of thyroid hormone resistance extends from the more typical mild attention-deficit syndromes to full-blown hypothyroidism with impaired growth. Different target tissues harboring the mutant receptors display variable sensitivity to thyroid hormone, with some tissues (eg, pituitary) displaying profound resistance and others (eg, heart) responding in a fashion suggesting hyperstimulation with thyroid hormone (ie, thyrotoxicosis). The latter effects (eg, tachycardia) may reflect the predominance of the normal α isoform, as opposed to defective β TR isoform, in the target tissue (eg, heart). These syndromes are rather unique in that they are inherited as autosomal dominant disorders, presumably reflecting the ability of the mutated receptors to interfere with
receptors produced from the normal allele, either by binding to the RE with higher affinity than the wild-type receptors and precluding access of the latter to target genes or by forming inactive heterodimers with the wild-type receptor proteins. A number of patients with thyroid hormone resistance have been described that lack mutations in the TR. In two cases, the defect has been assigned to defects in the transport and intracellular metabolism of thyroid hormone. Defects in the ER are rare, perhaps reflecting the critical role estrogens play in regulating lipoprotein metabolism. However, one male patient who harbors a mutation within the ligand-binding domain of the ER has been described. His clinical presentation was characterized by infertility as well as osteopenia, suggesting important roles for estrogens in the maintenance of spermatogenesis as well as bone growth even in male subjects. A novel mutation in the PPARγ receptor leads to a phenotype that clearly resembles that of patients with the metabolic syndrome (ie, severe insulin resistance, diabetes mellitus, and hypertension). A syndrome of mineralocorticoid resistance, or pseudohypoaldosteronism, has been described in a number of independent kindreds. Pseudohypoaldosteronism type I is characterized by neonatal renal salt wasting, dehydration, hypotension, hyperkalemia, and hyperchloremic metabolic acidosis despite the presence of elevated aldosterone levels. Heterozygous mutations in the MR are responsible for a milder form of the disease which is inherited in an autosomal dominant pattern with abnormalities largely confined to the kidney. A more severe form of the disease with generalized systemic involvement is inherited in an autosomal recessive pattern and appears to be due to loss-of-function mutations in genes encoding subunits of the amiloride-sensitive epithelial sodium channel. Of equivalent interest is the recent identification of an activating mineralocorticoid receptor mutation (Ser810-to-Leu810). This mutation results in early-onset hypertension that is markedly exacerbated by pregnancy. The mutation leads to constitutive activation of the MR and alters the specificity of ligand binding such that traditional MR antagonists, like progesterone, function as partial agonists.

Epidemiologic analysis of a large population reported that about 1 of 30 (3.2%) people in the United States (more than 8.5 million individuals) are currently affected by autoimmune diseases. Graves disease, type 1 diabetes, pernicious anemia, rheumatoid arthritis, Hashimoto thyroiditis, and vitiligo are the most prevalent such conditions, accounting for 93% of affected individuals. A more global approach at calculating prevalence led to a corrected estimate between 7.6% and 9.4% of the world’s population as affected by autoimmune diseases (2.5 in 30 people worldwide).

These autoimmune diseases have traditionally been looked upon as forming a spectrum. At one end are found organ-specific diseases with organ-specific targets. Hashimoto thyroiditis is an example in which a specific lesion affects the thyroid (lymphocytic infiltration, destruction of follicular cells) and autoantibodies are produced with absolute specificity for thyroid proteins. At the other end of the spectrum are the systemic autoimmune diseases, broadly belonging to the class of rheumatologic disorders. Systemic lupus erythematosus is an example of a disease characterized by widespread pathologic changes and a collection of autoantibodies to DNA and other nuclear constituents of all cells. Many organ-specific autoimmune diseases are autoimmune endocrinopathies. Furthermore, most endocrine glands are subject to autoimmune attack including the adrenals (autoimmune Addison disease), gonads (autoimmune oophoritis), pancreas (type 1 diabetes), pituitary (autoimmune hypophysitis), and thyroid (autoimmune thyroid disease) (Table 2-1).

By far the most common autoimmune endocrine diseases are those involving the thyroid and type 1 diabetes. When the target is the thyroid gland and the clinical manifestation is hypothyroidism (Hashimoto thyroiditis), the prevalence is about 1%. When the manifestation is hyperthyroidism (Graves disease), the prevalence is about 0.4%. Both thyroid autoimmune disorders affect women preferentially. When the targets of the autoimmune response are the β cells of the pancreas, the clinical presentation is type 1 diabetes. The prevalence of type 1 diabetes is close to that of Graves disease (0.2%-0.5%); however, it has no gender predilection.

Basic immunologic concepts as they apply to clinical autoimmune endocrine diseases as sole entities and as polyglandular failure syndromes are reviewed in this chapter.

BASIC IMMUNE COMPONENTS AND MECHANISMS

The immune system is constantly confronted with a variety of molecules and recognizes them as either self or foreign. The adaptive immune system has evolved to recognize virtually any foreign molecule, either in existence or yet to come. The repertoire of immune recognition molecules randomly formed by gene rearrangements is not limited by the genetic information encoded in the genome (Figure 2-1). As a result, an enormously wide array of immune recognition molecules is acquired by the human immune system. By way of illustration, the theoretical diversity of T-cell receptors (T-cell recognition molecules) by random rearrangements reaches $10^{15}$. This mechanism of rearrangement also applies to B-cell recognition molecules (ie, immunoglobulins). The random mechanism of gene rearrangement, however, produces immune recognition molecules that react with self components. Potentially dangerous immune cells carrying self-reactive recognition molecules are eliminated (negatively selected) during development of T lymphocytes in the thymus and of B lymphocytes in the bone marrow. It appears that only immune cells which react with foreign antigen strongly and with self antigen very weakly are positively selected and comprise the peripheral immune cell repertoire. This selection mechanism of immune cells is termed "central tolerance." Self-reactive immune cells that skip central tolerance and reach the periphery are managed by other control mechanisms against autoimmunity and are either eliminated, rendered unresponsive, or suppressed ("peripheral tolerance"). Failures in these mechanisms of immunologic regulation, as proposed by Mackay and Burnet in 1964, are central features of the concept of autoimmunity.

IMMUNE RECOGNITION AND RESPONSE

T and B lymphocytes are the fundamental and predominant immune cells. T lymphocyte precursors (pre-T cells) originate in the bone marrow and migrate to the thymus, where they undergo maturation and differentiation. At early stages, they express several T-cell surface molecules but still have genomic (not rearranged) configuration of their T-cell receptors (TCRs). These pre-T cells, destined to become T cells with TCR α/β chains (T α/β cells), pass through a critical phase during which self-reactive T cells are deleted by negative selection (see T-Cell Tolerance, later in this chapter). Few pre-T cells will express other types of chains on their

**FIGURE 2-1** Rearrangement of the T-cell receptor (TCR) α and β genes to form a functionally diverse receptor. During T-cell development, the TCR α and β gene segments rearrange by somatic recombination so that one of the Vα segments pairs with a single Jα segment, and a Vβ segment pairs with a single Dβ and Jβ segment. The C (constant) segments are brought together with the rearranged segments by transcription and splicing to generate the functional mRNA that will be translated into the α and β protein chains that compose the TCR.

TCR (T γδ cells). T αβ cells differentiate into either mature CD4 or CD8 cells. These now mature lymphocytes migrate to T-cell areas of peripheral lymphoid organs and exert their function as helper (T<h>h</> cells) or cytotoxic (T<sub>c</> cells) when activated.

B lymphocytes mature and differentiate in the bone marrow and then migrate to the B-cell areas of lymphoid organs. Influenced by factors derived from T<sub>h</> cells previously activated by professional antigen-presenting cells (APCs) such as macrophages, some B cells differentiate to become immunoglobulin M (IgM)-producing cells (plasma cells). Most of the other activated B cells that do not differentiate into plasma cells revert to the resting state to become memory B cells. When memory B cells are further activated, two events occur: isotype switching (immunoglobulin class switching) and hypermutation of the immunoglobulin-variable region to further increase diversity and specificity (affinity maturation).

Activation of B cells requires recognition of the antigen as a whole, while T cells require recognition of antigenic peptides bound to major histocompatibility complex (MHC) molecules on the surfaces of professional APCs. Therefore, T-cell recognition is said to be MHC restricted.

The human MHC (human leukocyte antigen; HLA) consists of a linked set of genes encoding major glycoproteins involved in antigen presentation (Figure 2–2). The complex locates to the short arm of chromosome 6 and divides into three separate regions: class I, class II, and class III genes. The class I “classic” region encodes HLA-A, HLA-B, and HLA-C loci; the nonclassic or class I-related region encodes HLA-E, HLA-F, and HLA-G loci and other immunity-related genes such as CD1. The class II region (HLA-D) encodes HLA-DR, HLA-DQ, and HLA-DP loci and other genes related to antigen processing, transport, and presentation, such as, transporter associated with antigen processing (TAP). The class III region encodes genes for tumor necrosis factors α and β (TNF-α and TNF-β); complement factors C2, C4, and B; and the steroidogenic enzyme 21-hydroxylase. MHC class I (classic) molecules are found on all somatic cells, whereas MHC class I nonclassic antigens are expressed only on some (e.g., HLA-F on fetal liver, HLA-G on placental tissues). CD1 molecules are expressed on Langerhans cells, dendritic cells, macrophages, and B cells (all professional APCs). MHC class II molecules are exclusively expressed on these professional APCs. However, virtually all cells except mature erythrocytes can express MHC class II
molecules under particular conditions (e.g., stimulation with interferon-γ [IFN-γ]). As a general rule, MHC class I molecules present peptides derived from endogenous antigens that have access to cytosolic cell compartments (e.g., virus) to CD8 T<sub>C</sub> cells. On the other hand, MHC class II molecules present peptides derived from antigens internalized by endocytosis into vesicular compartments (e.g., bacteria) to CD4 T<sub>H</sub> cells. MHC class II molecules also bind peptides derived from many membrane-bound self antigens.

APCs process and present antigen in order to activate T cells utilizing MHC-peptide presentation (Figure 2-3). T cells require at least two signals to become activated. The interaction of a TCR expressed on antigen-specific T cells and the antigenic peptide–MHC complex expressed on APCs provides the first signal. The second signal is delivered primarily by the interaction between costimulatory molecules CD80 (B7.1) and CD86 (B7.2) on APCs and CD28 on T cells. These two signals induce proliferation of T cells, production of interleukin-2 (IL-2), and expression of the antiapoptotic protein Bcl-xL. T<sub>H</sub> cells and T<sub>C</sub> cells are effector cells that require both signals in order to become activated. However, T<sub>C</sub> cells also need the “help” provided by T<sub>H</sub> cells. Until recently, it was thought that T<sub>H</sub> and T<sub>C</sub> cells needed to interact with the same APC simultaneously and that cytokines (such as IL-2) produced by the T<sub>H</sub> cell would then act on the T<sub>C</sub> cell to facilitate its response. New studies suggest that the interaction between another costimulatory molecule, CD40 ligand (CD154), present on T cells, and CD40, present on APCs, may provide an alternative explanation. It appears that T<sub>H</sub> cells–recognizing antigenic peptides presented by APCs deliver a signal through the CD154–CD40 complex that “licenses” APCs to directly stimulate T<sub>C</sub> cells (Figure 2-4). Thus, there is no need for simultaneous interactions of T<sub>H</sub> and T<sub>C</sub> cells while encountering the APC. CD154–CD40 interaction also enhances expression of CD80 and CD86 as well as secretion of cytokines (IL-1, -6, -8, -10, and -12 and TNF-α).

Yet another molecule on T cells, the CD28 homolog cytotoxic T lymphocyte antigen 4 (CTLA-4 or CD152), functions to suppress T-cell responses (see Figure 2-3). CD152 is expressed at low to undetectable levels on resting T cells. It is upregulated by the ligation of CD28 on T cells with CD80/86 on APCs, or by IL-2. CD152 and CD28 on T cells share the same counterreceptors, namely, CD80/86 on APCs. However, CD152 has a 20-fold higher affinity than CD28 for their ligands.
to the traditional model, Th cells and Tc cells recognize antigen on the same APC. The APC-activated Th cell produces IL-2, which contributes to the activation of Tc cells while in simultaneous interaction with the same APC. According to the proposed new model (A), APCs are licensed to activate Tc cells by Th or other stimuli (lipopolysaccharides, IFN-γ, viruses). APCs first interact with Th cells. The association of CD154 (CD40 L) on the Th cell and CD40 on the APC allows (or licenses) the latter to activate Tc cells directly (B). Thus, once licensed, APCs are capable of activating cytotoxic T cells without the need of simultaneous interaction with Th cells.

The integration of all these interactions may be as follows (see Figure 2–3): After processing antigen, APCs deliver an antigen-specific first signal through the MHC-peptide–TCR interaction on T cells. A second signal is provided by a costimulatory interaction of the CD80/86–CD28 complex that induces the expression of CD154 first and then CD152. Binding of CD154 on Th cells with CD40 on APCs enhances expression of CD80/86 and licenses APCs for direct activation of Tc cells. Other inflammatory cytokines as well as lipopolysaccharides and viruses may do the same. The increased expression of APC–CD80/86 and consequent binding of CD28 on T cells then perpetuates the activation and proliferation of these effector cells. However, the expression of CD152 48 to 72 hours after T-cell activation leads to the preferential binding of this molecule to CD80/86 on APCs because of its higher affinity for CD80/86. This may displace CD28 from CD80/86 and, in turn, suppress T-cell activity. This sequence of complex events is probably simplistic relative to what nature has to offer. A new B7 family of receptors has been reported: some with positive costimulatory capacity, many with a role in downregulating immune responses, yet others with dual functions. For some of these pathways such as B7H3/H4 (expressed in APCs with unknown counterreceptor on T cells), very little is known, but even for those pathways that have been extensively studied, such as the CD80/86:CD28:CTLA-4 (mentioned above); B7h:ICOS (inducible costimulator) and PD-L1/PD-L2:PD1, new insights are still being generated. The intricacies of controlling T-cell activation are enhanced by the complexity of the costimulatory pathways, such that there are multiple possible receptor–ligand interactions.

Activation and differentiation of B cells often require two signals also. Naïve B cells are triggered by antigen but may also require accessory signals that come from activated Th cells. Some antigens can directly activate naïve B cells without the need for Th cells (e.g., lipopolysaccharides from gram-negative bacteria or polymorphic protein structures). The former type of B-cell activation (MHC class II-restricted T cell help) is called thymus-dependent (TD). The latter type is called thymus-independent (TI). Th cells also control isotype switching and initiate somatic hypermutation of antibody variable-region genes (see Tolerance, later). Interaction between CD154 on Th cells and CD40 on B cells and the cytokines produced by Th cells are essential for isotype switching and formation of germinal centers in peripheral lymphoid organs. The immunoglobulin isotype switching is critical for the generation of functional diversity of a humoral immune response. Somatic hypermutation (point mutations of the variable-region genes of immunoglobulins during the course of an immune response) is necessary for the affinity maturation of antibodies.

Overall, the immune response is a combination of effector mechanisms that function to eliminate pathogenic organisms. These effector mechanisms include, as innate immunity, phagocytosis (by macrophages, neutrophils, monocytes, and dendritic cells) and cytotoxicity (by natural killer [NK] cells); and as adaptive immunity, antibody-dependent complement-mediated cytotoxicity, antibody-dependent cell-mediated cytotoxicity (ADCC), and cytotoxicity by T γδ cells that recognize heat shock proteins on target cells, and cytotoxicity by CD8 or CD4 Tc cells. CD8 and CD4 Tc cells are activated by the described recognition of specific antigenic peptides bound to class I (for CD8), class II (for CD4) MHC molecules on the APCs and classically by IL-2 from nearby activated CD4 Th cells. These cells kill the target by either secreting cytotoxins (perforin, granzyme) or by inducing apoptosis through the Fas–FasL (Fas ligand) interaction (killer cells carrying FasL molecules activate programmed cell death in target cells expressing Fas molecules). FasL or CD95L is a type II transmembrane protein that belongs to the TNF family. The binding of FasL with its receptor induces apoptosis. FasL–Fas receptor interactions play an important role in the regulation of the immune system.

The specificity of the immune response is crucial if self-reactivity is to be avoided. In order to ensure that lymphocyte responses and the downstream effector mechanisms they control are directed exclusively against foreign antigens and not against “self” components, a number of safety-check barriers must be negotiated before autoreactive lymphocytes can differentiate and proliferate.

**TOLERANCE**

**T-Cell Tolerance**

T cells developing in the thymus (pre-T cells) are destined to become T αβ cells through rearrangement of the TCR β gene initially, followed by the TCR α gene (Figure 2–5). If unproductive rearrangements of TCR genes occur (nonfunctional TCR α or β proteins), apoptosis of these pre-T cells follows (Figure 2–5A).
FIGURE 2-5  

A. **Central T-cell tolerance**: Mechanisms of central tolerance (at the thymus level) are depicted. From top to bottom, pre-T cells first rearrange their TCR. Unproductive (nonfunctional) rearrangements lead to apoptosis, while productive ones engage pre-T cells in self-antigen recognition. Clonal deletion indicates elimination of cells based on their high or no avidity for self-antigen (apoptosis). Surviving low-avidity cells reach the periphery as mature CD4 and CD8 cells.

B. **Peripheral T-cell tolerance**: May be accomplished through any of the five depicted mechanisms. **1. Clonal deletion**: After encountering self-antigen in the context of self-MHC molecules and simultaneous delivery of a second signal (CD80/86–CD28) by APCs (top left), autoreactive T cells become activated. These activated T cells express Fas molecules on their
If functional rearrangements of TCR α and β proteins occur, cells express TCR α/β dimer and CD3 molecules at low levels on the cell surface. TCR-rearranged cells proliferate 100-fold. Positive and negative selection occurs based on the ability of the rearranged TCR α/β to recognize antigenic peptides in association with self-MHC molecules on thymic epithelial and dendritic cells. Negative selection (clonal deletion) appears to take place in the thymus medulla, where pre-T cells—bearing TCRs specific for self peptides bound to self-MHC molecules are deleted. At least 97% of developing T cells undergo apoptosis within the thymus (central tolerance). Positively selected pre-T cells increase expression of TCR α/β, express either CD4 or CD8, and become mature T cells. These mature T cells exit the thymus and go to the periphery.

A differential avidity model in which the fate of T cells is determined by the intrinsic affinity of TCRs for their ligands has been advanced to explain the paradox between positive and negative selection. According to this model, T cells with high avidity for MHC-self peptide complexes would be eliminated (negative selection), whereas T cells with low avidity to MHC-self peptide complexes would be positively selected. If the avidity is close to zero, T cells would not be selected (lack of effective signal to survive). The biochemical factor or factors that signal survival (low avidity of TCR binding) versus apoptosis (triggered by high avidity interactions) have yet to be found.

Costimulatory interactions between CD28 and CD80/86 and between CD154, CD40, and adhesion molecules, such as lymphocyte function-associated antigen-1 (LFA-1), are also involved in preferential deletion of self-reactive T cells in the medullary region of the thymus. It is known that negative selection is not 100% effective and that some potentially autoreactive T cells do escape to the periphery. Not all self peptides would be presented to pre-T cells during their development in the thymus. Self peptides derived from seeded proteins (ie, intracytoplasmic enzymes) only timely expressed after rigid regulatory control (ie, puberty) in endocrine glands are believed to be a likely source. Therefore, the peripheral immune system must maintain tolerance through complementary control mechanisms.

"Peripheral tolerance" (Figure 2–5B) may be maintained by the induction of unresponsiveness to self antigen (anergy) or by the induction of regulatory T cells (T regs), such as suppressor T cells (active suppression). Peripheral clonal deletion (apoptosis) of autoreactive T cells that have escaped from the thymus may play an important role in limiting rapidly expanding responses, but there are many examples where autoreactive T cells persist. Some autoreactive T cells may never encounter the self antigen because it may be sequestered from the immune system (ignorance).

Lastly, immune deviation, whereby noninflammatory T\textsubscript{\textsc{hi}} responses suppress an autoreactive inflammatory T\textsubscript{\textsc{hi}} response, inducing peripheral tolerance, deserves further discussion. T\textsubscript{\textsc{hi}} cells, which regulate cell-mediated responses, secrete IFN-γ and small amounts of IL-4. In contrast, T\textsubscript{\textsc{lo}} cells, which provide help for antibody production, secrete abundant IL-4 and little IFN-γ. A prevailing concept in human autoimmunity is that T\textsubscript{\textsc{hi}} responses are believed to dominate. It has been shown in animal models that induction of T\textsubscript{\textsc{hi}} responses ameliorates T\textsubscript{\textsc{hi}} responses. Hence, unbalanced T\textsubscript{\textsc{hi}} immune deviation may lead to a breakage of peripheral tolerance. However, evidence to the contrary exists in some endocrinopathies. (See autoimmune response in the section on Autoimmune Aspects of Thyroid Disease, later in the chapter.)

Clonal deletion and anergy occur through apoptosis at the site of activation or after passage through the liver. High antigen dose and chronic stimulation induce peripheral elimination of both CD4 and CD8 T cells. Activated T cells express Fas molecules on their surfaces but are resistant to FasL-mediated apoptosis because of the simultaneous expression of Bcl-xL (apoptosis-resistance molecules), induced by CD28 ligation during activation (see Immune Recognition and Response, earlier in the chapter). Several days after activation, when Bcl-xL has declined, CD4 cells become susceptible to Fas-mediated apoptosis (activation-induced cell death; AICD). A similar mechanism via p75 tumor necrosis factor (TNF) receptor has been shown for CD8 cells. Therefore, autoreactive T cells might be deleted by apoptosis induced by chronic stimulation with self antigens, present abundantly in the periphery. However, autoreactive T cells specific for very rare self antigens may be difficult to eliminate.

Anergy also results from the lack of a second costimulatory signal. When nonhematopoietic cells stimulated by IFN-γ present antigen in an MHC class II-restricted fashion (as thyrocytes do inAITD), autoreactive T cells may be rendered unresponsive because of the absence of a CD28–CD80/86-mediated signal (nonhematopoietic cells do not express CD80/86 as professional APCs do). However, even if the two signals are provided, anergy may result from the lack of T\textsubscript{\textsc{hi}} cell-originated cytokines (IL-2, -4, -7, etc). It has also been shown that in vivo T-cell anergy may be
A Central B-cell tolerance

Unproductive BCR rearrangements drive pre-B cells to apoptosis. Functional rearrangements allow expansion and expression of IgM. Next, similar to T-cell clonal deletion, immature B cells that strongly bind self antigens in the bone marrow are eliminated by apoptosis. Some autoreactive immature B cells, instead of becoming apoptotic, however, resume rearrangements of their L-chain genes, attempting to reassemble new allelic...
induced by CD80/86–CD152 interaction (see also Immune Recognition and Response, discussed earlier).

**T-cell active suppression** is considered to be a major regulatory mechanism of peripheral tolerance; however, its mode of action is still under study. As mentioned above, nonhematopoietic cells stimulated by IFN-γ present antigen in an MHC class II-restricted fashion to T cells and render them anergic. These nonhematopoietic cells (nonprofessional APCs) may also present to CD4 T-suppressor cells (Tₜₛ, also known as CD4 + CD25 + FOXP3 + regulatory T cells, T regs). Before becoming unresponsive, these cells may induce specific CD8 T suppressor (Tₛ) cells. In turn, these CD8 Tₛ cells may regulate (via T-cell-suppressor factors or cytotoxicity) autoreactive T cells (see also Figure 2–5B).

**B-Cell Tolerance**

Instead of the thymus, the bone marrow provides the setting for central B-cell tolerance. Pre-B cells rearrange their B-cell receptor (BCR or membrane-bound immunoglobulin) early in development. The immunoglobulin heavy (H) chain genes rearrange first, followed by light (L) chain gene rearrangement. Unproductive rearrangements and pairings leading to formation of nonfunctional immunoglobulin drive pre-B cells to apoptosis (Figure 2–6A). Functional rearrangements (functional BCRs) allow immature B-cell expansion and expression of IgM and CD21 (a marker of functionality). Only one-third of the precursor cells reach this stage. The random rearrangement of the V, D, and J segments of immunoglobulin genes during this period inevitably generates self-recognizing immunoglobulins. Negative selection of autoreactive B cells occurs at the immature B-cell stage on the basis of the avidity of the BCR for self antigens. Similar to the T-cell clonal deletion, immature B cells that strongly bind antigens in the bone marrow are eliminated by apoptosis. Some autoreactive immature B cells, instead of undergoing apoptosis, resume rearrangements of their L-chain genes in an attempt to reassemble new κ or λ genes. This procedure, called **BCR editing**, permanently inactivates the autoreactive immunoglobulin genes. Soluble antigens, presumably because they generate weaker signals through the BCR of immature B cells, do not cause apoptosis but render cells unresponsive to stimuli (anergy). These anergic B cells migrate to the periphery, where they express IgD. They may be activated under special circumstances, making anergy less than sufficient as a mechanism of enforcing tolerance. Only immature B cells in the bone marrow with no avidity for antigens (membrane-bound or soluble) become mature B cells with the capacity to express both IgM and IgD. As with T cells, 97% of developing B cells undergo apoptosis within the bone marrow. Also, and as with T cells, **central clonal deletion, anergy, and BCR editing** eliminates autoreactive B cells, recognizing bone marrow-derived self antigens.

**Peripheral B-cell tolerance** (Figure 2–6B) is also crucial for protection against autoimmunity. It appears that in the absence of antigen, mature B cells are actively eliminated in the periphery by activated T cells via Fas–FasL and CD40–CD154 interactions. In the presence of specific antigen but without T-cell help, antigen recognition by BCRs induces apoptosis or anergy of mature B cells. If antigen and specific T-cell help are provided—that is, if antigen bound to the BCR is internalized, processed, and presented in an MHC class II-restricted fashion to a previously activated Tₜₜ cell specific for the same antigen—two events occur. One, the B cell becomes an IgM-secreting plasma cell, and—in the presence of the appropriate cytokines and after expression of CD40 (for Tₜₜ cell CD154 interaction)—class switching occurs. Two, further somatic hypermutation of the immunoglobulin variable region genes of such mature B cells, which changes affinity of BCRs for antigens, also occurs in germinal centers (see also Immune Recognition and Response, discussed earlier). Mutants with low-affinity receptors undergo apoptosis, while enhanced-affinity BCRs are positively selected. In the presence of CD40 ligation of CD154, antigen-stimulated B cells become memory B cells (see Figure 2–6B).

The ability of mature B cells to capture very low quantities of antigen via high-affinity BCRs allows them to amplify their antigen-presenting capacity to more than 1000 times that of other professional APCs. This particular property may become critical in the development of chronic organ-specific autoimmune diseases in which the source of antigen is limited. Thus, autoreactive B cells that happen to escape the control mechanisms described could amplify and perpetuate autoimmune responses in patients with failing endocrine organs when tissue destruction has left only minute amounts of residual antigen.

**AUTOIMMUNITY IS MULTIFACTORIAL**

Although the breakage of self-tolerance seems to be a central pathogenic step in the development of autoimmune diseases, autoimmunity is a multifactorial event. Specifically, defects in apoptosis-related molecules (Fas–FasL) of thymic dendritic cells
have been shown to impair central clonal deletion. Also, in the periphery, similar defects (Fas–FasL, CD152) on T cell–APC molecules may prevent apoptosis of autoreactive T cells. However, it is difficult to consider these general defects as causative of organ-specific disorders. Furthermore, clonal ignorance of T cells cannot be maintained if antigens sequestered from the immune system are released in blood or if cryptic epitopes of antigens that have never been recognized by the immune system are presented to T cells for recognition (after tissue destruction, for example). Defects of active suppression (T regs dysfunction, CTLA-4 downregulation), immune deviation (T<sub>H</sub><sub>1</sub>/T<sub>H</sub><sub>2</sub> imbalance), and defects in B-cell tolerance may all be involved in the pathogenesis of autoimmune diseases. How and why loss of immune self-tolerance occurs is not completely understood. Both genetic and environmental factors appear to be necessary.

### GENETIC FACTORS IN AUTOIMMUNITY

Epidemiologic studies demonstrate that susceptibility to most autoimmune diseases has a significant genetic component. In type 1 diabetes, for example, there is a clear association between race and susceptibility to disease—the incidence is approximately 40 times higher in Finland than in Japan. Family studies also demonstrate a strong underlying genetic component. The lifetime risk of developing type 1 diabetes in the United States general population is 0.4%, whereas in relatives of diabetics the risk is substantially higher (4% for parents, 5%-7% for siblings, 20% for HLA-identical siblings, 25%-40% for monozygotic twins).

The inheritance pattern of autoimmune disorders is complex. These disorders are polygenic, arising from several independently segregating genes. The most consistent genetic marker for autoimmune diseases to date is the MHC genotype. Considering again genetic susceptibility to type 1 diabetes, up to 95% of Caucasians developing diabetes express the HLA alleles DR3 or DR4—compared to about 40% of normal individuals. Individuals heterozygous for both DR3 and DR4 have the highest risk. It has been shown that the DQ rather than DR genotype is a more specific marker of susceptibility and that the association of both markers is due to the fact that they are products of closely linked genes. But what is more important than the fact that HLA genes are linked to diabetes is that HLA haplotypes are no longer simply undefined genetic markers. It has been shown that the polymorphisms of the DQ molecules are critical for high-affinity recognition of autoantigens (eg, islet cell antigens) by TCRs. HLA-DQ structure analysis suggests that the lack of aspartic acid at position 57 (Asp<sup>57</sup>) on the DQ β chain allows the autoantigen (processed peptide) to fit better in the antigen-binding groove formed by this molecule. To the contrary, the presence of Asp<sup>57</sup> allows the formation of a salt bridge with a conserved arginine at position 76 on the DQ α chain, preventing the accommodation of the immunogenic peptide recognized by the TCR. Several autoimmune diseases have been linked to HLA-DQB1 genes, including type 1 diabetes, celiac disease, bullous pemphigoid, autoimmune hepatitis, and premature ovarian failure, and the structure of the DQB1 molecule may be the reason for the increased susceptibility. Other
candidate genes associated with autoimmune endocrinopathies are discussed further under the single and polyglandular syndromes.

### ENVIRONMENTAL FACTORS IN AUTOIMMUNITY

Environmental factors also play a critical role in the pathogenesis of autoimmune disease. The strongest evidence for this statement comes from studies of monozygotic twins, which show that concordance rates for autoimmune disorders are imperfect (never 100%). As mentioned above, in type 1 diabetes, identical twins show less than 50% concordance.

The environmental factors thought to have greatest influence on disease development include infectious agents, diet, and toxins. In type 1 diabetes, viruses have been strong suspects. Up to 20% of children prenatally infected with rubella develop type 1 diabetes. Children with congenital rubella also have an increased incidence of other autoimmune disorders, including thyroiditis and dysgammaglobulinemia. The mechanisms by which these pathogens may induce autoimmune responses include molecular mimicry and direct tissue injury. The hypothesis of molecular mimicry suggests that immune responses directed at infectious agents can cross-react with self antigens, causing tissue or organ destruction. Support for this concept is found in well-known clinical syndromes such as rheumatic fever (immune responses directed against streptococcal M protein seem to cross-react with cardiac myosin, inducing clinical myocarditis). In autoimmune diabetes, the best-studied example of molecular mimicry is the B4 coxsackievirus protein P2-C. Coxsackie B4 virus has also been epidemiologically implicated in the development of type 1 diabetes. There is a striking amino acid sequence similarity between P2-C viral protein and the enzyme glutamic acid decarboxylase (GAD), found in pancreatic β cells (see Autoimmune Aspects of Type 1 Diabetes, discussed later).

The importance of diet in the development of autoimmune diseases remains controversial. An association between early exposure to cow’s milk proteins and the risk of type 1 diabetes has been observed in several epidemiologic studies. For example, one study demonstrated that primary immunity to insulin is induced in infancy by oral exposure to cow's milk insulin, but the relevance of this observation is still unknown. On the other hand, selected antigens (from bovine serum albumin to porcine insulin) have been administered orally to mice with a broad spectrum of autoimmune disorders, including nonobese diabetic (NOD) mice, with favorable outcomes. Those data in mice were so compelling that oral tolerance trials in humans have been conducted or are ongoing. Unfortunately, the results of already completed trials in other autoimmune diseases have been disappointing. Three large, randomized, controlled trials designed to delay or prevent type 1 diabetes—the two Diabetes Prevention Trial (DPT-1 and 2) and the European Diabetes Nicotinamide Intervention Trial—have failed to demonstrate a treatment effect. Thus, it should not be concluded that it is impossible to delay or prevent type 1 diabetes; rather, it may require testing of more potent interventions or combinations of therapies, guided by better understanding of the
immunopathogenesis of the disease, to demonstrate attenuation or amelioration of the destructive immune process leading to type 1 diabetes.

**SINGLE-GLAND AUTOIMMUNE SYNDROMES**

Organ-specific autoimmune endocrine disorders may present as single entities or may cluster in polyglandular syndromes. Most endocrine glands are susceptible to autoimmune attack. Some are affected more frequently than others (see Table 2–1).

**AUTOIMMUNE ASPECTS OF THYROID DISEASE**

Autoimmune thyroid disease can present in a polarized fashion with Graves disease (thyroid hyperfunction) at one end and Hashimoto thyroiditis (thyroid failure) at the other. This functional subdivision is clinically useful. However, both diseases have a common autoimmune origin.

**Genes and Environment**

Major susceptibility genes in autoimmune thyroid disease have yet to be identified. Although certain HLA alleles (mainly HLA-DR3 and DQA1*0501) have been shown to be present more frequently in Graves disease than in the general population, this association has frequently been challenged. In fact, no consistent association has been found between Graves disease and any known HLA polymorphism. Furthermore, the risk of developing Graves disease in HLA-identical siblings (7%) is not significantly different from that in control populations. HLA-DR5, -DR3, -DQw7 in Caucasian, HLA-DRw53 in Japanese, and HLA-DR9 in Chinese patients were found to be associated with Hashimoto thyroiditis. However, genetic linkage between Hashimoto thyroiditis and a specific HLA locus has not been demonstrated consistently. Overall, the HLA loci are likely to provide less than 5% of the genetic contribution to autoimmune thyroid disease, confirming the relative importance of non-HLA-related genes in susceptibility. For example, it has been shown that the inheritance pattern of autoantibodies to thyroperoxidase (TPO) is genetically transmitted. Other candidates are currently under study. However, autoimmune thyroid disease linkage to CTLA-4, HLA, IgH chain, TCR, thyroglobulin (Tg), TPO, and thyrotropin receptor (TSH-R) genes has been excluded. Recently, using positional genetics of a candidate gene, Graves disease susceptibility was mapped to a noncoding 6.13 kb 3' region of CTLA-4, the common allelic variation of which was correlated with lower messenger RNA levels of the soluble alternatively spliced form of CTLA-4 (sCTLA-4). sCTLA-4 is known to be present in human serum. It can bind CD80/86 molecules on APCs and inhibit T-cell proliferation in vitro. The reduction in the level of sCTLA-4 could potentially lead to reduced blocking of CD80/86, causing increased activation through CD28 of autoreactive T cells.

An important environmental factor influencing the natural history of autoimmune thyroid disease is that of iodine intake (dietary, or present in drugs such as amiodarone or in x-ray contrast media). There is considerable evidence that iodine adversely affects both thyroid function and antibody production in those with occult or overt autoimmune thyroid disease.

**Autoimmune Response**

In Graves disease, thyrocytes are the differentiated carriers of TSH-Rs and the target cells of autoantibodies and probably the autoimmune response. The development of autoantibodies that functionally stimulate the TSH-R mimicking the action of TSH was the first example of antibody-mediated activities of a hormone receptor in humans. Autoantibodies that may stimulate the calcium-sensing receptor (CaSR) (another G-protein–coupled receptor) and signal the inhibition of PTH production have been described in autoimmune hypoparathyroidism. Similarly, stimulating antibodies that bind to the adrenocorticotropic (ACTH) receptor may be involved in the pathogenesis of primary pigmented nodular adrenocortical disease (also referred to as nodular adrenal dysplasia).

In Graves disease, antibodies to the TSH-R present with different types of activity. Thyroid-stimulating immunoglobulins (TSIs), the cause of the hyperthyroidism, are detected by a bioassy that measures cAMP production in a cell line that expresses TSH-Rs. TSH-R autoantibodies (stimulating, blocking, or neutral) can be identified by their ability to prevent TSH binding to the TSH-R (TSH-binding inhibition immunoglobulins, TBI). No direct immunoassay for the measurement of TSH-R autoantibodies is available yet, and its development may be difficult because TSH-R autoantibodies are present at very low concentrations in patients with the disease.

A particular feature of Graves disease is its early clinical presentation. Unlike other autoimmune endocrinopathies (type 1 diabetes, Hashimoto thyroiditis, autoimmune Addison disease), in which much of the target organ has to be destroyed before the disease is manifested, Graves hyperthyroidism often presents with an enlarged and active gland. Minimal lymphocytic infiltration is present when hyperthyroidism (due to the presence of TSH-R-stimulating antibodies) develops. This unique feature may ultimately allow early immune intervention in preference to current ablative therapeutic options.

Another peculiar feature of Graves disease is the helper T-cell response observed in this disease. The activation of antibody-producing B cells by T4 helper lymphocytes in Graves disease is well recognized. At present, a prevailing concept of human autoimmunity suggests that as in acute allograft rejection, "deviation" toward a T1 helper response dominates its pathogenesis. Counterdeviation toward T2 is thought to be a consequence of tolerance induction and has been postulated as a potential therapeutic approach. Graves disease seems to challenge that concept. Analysis of TSH-R-specific T-cell clones from patients with Graves disease has provided direct evidence for polarization of T4 responses; however, instead of T1 deviation, T10 and T17 responses have been observed. As mentioned before, T17 cells, which regulate
cell-mediated responses, secrete mainly IFN-γ and small amounts of IL-4. In contrast, T_{HH} cells that regulate antibody production (such as TSH-R autoantibodies in Graves disease) preferentially produce IL-4 and little IFN-γ. T cells expressing both IL-4 and IFN-γ are known as T_{H1} cells. These experimental results suggest that in Graves disease T_{H1} to T_{H2} cell responses appear to be dominant. Hence, in human autoimmunity, Graves disease appears to be an exception to the usual T_{H1} cell pattern.

In Hashimoto thyroiditis, the hallmark of the humoral immune response is the presence of autoantibodies to TPO. Although the effector mechanism for TPO (or thyroglobulin [Tg]) autoantibodies is still controversial, under special circumstances (at least in vitro) the autoantibodies are themselves cytotoxic agents or activators of cytotoxic T lymphocytes. Furthermore, in secondary T-cell responses, antibodies may play a critical role in antigen processing or presentation to T cells. In short, macrophages internalize (and subsequently process) antigen by phagocytosis and antigen-antibody complex uptake via Fc receptors. B cells have membrane-bound antibodies (B-cell receptors; BCRs) which provide a much more powerful system for antigen capture. Indeed, recombinant TPO-specific membrane-bound autoantibody captures antigen and allows presentation efficiently. Antibody binding also modulates antigen processing of immune complexes, enhancing or suppressing the presentation of different T-cell peptides. Hence, APCs (internalizing immune complexes through Fc receptors) and B cells (capturing antigen through BCRs) can influence the secondary T-cell response that perpetuates autoimmune disease. The potential role of autoantibodies in modulating presentation of T-cell determinants in thyroid (and diabetes) autoimmunity is being explored.

**Animal Models of Autoimmune Thyroid Disease**

The classic immunologic approach to development of an animal model of an autoimmune disease is to immunize the animal with soluble antigen in adjuvant. For autoimmune thyroid disease, the induction of thyroiditis in rabbits using human Tg was one of the earliest attempts to do this—by Rose and coworkers in 1956. In subsequent studies, mice immunized with human or murine Tg developed experimental autoimmune thyroiditis. Immunization with TPO (human or porcine) induces thyroid autoantibodies and, as in the case of Tg, causes thyroiditis to develop in particular MHC strains of mice. However, unlike spontaneous thyroiditis in chickens, none of the immunized mouse models of thyroiditis develop hypothyroidism.

In 1996, Shimojo and coworkers developed a mouse model that clearly mimics some of the major features of Graves disease. This was achieved by the ingenious approach of immunizing mice with fibroblasts stably transfected with the cDNA for the human TSH-R and syngeneic MHC class II (Figure 2-7). Most of the animals had moderately high TBIll activity in their sera, and about 25% were clearly thyrotoxic, with elevated T₄ and T₃ values, detectable TSI activity, and thyroid hypertrophy. For the first time, therefore, an animal model was established in which a significant number of affected subjects have the immunologic and endocrinologic features of Graves hyperthyroidism. More recently, other models have become available. The general rule for induction of an antibody response to the TSH-R in the form of TSI and consequent Graves disease appears to be the need to express the antigen in a native form in an MHC class II carrying cell. Thus, TSH-R-transfected B cells (M12 cell line), TSH-R adenovirus-infected dendritic cells, and even naked TSH-R DNA or TSH-R adenovirus parenterally delivered and probably captured and expressed by MHC class II expressing cells, have been used to induce TSI and Graves-like disease. However, the focal thyroiditis that accompanies human Graves, as well as the extrathyroidal manifestations that define the disease, have never been reliably reproduced in any of these models. Nevertheless, these models open up new ways of investigating the pathogenesis of Graves disease.

**AUTOIMMUNE ASPECTS OF TYPE 1 DIABETES**

Most type 1 diabetes results from autoimmune destruction of pancreatic β cells in a process that can span several years. This results in glucose intolerance and clinical disease when the majority of β cells have been destroyed. The destruction is marked by circulating antibodies to pancreatic β cells and by massive infiltration of mononuclear lymphocytes into the islets of Langerhans while pancreatic β cells remain. The lymphocytes disappear when the β cells are gone. Although insulin is available for replacement therapy, type 1 diabetes remains a chronic disorder of major
susceptibility to develop type 1 diabetes is associated with Asian populations, DRB1*0405 is the major susceptibility haplotype. The autoantibodies associated with β-cell destruction can be precipitated by an autoimmune response.

### Genes and Environment

The susceptibility to develop type 1 diabetes is associated with certain alleles of the MHC class II locus that have been statistically linked to a variety of autoimmune disorders. The most recent analyses indicate that in Caucasians, HLA-DR3, DQ2 (DQB1*0201) and HLA-DR4 (DRB1*0401), DQ8 (DQB1*0302) haplotypes are most strongly associated with type 1 diabetes. In Asian populations, DRB1*0405 is the major susceptibility haplotype. In contrast, the DR2, DQ6 (DQB1*0602) haplotype is negatively associated with type 1 diabetes. More importantly, susceptibility requires both HLA-DQ β chain alleles to be negative for aspartic acid at position 57 (Asp

Non-HLA candidate genes consistently associated with type 1 diabetes include the "variable number of tandem repeats" (VNTR) polymorphisms in the insulin gene and the CTLA-4 gene (CD152). The VNTR polymorphisms are located adjacent to defined regulatory sequences that influence insulin gene expression. Of immunologic importance, CTLA-4 gene (see Immune Recognition and Response, discussed earlier) is the other non-HLA candidate gene consistently found to be associated with type 1 diabetes.

Although environmental factors definitely play a role in the development of type 1 diabetes (eg, Coxsackie B4 virus, mumps virus, rubella virus, Kilham rat virus in the bio breeding [BB]-rat; or cow's milk formula exposure), more studies are needed to establish a definite etiologic link.

### Autoimmune Response

The autoantibodies associated with β cell destruction can be present up to several years before the clinical onset of disease and are thus excellent markers of disease risk. Furthermore, they have served as important tools to identify human pancreatic β cell autoantigens. In 1990, Baekkeskov and coworkers identified a 64-kDa islet cell protein as the smaller isoform of the enzyme that synthesizes γ-aminobutyrate (GABA): glutamic acid decarboxylase (GAD65). This autoantigen was shown to be recognized by 70% to 80% of prediabetic and newly diagnosed type 1 diabetic patients' sera. A second component of the 64-kDa antigen was shown to be a putative tyrosine phosphatase, termed IA-2. IA-2 is recognized by 60% to 70% of prediabetic and newly diagnosed type 1 diabetic patients. Together, GAD65 and IA-2 autoantibodies detect over 90% of individuals who develop type 1 diabetes and can be used to detect individuals at risk several years before the clinical onset of disease.

Although autoantibody responses to GAD65 are not easily detected, there is strong evidence to suggest that GAD65 is an important T-cell autoantigen in the NOD mouse. Thus, GAD65 is the earliest known target of the autoimmune T-cell response in the NOD mouse. Administration of the protein in a tolerogenic form prevents disease in NOD mice. In contrast, induction of tolerance to other potential autoantigens in this model (such as carboxypeptidase H and hsp60) does not prevent disease. The NOD mouse does not develop autoimmunity to the IA-2 molecule and thus distinguishes itself from the human disease with regard to this target antigen (see Models, discussed later).

Insulin is a third well-characterized autoantigen in type 1 diabetes. Insulin autoantibodies can be detected in about 50% of newly diagnosed children with type 1 diabetes. Insulin-specific T-cell clones can transfer disease in the NOD mouse. Furthermore, administration of whole insulin, insulin B chain, or an insulin peptide epitope in a tolerogenic form can protect against disease in NOD mice. Because animals receiving insulin or insulin B chain continue to have intra-islet insulinitis—in contrast to young NOD mice treated with GAD65 in a tolerogenic way—it has been suggested that insulin reactivity is more distal in disease progression. Additional but less well-characterized proteins have been implicated as targets of autoantibodies in type 1 diabetes in humans.

Autoantibodies, although they are good markers of disease, do not seem to be directly involved in destruction of pancreatic β cells. Adptive transfer of diabetes to NOD mice with spontaneous, combined immunodeficiency (NOD-SCID) lacking B cells, can be mediated by T cells alone. However, because β-cell-deficient NOD mice do not develop disease, it is possible that B lymphocytes function as important APCs in the islet to perpetuate an ongoing autoimmune response and thus are essential for presentation of rare antigens such as GAD65 and IA-2. (See also autoimmune response in the section on Autoimmune Aspects of Thyroid Disease, discussed earlier.)

An important question is whether GAD65, IA-2, and insulin are major target antigens of T-cell mediated β-cell destruction that results in type 1 diabetes in humans. Proliferative and cytotoxic T-cell responses to GAD65 are detected in the peripheral blood of newly diagnosed type 1 diabetes patients, but their pathogenicity has not been addressed. Induction of neonatal tolerance to GAD65 specifically prevents diabetes in the NOD mouse model. The role of IA-2 in destructive autoimmunity to the pancreatic β cell in humans is suggested by the high predictive value of IA-2 antibodies for clinical onset of diabetes.

Both GAD65 and IA-2 are neuroendocrine proteins, which are expressed at significant levels in the brain and β cell. Stiff-man syndrome—a very rare neurologic disorder in humans with a high coincidence of diabetes—is characterized by a strong autoantibody response to GAD65, the titer of which is several orders of magnitude higher than in diabetes. It has been suggested that impairment of GABA-secreting neurons in stiff-man syndrome is mediated by GAD65 autoantibodies, whereas development of type 1 diabetes is associated with a cellular immune response to GAD65. The low incidence of stiff-man syndrome compared with type 1 diabetes (only one in 10⁷ type 1 diabetic patients develops...
stiff-man syndrome, whereas 40% of stiff-man syndrome patients develop type 1 diabetes) probably reflects in part the protection of GABAergic neurons by the blood–brain barrier and the absence of MHC class II antigen expression in normal neurons. The cellular localization of IA-2 expression in brain is not known, and there are no known disorders of the central nervous system that involve autoimmunity to IA-2.

In the NOD mouse, the destruction of pancreatic β cells requires both the CD4 T-helper (T_{H1}) cells and CD8 cytotoxic (T_C) cells. Whereas T_{H1} cells seem to be required for the development of an autoimmune response to the islets and generation of intrainsulitis, T_C cells are probably the effector cells of β-cell destruction. Furthermore, there is evidence that in the CD4 lineage, the T_{H1} subset is important for development of disease in the NOD mouse. T_{H1} cells are induced by IL-12 and are biased toward secreting IFN-γ and IL-2. In contrast, there is evidence that the T_{H2} cytokine IL-4 exerts a dominant-negative effect on diabetes progression in the NOD mouse. In humans, low autoantibody titers associated with type 1 diabetes and high titers associated with a protective haplotype (DR2) suggest that a strong T_{H2} response can be inhibitory for β-cell destruction. A role for T_{H1} cells in human disease is also suggested by results of cytokine profiles of peripheral human NK cells in identical twins which are discordant for the development of diabetes. This is different from the observed T_{H1} responses in Graves disease (see Autoimmune Aspects of Thyroid Disease, discussed earlier).

Recently, it has been suggested that it is not the presence of autoantibodies to GAD65 but the absence of the corresponding anti-idiotypic antibodies that defines type 1 diabetes. Anti-idiotypic antibodies bind to the idioype (binding region) of other antibodies. Investigators found that while diabetes patients are positive for GAD65 antibodies because they lack certain anti-idiotypic antibodies, healthy individuals are negative for GAD65 antibodies because of the very presence of anti-idiotypic antibodies directed against GAD65 antibodies in their serum.

**Animal Models of Autoimmune Diabetes Mellitus**

The nonobese diabetic (NOD) mouse has been invaluable for studies of molecular mechanisms of autoimmunity directed toward the pancreatic β cells and the development of diabetes. It has several features, however, which distinguish it from the human disease. The incidence of diabetes is two to three times higher in female than in male NODs, whereas in humans there is a slight preponderance of type 1 diabetes in males. Furthermore, while the induction of organ-specific autoimmunity and inflammation in humans may be caused by human pathogens or toxins, autoimmunity seems to be the default mechanism in the NOD mouse. Thus, mice in clean, pathogen-free environments have a high incidence of disease, whereas a variety of regimens that stimulate the immune system of the mouse, such as viral infection or injection of complete Freund adjuvant, prevent disease. To date, more than 125 treatments for successful prevention or delay of diabetes in the NOD mouse have been identified, but none have been identified for humans.

The bio breeding (BB) rat develops spontaneous T-cell-mediated diabetes. The BB-rat disease is significantly different from the human disease in that it is accompanied by autoantibodies to lymphocytes and a severe lymphocytopenia, which is essential for development of β-cell autoimmunity and diabetes in this model.

In an attempt to develop better models of diabetes, “humanized” transgenic mice that express diabetes-prone human MHC class II molecules were developed. Since these animals did not develop spontaneous diabetes, they were backcrossed into the NOD background. However, backcrossing to NOD once again prevented the development of diabetes. Other animal models of type 1 diabetes, some of them carrying human MHC class II diabetes-susceptibility genes, were developed by expression of ectopic molecules in the islets using the rat insulin promoter (RIP). In some of these models, diabetes needed to be induced by immunization with, for example, insulin peptides or lymphocytic choriomeningitis virus. However, none of these models fully reflect the human disease in that the immune attack was initiated against target human β-cell autoantigen(s) in an MHC class II–restricted fashion, without the need for aberrant protein(s) (foreign to the pancreatic β-cell) expression.

Although some of the models of type 1 diabetes described have been very useful for studies of basic immunologic mechanisms associated with pancreatic β-cell autoimmunity, other models of type 1 diabetes closer to what occurs in humans are needed if immunoprevention and immunomodulatory techniques are to be tested. At a minimum, human susceptibility genes and human target antigens need to coexist in an animal model to mimic human autoimmune responses.

**AUTOIMMUNE ASPECTS OF OTHER ENDOCRINOPATHIES**

**Autoimmune Adrenal Failure**

Autoimmune Addison disease seldom develops as a single-gland syndrome. In about 50% of cases, the disease is associated with other gland and organ failure. Anderson and coworkers described the existence of adrenal-specific autoantibodies for the first time in 1963. Using immunofluorescence techniques on sections of human, bovine, or monkey adrenals, antibodies specifically recognizing the adrenal cortex (ACA) were described. Steroid-producing cell autoantibodies (SCA) reactive with cells of the adrenals, gonads, and placenta were described by Anderson and coworkers in 1968. SCAs are detected predominantly in ACA-positive patients with Addison disease who have premature ovarian failure in the context of autoimmune polyglandular syndrome type I (APS-1; see Autoimmune Polyglandular Syndromes, discussed later).

Steroid 21-hydroxylase has been identified as a major adrenal autoantigen in ACA-positive patients with Addison disease. Using a sensitive assay based on the immune precipitation of radiolabeled recombinant 21-hydroxylase, workers in one study reported positive testing in sera from 72% of patients with isolated Addison
disease, 92% of patients with APS-I, 100% of patients with APS-II, and 80% of patients who were positive for ACA by immunofluorescence but did not have clinically overt Addison disease (apparently healthy blood donors showed 2.5% positivity) (Table 2–2). Another study measured ACA in 808 children with organ-specific autoimmune diseases without adrenal insufficiency. ACAs were detectable in 14. Ten of these ACA-positive children (also positive for 21-hydroxylase antibodies) and 12 ACA-negative children were prospectively followed with adrenocortical function testing and antibodies. Overt Addison disease developed in 9 (90%) ACA/21-hydroxylase antibody-positive children within 3 to 121 months, and the one remaining child had subclinical hypoadrenalism throughout an extra 24-month observation period. The progression to adrenal failure was not related to ACA titer, sex, baseline adrenal function (subclinical insufficiency vs. normal function), type of associated autoimmune disease, or HLA status. Although ACA 21-hydroxylase antibodies appear to be highly predictive in children, in adults the cumulative risk of developing Addison disease in patients with other organ-specific autoimmune diseases and positive ACA 21-hydroxylase antibodies is about 32%. Steroid 17α-hydroxylase is another adrenal autoantigen. 17α-Hydroxylase antibodies were found in 5% of patients with isolated Addison disease, 55% of patients with APS-I, 33% of patients with APS-II, and 20% of sera from patients who were positive for ACA but did not have clinically overt Addison disease (see Table 2–2). Antibodies against another adrenal autoantigen, cytochrome P450 side-chain cleavage enzyme (P450scс), were found to be present in 9% of patients with isolated Addison disease, 45% of patients with APS-I, 36% of patients with APS-II, and 20% of sera from patients who were positive for ACA but did not have clinically overt Addison disease (see Table 2–2). The prevalence of P450scс antibodies in these groups of patients was always lower than that of 21-hydroxylase antibodies but similar to that of 17α-hydroxylase antibodies. Furthermore, almost all sera that were positive for 17α-hydroxylase or P450scс antibodies were also positive for 21-hydroxylase antibodies. In addition, a comparison of SCAs measured by immunofluorescence with 17α-hydroxylase and P450scс antibody measurements suggested that 17α-hydroxylase and P450scс are major components of the SCA antigen just as 21-hydroxylase is the major component of ACA antigen.

Overall, immune responses in autoimmune adrenal disease may involve other antigens, but reactivity to the three described, particularly 21-hydroxylase, appears to predominate. Although inhibition of enzymatic activity by these antibodies has been shown in vitro, no clear relationship to the pathogenesis of the clinical syndrome has yet been established.

**Autoimmune Oophoritis and Orchitis**

An autoimmune origin for premature ovarian failure with concomitant Addison disease or oophoritis can be based on the following human and animal data: (1) the presence of autoantibodies to SCA in most cases, (2) the characterization of shared autoantigens between the adrenals and the ovaries (ie, 17α-hydroxylase and P450scс), (3) the histologic features of the ovaries (lymphocyte and plasma cell infiltrate involving steroid-producing cells), and (4) animal models of the syndrome. There is some evidence of autoimmunity in idiopathic premature ovarian failure not associated with Addison disease (cellular immune abnormalities, presence of various ovarian antibodies in some patients, and associations with type 1 diabetes and myasthenia gravis); however, the absence of histologic confirmation makes the autoimmune pathogenesis less credible.

Less is known about the autoimmune pathogenesis of human orchitis. Animal models, however, have shown that infectious or traumatic injury to the testes can induce autoimmune responses in this immune-privileged tissue (defined as sites where antigens are not presented to the host immune system; see Tolerance, discussed earlier).

**Autoimmune Hypophysitis**

Autoimmune hypophysitis (also called lymphocytic hypophysitis) should be considered in the differential diagnosis of pituitary abnormalities in women (8:1 female: male ratio) during the latter half of pregnancy and in the first 6 months postpartum, as well as in patients with coexisting autoimmune disorders, for example, thyroiditis, adrenalitis, autoimmune hypoparathyroidism, or atrophic gastritis. More than 380 cases have been described since the original report in 1962. Antipituitary antibodies have been detected in a minority of patients. Owing to the lack of markers for the disease, the diagnosis can only be confirmed with histologic examination. Nevertheless, because of the usually transient endocrine and compressive features of this condition, conservative management based on clinical suspicion may prevent the consequences of unnecessary pituitary surgery. Granulomatous hypophysitis—another form of autoimmune hypophysitis—appears to have a similar autoimmune pathogenesis but more commonly affects postmenopausal women and men. The presence of regulatory T cells in this form of hypophysitis, however, makes the autoimmune pathogenesis less clear.

**Autoimmune Hypoparathyroidism**

Autoimmune hypoparathyroidism, also called idiopathic hypoparathyroidism, is one of the major components of APS type I (APS-I;

see next section). It also presents as a sporadic disease, sometimes associated with Hashimoto thyroiditis in women. The fact that autoimmune hypoparathyroidism presents in association with other autoimmune diseases and also the presence of autoantibodies reactive with parathyroid tissue in many affected patients suggests an autoimmune pathogenesis. Parathyroid autoantibodies have been reported to show a complement-dependent cytotoxic effect on cultured bovine parathyroid cells. At least one major parathyroid autoantigen has been identified as the CaSR. The CaSR is of great importance in the regulation of parathyroid hormone secretion and renal tubular calcium reabsorption. This receptor is a member of the 7-membrane-spanning domain G protein–coupled receptor family. It is also expressed in thyroid C cells, the pituitary, the hypothalamus, and in other regions of the brain. The relationship of the autoimmune response directed against the receptor to the pathogenesis of the disease is not clear. However, antibody-mediated stimulation of the CaSR with consequent inhibition of PTH synthesis and secretion has been suggested. The prevalence of the CaSR antibodies in clinically diagnosed iatrogenic hypoparathyroidism was found to be 56% in one study. Measurement of these antibodies may have value in predicting the development of autoimmune hypoparathyroidism in patients with autoimmune endocrinopathies who are at risk. Furthermore, hypercalcemia in a patient with multiple autoimmune disorders, responsive to glucocorticoids, has been recently described as secondary to the presence of a blocking IgG4 autoantibody directed against the CaSR and apparently capable of blocking the inhibitory actions of the ligand calcium (see also Chapter 8).

**AUTOIMMUNE POLYGLANDULAR SYNDROMES**

Associations of multiple autoimmune endocrine disorders have been classified in different syndromes. APS type I and type II (APS-I and -II) can be clearly separated clinically (Table 2–3). Some authors have attempted to subdivide APS-II (ie, APS-II and -III) on the basis of the association of some autoimmune disorders but not others. Little information is gained, however, by making this subdivision in terms of understanding pathogenesis or prevention of future endocrine failure in patients or their relatives. Other autoimmune associations, not always described in syndromes, are also classically recognized. Vitiligo, for example, seems to accompany multiple autoimmune endocrinopathies. There is now convincing evidence of linkage between **NALP1** (NACHT leucine-rich-repeat protein 1), a gene involved in immune regulation, and the presence of vitiligo associated with at least one endocrine autoimmune disease including but not limited to type 1 diabetes, Addison disease, and thyroiditis.

**AUTOIMMUNE POLYGLANDULAR SYNDROME I (APS-I)**

APS-I is an autosomal recessive disorder with 25% incidence among siblings of affected individuals. Also known as APECED, or autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy, APS-I is characterized by the triad of chronic mucocutaneous candidiasis, autoimmune hypoparathyroidism, and adrenal insufficiency (only two are required in the index case for the diagnosis, and only one in the siblings). Chronic mucocutaneous candidiasis (involving oral mucosa and nails or, less frequently, the esophagus) is usually first manifested as the initial problem early in life. In most individuals, the development of autoimmune hypoparathyroidism, a major clinical phenotype, usually follows. Specifically for hypoparathyroidism, the presence of antibodies to **NALPS** (NACHT leucine-rich-repeat protein 5), a gene highly expressed in parathyroid and ovary, have been recently described. In one study these antibodies were detected in 49% of patients with known APS-I and hypothyroidism (see also Chapter 8). Addison disease is another component of the triad that can manifest prior to, concomitantly with, or following hypoparathyroidism. Lifelong surveillance is important since decades may elapse between the development of one feature of the disorder and the onset of another. There is no female preponderance in this syndrome, and it is not HLA-associated. APS-I may occur sporadically or in families. The genetic locus responsible for the disease has been mapped to the long arm of chromosome 21 (21q22.3). The haplotype analysis of this region in different populations has shown that APS-I is linked to different mutations in a gene identified as the autoimmune regulator (**AIRE**). **AIRE** encodes a putative nuclear protein with transcription factor motifs (including two zinc finger motifs). It is expressed in different tissues but particularly in the thymus. The mechanism by which mutations of this putative transcription factor lead to the diverse manifestations of APS-I is still unknown. In mice, however, the absence of the analogous protein “aire” influences ectopic expression of peripheral tissue antigens in thymic medullary epithelial cells (MECs), resulting in the development of an autoimmune disorder similar to APS-I and establishing **aire/AIRE** as an important factor in the induction of central tolerance. Other immune response-related genes as well as environmental factors probably play a role in development of the syndrome. Several studies of large cohorts of patients from different ethnic backgrounds have reported the appearance of chronic candidiasis at different sites in all patients. Hypoparathyroidism and Addison disease present with similar high frequency (see Table 2–3). The occurrence of the diagnostic triad reportedly presents in 57% of patients. Female hypogonadism, presenting as total or partial failure of pubertal development or as premature ovarian failure in adults, has been reported in up to 60% of patients. Male hypogonadism is less frequent (14%). Type 1 diabetes is not as frequent as in APS-II, but if present, usually develops early (under 21 years of age). Autoimmune hypothyroidism (atrophic thyroiditis) is also less frequent than in APS-II; however, thyroid autoantibodies may be present in many euthyroid patients. Other manifestations are described in Table 2–3. Acute autoimmune hepatitis is reportedly less common than chronic hepatitis, which appears to be present in most individuals. Autoantibodies to aromatic L-amino acid decarboxylase (AADC) are associated with chronic active autoimmune hepatitis and vitiligo, which are found in APS-I. These antibodies, if present, can be helpful in making the

Diagnosis. Autoantibodies against tryptophan hydroxylase have been associated with gastrointestinal dysfunction in APS-I. Autoantibodies to the H⁺-K⁺-ATPase and to intrinsic factor are associated with pernicious anemia, and autoantibodies to tyrosinase are associated with vitiligo. Other autoantibodies associated with the single gland disorders that make up this polyglandular syndrome have been discussed above.

## AUTOIMMUNE POLYGLANDULAR SYNDROME II (APS-II)

APS-II is the most common of the polyglandular failure syndromes. It affects women in a 3:1 ratio to men. APS-II is diagnosed when at least two of the following are present: adrenal insufficiency, autoimmune thyroid disease (thyroiditis with hypothyroidism or Graves disease with hyperthyroidism), and type 1 diabetes. Historically, Schmidt (1926) first described the association of Addison disease and thyroiditis. Carpenter and coworkers in 1964 included type 1 diabetes in the syndrome. Other components of APS-II include the following (see Table 2–3): primary hypogonadism, myasthenia gravis, celiac disease, pernicious anemia, alopecia, vitiligo, and serositis. The most frequent association appears to be with type 1 diabetes (over 50%) and autoimmune thyroid disease (70% in some series). Adrenal insufficiency may be concurrent, may be delayed in onset for up to two decades, or may never manifest. Some diabetic patients (2%-3%) develop celiac disease. Gluten-free diet is usually effective. If the celiac disease is untreated, hypocalcemia (not due to hypoparathyroidism), osteopenia, and occasionally gastrointestinal lymphoma may occur.

Although this syndrome and its components aggregate in families, there is no identifiable pattern of inheritance. Susceptibility
is probably determined by multiple gene loci (HLA being the strongest) that interact with environmental factors. Many of the disorders of APS-II are associated (some genetically linked) with the HLA haplotype identified in single organ disorders. HLA-A1, -B8, -DR3 and -DR4, DQA1*0501, and DQB1*0201 have all been described as associated with APS-II.

**MANAGEMENT OF AUTOIMMUNE POLYGLANDULAR SYNDROMES**

Hormonal replacement therapy remains the only form of treatment of the APS. The clinical management of these disorders mandates early diagnosis of associated components. Since the age at onset of associated disorders is clinically unpredictable, long-term follow-up is needed. Endocrine disorders are treated as they develop and are diagnosed. Hormonal treatments for the specific gland failures are described elsewhere in this book. However, specific combinations of endocrine organ failure require specific management. For example, thyroxine replacement can precipitate life-threatening adrenal failure in a patient with untreated Addison disease. Furthermore, hypoglycemia or decreasing insulin requirements in a patient with type 1 diabetes may be the earliest symptom/sign of adrenal insufficiency. Hypocalcemia, seen in APS-II, is more commonly due to celiac disease than hypoparathyroidism. Treatment of mucocutaneous candidiasis with ketoconazole in patients with APS-I may induce adrenal insufficiency in a failing gland (ketoconazole is a global P450 cytochrome inhibitor). These antifungal drugs may also elevate liver enzymes, making the diagnosis of autoimmune hepatitis—requiring treatment with immunosuppressants—more difficult in these patients.

Screening of affected individuals as well as their relatives is the only way of preventing morbidity and mortality. Annual measurement of TSH is recommended as cost-effective in first-degree relatives of patients with type 1 diabetes. Autoantibody measurements may help in the preclinical assessment of several disorders. Complete blood counts, electrolytes, calcium and phosphorus levels, thyroid and liver function tests, blood smears (including RBC indices), and vitamin B₁₂/plasma methylmalonic acid measurements are all recommended in the follow-up of APS-I. For APS-II patients with type 1 diabetes, thyroid disease and celiac disease coexist with sufficient frequency to justify not only TSH measurement but also screening for endomyosal antibodies containing transglutaminase antibodies, which are prevalent in celiac disease.

**IMMUNODEFICIENCY, POLYENDOCRINOPATHY, AND ENTEROPATHY, X-LINKED SYNDROME**

Another autoimmune polyglandular failure syndrome, immunodeficiency, polyendocrinopathy, and enteropathy, x-linked (IPEX) syndrome, is characterized by development of overwhelming systemic autoimmunity in the first year of life resulting in the observed triad of watery diarrhea, eczematous dermatitis, and endocrinopathy seen most commonly as type 1 diabetes mellitus. Most children have other autoimmune phenomena including Coombs positive anemia, autoimmune thrombocytopenia, autoimmune neutropenia, and tubular nephropathy. The majority of affected males die within the first year of life of either metabolic derangements or sepsis; a few survive into the second or third decade.

Diagnosis is based on clinical findings. FOXP3 is the only gene currently known to be associated with IPEX syndrome. Approximately 50% of males with IPEX syndrome have mutations identified in FOXP3. Genetic testing is clinically available. FOXP3 is expressed primarily in lymphoid tissues (thymus, spleen, and lymph nodes), particularly in CD4+ CD25+ regulatory T lymphocytes. In mice, it is required for the development and suppressive function of this important regulatory T-cell population. In humans, it is not expressed at baseline in CD4+ CD25− or CD8+ T cells but is expressed upon T-cell activation. The FOXP3 protein is absent (due to nonsense, frameshift, or splicing mutations) in individuals with severe, early-onset IPEX syndrome. Some individuals with FOXP3 point mutations express a protein that appears to have decreased function, thereby leading to a milder form of the disease. Peripheral blood mononuclear cells from individuals with IPEX syndrome show an excess production of the Th2 cytokines IL-4, IL-5, IL-10, and IL-13 and decreased production of the Th1 cytokine IFN-γ.

Treatment options include: immunosuppressive agents (eg, cyclosporin A, tacrolimus) alone or in combination with steroids; sirolimus (rapamycin) for persons in whom tacrolimus therapy is toxic or ineffective; granulocyte colony-stimulating factor (G-CSF, filgrastim) for autoimmune neutropenia; nutritional support; and standard treatment of diabetes mellitus and autoimmune thyroid disease. If performed early, bone marrow transplantation (BMT) using nonmyeloablative conditioning regimens can resolve clinical symptoms. If the family-specific mutation is known, FOXP3 sequence analysis in at-risk males can be undertaken immediately after birth to permit early diagnosis and BMT before significant organ damage occurs; otherwise, monitoring at-risk males for symptoms is needed to enable early diagnosis and treatment.

IPEX syndrome is inherited in an x-linked manner. The risk to siblings of the proband depends on the carrier status of the mother. If the mother of the proband is a carrier, the chance of transmitting the disease-causing mutation in each pregnancy is 50%. Males who inherit the mutation will be affected; females who inherit the mutation are carriers and will not be affected. Affected males pass the disease-causing mutation to all of their daughters and none of their sons. Prenatal testing for pregnancies at risk is possible for families in which the disease-causing mutation has been identified.

**POEMS SYNDROME (OSTEOSCLEROTIC MYELOMA)**

The POEMS (polyneuropathy, organomegaly, endocrinopathy, M spike, skin abnormalities) syndrome, which is frequently seen as a concomitant of Castelman disease (giant cell lymph node...
hyperplasia), includes a variety of endocrinopathies of the adrenal, thyroid, pituitary, gonads, parathyroids, and pancreas.

The POEMS syndrome displays a number of endocrinopathies in the setting of lymphoproliferative disorders and presumed B-cell dysfunction. Aside from one report in which 2 of 11 patients with monoclonal gammopathy and some form of autoimmunity had POEMS, the endocrinological manifestations of POEMS are not yet established as autoimmune in origin. When associated with Castleman, Kaposi-associated herpes virus (HHV8) may be implicated in the pathogenesis of the lymphoproliferation and the gammopathy.

Two-thirds of patients with POEMS reportedly had at least one endocrine abnormality at presentation. During the course of disease, endocrine abnormalities developed in another 10% of patients with POEMS. Hypogonadism seems to be the most common endocrine abnormality. Elevated levels of follicle-stimulating hormone (FSH) in the absence of primary hypogonadism have been reported. One-third of patients reportedly have erectile dysfunction with low serum testosterone levels. Fourteen percent of patients have hypothyroidism requiring therapy. An additional 12% had mild increases in TSH levels but normal thyroxine levels in one series. Sixteen percent of patients with POEMS have abnormalities of the adrenal-pituitary axis at presentation; with 5% of patients developing adrenal insufficiency later in the course of their disease. Three percent of patients have diabetes mellitus. Serum levels of parathyroid hormone were increased in three of four patients in whom it was measured in one series of 99 POEMS patients. Finally and although still hypothetical for POEMS, autoantibody-mediated mechanisms of disease (Graves disease) have been described in patients with other gammopathies.

EVIDENCE-BASED ENDOCRINOLOGY AND CLINICAL EPIDEMIOLOGY

David C. Aron, MD, MS

The individual practitioner faces a multiplicity of potential diagnoses, limitations in diagnostic capacity, subclinical disease identified by tests rather than by clinical manifestations, and rapid changes in scientific knowledge. The paradigm of clinical decision-making based on the assumption that all that is needed to guide clinical practice is personal experience (however unsystematic), understanding of pathophysiology, and thorough training plus common sense is insufficient to address these challenges. Moreover, the integration of relevant research findings into clinical practice has been haphazard; the lag time between development of scientific knowledge and introduction into practice can be many years, and there is marked variation in practice. A systematic approach based on principles of clinical epidemiology can help address some of these issues. This quantitative approach has formed the primary, albeit not the only, basis of the evidence-based medicine movement. This movement posits that understanding certain rules of evidence is necessary to interpret the literature correctly and that physicians who practice based on the above understanding will provide superior care. This chapter will summarize some of the principles of clinical epidemiology and evidence-based endocrinology and some of their limitations.

CLINICAL EPIDEMIOLOGY

Clinical epidemiology consists of the application of epidemiologic principles and methods to problems encountered in clinical medicine. Clinical epidemiology emphasizes a quantitative approach and is therefore concerned with counts of clinical events. Its applications are paramount (1) in diagnostic testing and how the results modify the probability of a particular disorder being present and (2) in treatment decisions in which the potential benefits and harms must be addressed. The techniques of clinical epidemiology have become increasingly important as practitioners confront the complexity of contemporary medical practice.

DIAGNOSTIC TESTING: TEST CHARACTERISTICS

The appropriate choice and interpretation of diagnostic tests, whether biochemical assays, radiologic procedures, or clinical findings, have always been essential to the clinical practice of endocrinology. These tests, when introduced in the medical literature, are accompanied by varying degrees of validation. The clinician's
assessment of the utility of tests, now even more important with the emphasis on cost-effectiveness, can be improved by knowledge of test EBM principles. We review some of these concepts as they apply to diagnosis and management of endocrine disorders, including the topics of test characteristics such as sensitivity and specificity, receiver-operating characteristic (ROC) curves, likelihood ratios, predictive values, and diagnostic accuracy.

The evaluation of endocrine function begins with a clinical question. The more vague the question, the more difficult it is to obtain a clear answer. Part of this step involves a clinical judgment about the likelihood of the disease prior to obtaining a test and its results. This pretest probability is combined with the performance characteristics of the test and its use (sensitivity and specificity, ROC curves, likelihood ratios, predictive values, and diagnostic accuracy) in order for proper interpretation. Variation is inherent in biological systems. Therefore, diagnostic tests must take into account not only variability of the tests themselves and how they are performed but also variability in the populations in whom the tests were developed, both with the disease and without the disease. Key aspects in the analysis of a test include reproducibility (precision) and accuracy. Reproducibility describes how close the test comes to producing the same results every time and depends on such factors as intraobserver and interobserver variability (as in the assessment of a physical finding or x-ray) and, in the case of biochemical tests, characteristics such as intra-assay and interassay coefficients of variation (CVs). Although studies utilizing radioimmunoassays and other assays routinely report intra-assay and interassay CVs, few papers publish multiple results performed on the same patient (intraindividual variation). There have also been relatively few studies on the reliability of measurements (i.e., the degree of intraindividual variation). One study found that the minimum number of replicate measurements necessary to achieve satisfactory reliability of the mean of basal levels was 3 for plasma cortisol and 18 for salivary cortisol. Responses to dynamic tests required fewer replicates to achieve the same reliability (one to two samples).

Reproducibility depends on the conditions under which the test is performed. Clinicians must be aware of the distinction between efficacy and effectiveness when translating published results into practice. As applied to diagnostic testing, efficacy refers to the degree to which the test has been shown scientifically to accomplish the desired outcome. In contrast, effectiveness refers to the degree to which the test achieves this outcome in actual clinical practice. Most large studies have been performed in research venues and thus are efficacy studies, whereas the effectiveness of most tests in practice has not been extensively evaluated. In comparing one's own results with a published report or laboratory normal range, it is important to take into account those conditions (e.g., test performed in a hospital vs a physician's office).

Accuracy describes how close the test comes to producing results that are a true measure of the phenomenon of interest; systematic bias of a highly reproducible test may produce the same incorrect result every time. Like reproducibility, accuracy depends on the conditions under which the test is performed; accuracy in the clinical practice setting may differ from that in the experimental setting where many extraneous influences are controlled.

When interpreting a test, the result is usually compared to a normal range. Frequently, the normal range is developed by using a reference population assumed (or preferably shown) to be disease free. For example, when designing a test to be used in the diagnosis of Cushing syndrome, the reference group should be made up of individuals who have clinical features suggestive of Cushing syndrome but who in fact do not have the disorder. However, reference groups may be made up of individuals who are readily accessible and not more appropriate comparisons. It is also important to note that in establishing a normal range based on a Gaussian or normal distribution, encompassing the mean ± two standard deviations, 95% of disease-free individuals have a result outside the limits of normal. (It is important to note that the definition of normal based on a Gaussian distribution of values is only one of a number of definitions of normal. Some others include the one most representative or most common in a class, the one most suited to survival, and the one that carries no penalty [i.e., no risk].) Figure 3–1 illustrates a normal range and a range in a population with disease. A result outside normal limits is not equivalent to disease. Moreover, values within the normal range do not necessarily exclude disease. Values in the population of individuals with disease are determined separately, and the overlap with the normal range is assessed.

**Sensitivity and Specificity**

Ideally, a diagnostic test has no overlap between the results of individuals with the disease and those without the disease. The reality, however, is different. Test characteristics that describe this overlap are sensitivity and specificity, and they are typically illustrated in a 2 × 2 table. As shown in Figure 3–2, sensitivity and specificity are collectively known as operating characteristics. Sensitivity refers to the ability to identify correctly individuals with a disease. The sensitivity of a sign or symptom (or diagnostic test) is the proportion of patients with disease who have a positive test result, sign, or symptom. In contrast, specificity refers to the ability to identify correctly individuals without a disease. The specificity of a test is the proportion of healthy patients who have a negative test result or who lack that sign or symptom.

Thus, the sensitivity of a test equals the number of individuals with disease who have a positive test (true positive [TP] divided by the number of individuals with disease [true positives plus false negatives [FN]), whereas specificity equals the number of individuals without the disease who have a negative test (true negatives divided by the number of individuals without disease [true negatives plus false positives [FP]). Sensitivity is sometimes termed PPV or positivity in disease, and specificity is sometimes termed NPV or negativity in health. In theory, sensitivity and specificity are characteristics of the test itself and not of the patients on whom the test is applied. However, this may not be correct in practice. The sensitivity of a test may be affected by the stage or severity of the disease. The specificity of a test may depend on the characteristics of the reference population. The nature of the groups used to establish the cut-points that differentiate normal from abnormal must be appropriate and should be specified in any report of a diagnostic test. The value chosen for a cutoff point
Normal subjects with test values above the given threshold have true-positive results (ie, abnormal results), whereas some subjects with disease have test values below that threshold (ie, normal or false-negative results). The bottom panel illustrates the results for a less-than-ideal test. Normal subjects with test values above the given threshold have abnormal results (ie, false-positive results), whereas some subjects with disease have test values below that threshold (ie, normal or false-negative results).

FIGURE 3-1 Defining a normal range and diagnostic testing. The top panel shows the Gaussian (normal) distribution of test values in a population of individuals. The middle panel illustrates two such curves that describe the findings in an ideal test. In this case, there is no overlap in the results between normal subjects and subjects with disease (ie, there are no false-positive results and no false-negative results). The bottom panel illustrates the results for a less-than-ideal test. Normal subjects with test values above the given threshold have abnormal results (ie, false-positive results), whereas some subjects with disease have test values below that threshold (ie, normal or false-negative results).

Also affects the sensitivity and specificity. To assist the clinician in assessing a report on a diagnostic test, a series of questions has been proposed (Table 3–1).

The overnight dexamethasone suppression test is commonly used as a screening test in the diagnosis of Cushing syndrome, and its use illustrates some of the issues in diagnostic testing. As shown in Figure 3–3, combining the results of a number of studies indicates a sensitivity of 98.1% and specificity of 98.9%. However, the individual studies varied, with sensitivities ranging from 83% to 100% and specificities from 77% to 100%. Moreover, the studies used different cortisol assays, doses of dexamethasone, and criteria for a positive test. Caution must be exercised in drawing conclusions from the combining of such data. In order to apply the sensitivity and specificity of a test derived from one study sample to a different population, the test cannot deviate from methods used (eg, dose of dexamethasone, type of cortisol assay, timing of dexamethasone administration, and cortisol assay) when the optimal cutoff was determined, and the sample studied must be similar to the new population to be tested. To meet this latter prerequisite, the sample studied must account for variability of diseased individuals. This requires that subjects with disease be defined using the best available gold standard (independent of the test in question) and include a broad enough cross-section of those with disease (eg, mild versus severe disease, different etiologies of disease, as well as age, sex, and race) to establish a reliable range of measurements. The characteristics of the reference sample of subjects without the disease are equally important. Although the 1-mg overnight dexamethasone suppression test is still believed to have excellent, albeit less than 100% sensitivity, it has serious problems with specificity, and false-positive results have been described with a variety of drugs as well as medical, surgical, and psychiatric conditions.

One additional method of reporting the performance of a test is diagnostic accuracy. This can also be derived from the 2 × 2 table. Diagnostic accuracy is defined as the ability of a test to identify correctly those with the disease and those without the disease:

\[
\text{Diagnostic accuracy} = \frac{\text{TP} + \text{TN}}{\text{TP} + \text{TN} + \text{FP} + \text{FN}}
\]

From Crapo composite data on the 1-mg overnight dexamethasone suppression test, the diagnostic accuracy is calculated as 98.7%. In addition to the characteristics of the study subjects, the number of subjects included in the sample is also critical to assess the accuracy of the test. Each operating characteristic determined in a study should be accompanied by a confidence interval (CI)—a range of values calculated from sample size and standard error which expresses a degree of confidence (usually 90%, 95%, or 99%) that the unknown true sensitivity or specificity lies in that interval. CIs are a measure of the precision of an estimate. The range of a CI depends on two factors: (1) the number of observations; and (2) the spread in the data (commonly measured as a standard deviation). The fewer the number of observations, the larger the range of the CI, and the greater the standard deviation of the data, the larger the range of the CI.

In addition to the limitations on the operating characteristics based on the samples from which the data are derived, sensitivity and specificity are not independent of each other. They vary with the cutoff level chosen to represent positive and negative test results. In general, as sensitivity increases, specificity decreases and...

<th>- Present</th>
</tr>
</thead>
<tbody>
<tr>
<td>+</td>
<td>a True positive (TP)</td>
<td>b False positive (FP)</td>
</tr>
<tr>
<td>-</td>
<td>c False negative (FN)</td>
<td>d True negative (TN)</td>
</tr>
</tbody>
</table>

Sensitivity = \( \frac{a}{a + c} = \frac{TP}{TP + FN} \)

Specificity = \( \frac{d}{b + d} = \frac{TN}{TN + FP} \)

Positive predictive value = \( \frac{a}{a + b} = \frac{TP}{TP + FP} \)

Negative predictive value = \( \frac{d}{c + d} = \frac{TN}{TN + FN} \)

Diagnostic accuracy = \( \frac{a + d}{a + b + c + d} = \frac{(TP + TN)}{(TP + FP + TN + FN)} \)

Likelihood ratio for a positive test result (LR+):

\[
LR_+ = \frac{TP/FP}{(TP + FN)/(FP + TN + FN)} = \frac{TP rate/FP rate}{(TP/FN)/(FP/TN + FN)} = \frac{sensitivity}{(1 - specificity)}
\]

Likelihood ratio for a negative test result (LR-):

\[
LR_- = \frac{FN/TN}{TN/FN + FP} = \frac{(1 - sensitivity)/specificity}{(FN/(TP + FN))/(TN + FP)}
\]

**FIGURE 3-2** This 2 x 2 table graphically depicts how tests can be performed in individuals with and without a disease.

As specificity increases, sensitivity decreases. This phenomenon is depicted graphically in an ROC curve.

### Receiver-Operating Characteristic Curves

An ROC curve graphically illustrates the trade-off between the false-negative and false-positive rates for different cutoff points of a diagnostic test. In an ROC curve, the true-positive rate (sensitivity) is plotted on the vertical axis and the false-positive rate (1 - specificity) is plotted on the horizontal axis for different cutoff points for the test. The dotted diagonal line in Figure 3–4 corresponds to a test that is positive or negative just by chance (ie, the true-positive rate equals the false-positive rate). Such a test provides no useful information. Ideally, a test would provide results that could be plotted on one point in the top left corner—100% true-positive rate and 100% true-negative rate. The closer an ROC curve is to the upper left-hand corner of the graph, the more accurate it is, because the true-positive rate is 1 and the false-positive rate is 0. As the criterion for a positive test becomes more stringent, the point on the curve corresponding to sensitivity and specificity (point A) moves down and to the left (lower sensitivity, higher specificity); if less evidence is required for a positive test, the point on the curve corresponding to sensitivity and specificity (point B) moves up and to the right (higher sensitivity, lower specificity). Analysis of the area between the actual results and the straight line indicates how good the test is. The greater the area under the curve, the better the test.

Depending on the purpose of the test, the curves may be used to decide an optimal cutoff level for a single test. For example, with a screening test, high sensitivity is typically desired, and the trade-off is lower specificity. The cutoff point may also be chosen depending on health costs (morbidity and mortality associated with an error in diagnosis), financial costs, or need for maximal information (the operating position giving the greatest increase in posttest probability).

ROC curves may also be used to compare two or more tests by comparing the areas under the curves, which represent the inherent accuracy of each test. An example of the comparison of the performance of different tests for the diagnosis of pheochromocytoma is given in Figure 3–5. It is important to remember, however,
that ROC curves are only as good as the operating characteristics from which they are generated.

Finally, determining cost-effective diagnostic strategies requires careful evaluation not only of a test in isolation, but also in the context of the other information available and the likelihood of disease. This is the essence of Bayesian models of decision-making. In this model, the physician updates his or her belief in a hypothesis with each new item of information, with different weights given to the new information depending on its operating characteristics. Consideration must be given to the question of the value added by a test or procedure. This can be assessed with ROC curves and statistical models.

**Predictive Values, Likelihood Ratios, and Diagnostic Accuracy**

Sensitivity and specificity are important test characteristics, yet the clinician wants to know how to interpret a test result. Predictive values help in this regard. As shown in Figure 3–6, the **positive predictive value** is the proportion of patients with a positive test who actually have the disease. Similarly, the **negative predictive value** is the proportion of those with a negative test who do not have the disease. Because each of these values are calculated using results from both individuals with and without the disease in question, the prevalence of the disease has a great impact on the values. For any given sensitivity and specificity, the lower the prevalence of disease (or the lower the pretest probability), the more false-positive results there are (Figure 3–6).

The **likelihood ratio**, which is derived from sensitivity and specificity, is an expression of the odds that a sign, symptom, or test result is expected in a patient with a given disease as opposed to one without the disease. Two forms of the likelihood ratio exist, the likelihood ratio for a positive finding and the likelihood ratio for a negative finding. Calculations are shown in Figure 3–2. Likelihood ratios offer some advantages over sensitivity and specificity. They are the most useful in calculating posttest probabilities given prevalence (a probability) and likelihood ratios. A convenient nomogram for this has been published (Figure 3–7).
The chance (ie, the true-positive rate equals the false-positive rate). The diagonal line corresponds to a test that is positive or negative just by chance (ie, the true-positive rate equals the false-positive rate). The closer an ROC curve is to the upper left-hand corner of the graph, the more accurate it is, because the true-positive rate is 1 and the false-positive rate is 0. As the criterion for a positive test becomes more stringent, the point on the curve corresponding to sensitivity and specificity moves down and to the left (lower sensitivity, higher specificity); if less evidence is required for a positive test, the point on the curve corresponding to sensitivity and specificity moves up and to the right (higher sensitivity, lower specificity).

Analysis of the area between the actual results and the straight line indicates how good the test is. The greater the area under the curve, the better the test.

**FIGURE 3-4** Receiver-operating characteristic (ROC) curve. In an ROC curve, the true-positive rate (sensitivity) is plotted on the vertical axis, and the false-positive rate (1 - specificity) is plotted on the horizontal axis for different cutoff points for the test. The dotted diagonal line corresponds to a test that is positive or negative just by chance (ie, the true-positive rate equals the false-positive rate). The closer an ROC curve is to the upper left-hand corner of the graph, the more accurate it is, because the true-positive rate is 1 and the false-positive rate is 0. As the criterion for a positive test becomes more stringent, the point on the curve corresponding to sensitivity and specificity moves down and to the left (lower sensitivity, higher specificity); if less evidence is required for a positive test, the point on the curve corresponding to sensitivity and specificity moves up and to the right (higher sensitivity, lower specificity).

Analysis of the area between the actual results and the straight line indicates how good the test is. The greater the area under the curve, the better the test.

**FIGURE 3-5** Receiver-operating characteristic (ROC) curves for diagnostic tests for pheochromocytoma. Receiver-operating characteristic (ROC) curve. In an ROC curve, the true-positive rate (sensitivity) is plotted on the vertical axis, and the false-positive rate (1 - specificity) is plotted on the horizontal axis for different cutoff points for the test. A diagonal line drawn for the points where true positive rate = false positive rate corresponds to a test that is positive or negative just by chance. The closer an ROC curve is to the upper left-hand corner of the graph, the more accurate it is, because the true-positive rate is 1 and the false-positive rate is 0. As the criterion for a positive test becomes more stringent, the point on the curve corresponding to sensitivity and specificity moves down and to the left (lower sensitivity, higher specificity); if less evidence is required for a positive test, the point on the curve corresponding to sensitivity and specificity moves up and to the right (higher sensitivity, lower specificity).

Analysis of the area between the actual results and the line representing chance alone indicates how good the test is. The greater the area under the curve, the better the test. The area under the curve from plasma-free metanephrines exceeds that of other tests indicating that it is more accurate overall.

**AN APPROACH TO DIAGNOSIS IN PRACTICE**

In approaching a case, the clinician makes a series of inferences about the nature of a patient's condition and proceeds toward a working diagnosis along with some alternatives—generation of a differential diagnosis. Although one could create a listing of all possible causes of the patient's complaint (ie, a probabilistic differential diagnosis), experienced clinicians generate a differential diagnosis that is a combination of probabilistic (ie, considering first those disorders that are more likely), prognostic (ie, considering first those disorders that are more serious if missed), and pragmatic (ie, considering first those disorders that are most responsive to treatment). The clinician then refines the diagnostic hypotheses, sometimes using clues from the history and physical examination and often with the use of laboratory or radiologic tests. In so doing, the clinician tries to reduce the inherent uncertainty so that the most appropriate course of treatment can be prescribed.
The first step in this process is to understand the concept of probability. A probability is an expression of likelihood and thus represents an opinion of the relative frequency with which an event is likely to occur. In the case of diagnosis, probability is a numerical expression of the clinician's uncertainty about a diagnosis; expressing a clinical opinion in subjective terms such as likely and possible is fraught with imprecision and misunderstanding. Certainty that a disease is present is assigned a probability of one, and an clinician's opinion of the disease being present or absent usually falls somewhere in between. Of course, probabilities are derived from different data sources that vary in their reliability and application to a given patient, such as the clinician's experience (remembered cases), research studies, and population-based epidemiologic studies. Therefore, some degree of uncertainty is inherent in a given probability, and the confidence with which one can rely on a given probability depends to a large extent on the data underlying it.

The diagnostic approach to minimizing uncertainty requires four steps. First, the clinician starts with an estimate of probability based on initial clinical impressions. This starting point is dubbed the pretest or a priori probability and is a number between zero and one that expresses the likelihood of disease. For example, a clinician who sees a large population of patients with diabetes mellitus may think that a 55-year-old patient with polyuria, polydipsia, weight loss, and fatigue has a probability of 0.70 of having diabetes mellitus (ie, if there were 100 such individuals, 70 would have diabetes).

Second, the clinician determines the threshold probability for treatment. The treatment threshold probability is defined as the probability of disease at which one is indifferent between giving treatment and withholding treatment. Establishing a treatment threshold probability takes into account the costs (not just in the monetary sense) and benefits of treating or not treating. Because probability is predicated on the lack of certainty about the presence or absence of disease, it is inevitable that some patients who are not diseased receive treatment and others who are diseased do not receive treatment. Third, if the pretest probability is greater than the threshold probability, the clinician chooses to treat; if it is less than the threshold probability, the clinician opts not to treat. If the clinician is not comfortable enough about the presence or absence of disease, he or she may choose to order further tests with the objective of getting closer to certainty. The fourth step involves taking information gained from the test and using it to update the pretest probability. The updated, or posttest, probability can also serve as a new pretest probability for the next step in hypothesis testing (Figure 3–8).

Treatment threshold probability depends on the effectiveness of treatment, including its adverse effects. In general, treatment threshold probability is generally low when treatment has a high benefit for diseased patients and/or a low risk of harm for nondiseased patients. Likewise, the treatment threshold probability is generally high when there is a high risk to nondiseased patients and/or a low benefit to diseased patients. For example, an endocrinologist evaluating an incidentally found pituitary microadenoma would need to be as certain as possible that the patient suffered from hormone hypersecretion before recommending surgical resection because of the high risk of harm to nondiseased patients relative to the benefit to diseased patients. The same principles apply to diagnostic testing. There is a test-threshold defined as the probability of disease at which one is indifferent between performing a test and not performing a test. Depending on the circumstances, one would treat without performing the test or not perform the test and ignore the issue entirely.

Tests can be combined in the hope that diagnostic accuracy is enhanced. Two tests can be performed in parallel (simultaneously) or in series (sequentially). When two tests are performed in parallel, a positive result in either test establishes the diagnosis; when
two tests are performed in series, positive results in both tests are required to make the diagnosis. Thus, parallel testing increases sensitivity at the cost of specificity, whereas series testing increases specificity at the cost of sensitivity. For this approach to be better than one test alone, the second test has to provide information not provided by the first test. A common practice is to repeat the same test. This approach may be quite logical when the disorder is intermittently active (e.g., intermittent Cushing syndrome) or when there is concern about the way the first test was performed. When tests are performed in series, the first test is usually the one with the higher sensitivity so that as many patients with the disease are discovered. False-positive results are then identified by a second test with higher specificity. Another approach to sequential testing uses as the first test the one with highest specificity so that fewer patients without the disease go on to further testing. This approach makes sense when the second test is associated with more morbidity. Adjusting cut-points for the first test can make it 100% specific (at the cost of some sensitivity). This approach has been used frequently in tests related to Cushing syndrome. One caveat applies to the method of choosing the cutoff point. In addition to considering whether the patients without the disease are an appropriate control group, attention should be paid to sample size. Caution must be exercised when applying test characteristics derived from small samples.

**CLINICAL EPIDEMIOLOGIC PRINCIPLES APPLIED TO TREATMENT DECISIONS**

Critical to decision-making is the appropriate interpretation of the results of clinical trials and the impact of treatments on clinical events. The use of a $2 \times 2$ table can facilitate this process (Figure 3–9).

The **event rate (ER)** is the rate of occurrence of the outcome of interest. The **relative risk reduction (RRR)** is the proportional reduction in rates of bad outcomes between experimental and control participants in a trial, and it can be calculated as:

$$RRR = \frac{1 - \text{Relative risk of experimental treatment}}{\text{Relative risk of control treatment}}$$

$RRR$ is usually reported accompanied by a 95% CI. **Absolute risk reduction (ARR)** is the absolute arithmetic difference in rates of poor outcomes between experimental and control participants in a trial and is usually accompanied by a 95% CI. Another way to think about this is to ask how many patients would have to be treated in order to prevent one negative outcome or achieve one additional favorable outcome. This is termed **number needed to treat (NNT)**, and it is calculated as $1/ARR$ and accompanied by a 95% CI. An example is provided (see Figure 3–9) from the results of a clinical trial. In the United Kingdom Prospective Diabetes Study (UKPDS-38), hypertensive patients with type 2 diabetes were randomized to tight versus less tight blood pressure control. The patients with tight blood pressure control had fewer diabetes-related complications and fewer deaths due to diabetes compared to the patients with less tight blood pressure control. Over a period of 8 years of treatment, 15.9% of patients in the less tight control group had died of diabetes complications compared with 10.9% in the tight control group.

To apply these statistics in clinical decision-making to patients, it is necessary to calculate ARR, RRR, and NNT. The RRR of 32% indicates that approximately one-third of the expected deaths were prevented by tight control of blood pressure. However, although the RRR may be similar across different risk groups, the ARRs are not. ARRs become smaller when event rates are low, whereas RRR remains constant. Thus, RRR can be misleading.

Relative risks

- **RRa** — risk rate of the negative outcome occurring in the experimental group = \( \frac{a}{a+b} \)
- **RRb** — risk rate of the negative outcome occurring in the control group = \( \frac{c}{c+d} \)
- **RR** — the relative risk of the negative outcome occurring in experimental treatment compared to control treatment = \( \frac{RRa}{RRb} = \frac{(a/(a+b))}{(c/(c+d))} \)
- **Relative risk reduction (RRR)** = \( (1 - RR) \times 100\% \)
- **Absolute risk reduction (ARR)** = \( RRb - RRa \)
- **Number needed to treat (NNT)** = \( \frac{1}{ARR} \)

**EXAMPLE:**

**FIGURE 3—9** A 2 x 2 table for treatment groups and outcomes.

The lower the ER in the control group, the larger the difference between RRR and ARR. In other words, the benefits of treatment as reflected in ARR are usually greater in patients at higher risk of negative outcomes than in patients at lower risk of negative outcomes.

The RRR fails to discriminate absolute treatment effects that are clinically significant from those that are trivial. The NNT is 20, so that one would need to treat 20 patients for 8 years with tight blood pressure control to prevent one death from diabetes. NNT can be readily used to compare different treatments. In this case, RRR was 32% and ARR was 5.1%. If a different treatment with the same RRR of 32% has an ARR of 0.51%, the NNT would be 196, indicating that a much greater effort would be needed to achieve one additional favorable outcome. This might or might not be worth the effort, depending on a variety of factors. One method by which treatment thresholds can be determined is with the method of decision analysis.

### DECISION ANALYSIS

Decision analysis is a mathematical tool designed to facilitate complex clinical decisions in which many variables must be considered simultaneously. This analytical procedure selects among available diagnostic or therapeutic options based on the probability and predetermined value (utility) of all possible outcomes of those options. Decision analysis provides a systematic framework for organizing all data relevant to the decision so that relevant uncertainties are less likely to be overlooked. Performing a decision analysis requires clear definition of the relationship between possible courses of action and their associated outcomes and assignment of numerical values to various courses of action. In so doing, decision analysis simplifies comparisons among different strategies.

There is substantial variation in duration and severity of disease between individuals. Choosing a treatment option in the setting...
of unpredictable effects is a difficult problem, and expected value decision-making is a useful tool. When individual outcomes are uncertain, expected value is the result that is expected on average. In preparing to perform a decision analysis, one first must define the problem with a clear statement of the strategies to be examined. Two or more strategies may be included. Clinical decisions have effects over different time frames. An important step in defining a decision problem is to decide the time horizon for outcomes to be evaluated. For example, if strategies for diabetes treatment are to be compared, a period of weeks to months may be appropriate for evaluating the risk of hypoglycemic episode. However, this relatively short time horizon would not be appropriate when the study outcome is diabetic retinopathy, where a time horizon of years would be a better choice. After choosing the problem and a single time horizon, carrying out a formal analysis typically involves six general steps:

1. Construction of a decision tree that maps out all the possibilities
2. Determination and assignment of probabilities
3. Assignment of utilities to each potential outcome
4. Determination of the expected utility
5. Choosing the course of action with the highest expected utility
6. Evaluation of the sensitivity of the chosen course of action to changes in probabilities and utilities

In a decision tree, the term decision alternative refers to one of the potential strategies to be analyzed (Figure 3–10). Each alternative should be listed. Figure 3–11 shows a sample decision tree that outlines strategies of medical versus surgical treatment for disease. The decision itself is represented by a box called a decision node. All of the possible outcomes for each decision alternative are listed. An event that has outcomes under the control of chance is denoted by a chance node. The symbol for a chance node is a circle. The series of events leading to the clinical outcomes is represented by a series of chance nodes and decision nodes. The decision tree is usually written from left to right, with the initial decision node on the far left and the final outcomes on the far right. A final outcome is represented by a terminal node. There may be any number of outcomes at a chance node. The listed outcomes should include all possible outcomes, and they must not overlap. In addition to this assumption of mutual exclusivity, structuring a tree in this fashion assumes that the probability of occurrence of one event does not influence the probability of occurrence of another event(s). The decision tree structure should be as similar as possible for all strategies, because differences may lead to a structural bias in the analysis.

The decision tree described above is relatively simple, and this approach cannot readily represent complex, dynamic clinical situations with recurring events. More elaborate models, such as Markov models, can be used to represent the passage through multiple health states. Patients may transition from one health state to another with some probability within a specified time period or model cycle. Like each terminal node in a static decision tree, each health state in the Markov model is associated with a specific clinical measure, utility, or cost. A key assumption of the Markov model is that the future is determined only by the individual's present health state; events prior to that health state or how long it took to arrive there do not affect the individual's future, a simplifying assumption that may not hold true for some health problems.

One strength of the decision analysis process is that it may be used for a variety of outcome measures. The outcome measure of interest determines the information needed for analysis. For example, one may use clinical measures such as survival following total thyroidectomy for differentiated thyroid cancer, preservation of vision after laser photocoagulation, or meeting a target level for glycosylated hemoglobin. Economic measures provide measures of

---

**FIGURE 3–10** Balancing outcomes and a decision tree.
cost and resource use. When cost measures are included, it is important to consider whose perspective is represented; analyses may reflect the viewpoint of society as a whole, payers, or patients.

A detailed analysis of costs may be used for cost-effectiveness analysis or cost-utility analysis. Utility measures reflect outcome preferences. For an individual, utilities represent quality of life preferences. They are quantitative values used to summarize multiple dimensions, which may be conflicting. For example, decision-makers frequently must choose among strategies that have differing effects on length of life and quality of life and involving trade-offs between the two. Utilities are traditionally scored on a scale from 0 to 1. The ideal situation, often perfect health, is scored as a 1. The worst situation, death, is scored as a 0, and this assumes that there are no utilities worse than death. Intermediate states are assigned values between 0 and 1. For example, living with diabetes mellitus may receive a score of 0.80—less than perfect, but preferable to death. Among the assumptions underlying this approach are: stability of estimates of utilities, that is, the estimates obtained prior to experiencing an event will not change after the event has been experienced; and the it-does-not-matter-how-you-get-there assumption (ie, death or other outcomes have the same utility regardless of the route a patient takes in getting there).

There are different ways to obtain utility values for different health states. One relatively simple method is the visual analog scale, in which a subject is asked to rate a given health state on a scale from 0 to 100. There also are more specific ways of determining utility. The standard gamble approach was developed by von Neumann and Morgenstern as a method for assessing utility. One advantage of this method is that it incorporates the participant’s attitudes about risk taking, because the process involves consideration of a hypothetical gamble. For example, consider a 74-year-old diabetic man with known coronary artery disease and a chronically infected lower extremity ulcer. His physicians suggest a below-the-knee amputation (BKA), but they also discuss the option of a course of antibiotics instead of surgery. Assume that antibiotics have a 10% cure rate and that an amputation has a 95% cure rate. To assess utility from the patient’s perspective, it is necessary to list all of the possible outcomes; rank the outcome states in the order of preference; assign a utility of 1 to the most preferred outcome and 0 to the least preferred outcome; and formulate situations where a patient is indifferent about choosing between a gamble (between outcomes of known utility) and a sure thing (involving an outcome with unknown utility). This is how the utility of each intermediate outcome is determined. For example, suppose the patient decides that a cure with antibiotics is an appealing outcome. This outcome is compared to those with known utilities—perfect health and death. When asked to choose between a cure with antibiotics and a gamble in which he has a 90% chance of achieving perfect health and a 10% chance of dying, he is unable to choose (indifferent). Thus, the utility for the outcome of cure with antibiotics is 0.9. However, a surgical cure with an amputation is a less appealing scenario. The utility for an amputation is only 0.75. By a similar process, the utility of a failure of antibiotics necessitating an amputation is 0.5. The utility scores can then be incorporated into a decision tree (see Figure 3–11). The expected utility for each decision alternative may be obtained by adding each (utility × probability) value. The utility for each outcome is on the right. The probabilities are below the outcome branches. The utility for antibiotic treatment = (0.1 × 0.9) + (0.9 × 0.5) = 0.54, whereas the utility for BKA = (0.95 × 0.75) + (0.05 × 0) = 0.71. In terms of the patient’s quality of life, the expected value of amputation is greater than the expected value of antibiotic treatment. Different utilities for these health states would alter the analyses.

The time trade-off method is another way of determining utility. The utility may be described as a number between 0 and 1. For example, a subject may consider 10 years with pain from diabetic neuropathy equivalent to 5 years in perfect health. The utility of diabetic neuropathy would be 0.5. Alternatively, the utility may be expressed in quality-adjusted life years (QALYs). To determine the number of QALYs associated with an outcome, the time horizon for the outcome state is specified. Often, this is a patient’s life expectancy in a particular outcome state. The number of years in full health that the subject sees as equivalent to the specified time with that outcome is the corresponding number of QALYs.

**Determine the Probability of Each Chance Event**

Once the decision tree structure is formed, the probability of each chance event may be determined. In general, this is best performed by taking a systematic review of published, peer-reviewed literature. However, this approach assumes that probabilities derived from a period in the past accurately reflect the probabilities.
in the future. Moreover, it assumes that the probabilities derived from other settings apply to the one in question. However, all these probabilities must reflect actual practice. For example, if decision analysis is being used to determine the best strategy for specific individual patients, the probabilities must be those of the site when the care is to be delivered. At times, not all of the information needed for the decision tree is available. This frequently occurs during analysis of a relatively new practice. If possible, these probabilities must reflect actual practice. For example, if decision analysis is being used to determine the best strategy for other settings apply to the one in question. However, all expected outcome for each strategy has been calculated. The strategy with the more favorable outcome is the preferred strategy.

**Deciding on a Strategy: Averaging Out and Folding Back the Tree**

The goal of decision analysis is to identify the strategy that leads to the most favorable expected outcome. To calculate the expected outcome, one starts at the outcome measures (typically the far right). Each group of branches, which start at a single chance node, is reduced to a single numerical value by multiplying each outcome measure by the probability associated with that outcome and adding all of the values. This is the process of folding back the decision tree. This process is repeated until there is a single numerical value for each strategy at the initial decision node. At this point, the expected outcome for each strategy has been calculated. The strategy with the more favorable outcome is the preferred strategy.

**Discounting Future Events**

A greater value is placed on current events than future events. It is better to pay $100 in 10 years rather than pay $100 now. Similarly, if one is to have a disease, it is preferable to have a disease in the future than to have it today. The value of a future event then depends on how far in the future it occurs. Discounting refers to calculating the present value of an outcome that occurs in the future. The discount rate is the annual rate at which costs are discounted, which is usually the rate of interest that money would bring if it were invested.

**Sensitivity Analysis**

Sensitivity analysis is an important part of the decision analysis process that tests the stability or robustness of a conclusion over a range of structural assumptions, value judgments, and estimates of probability. The initial analysis, or base case analysis, uses the best estimates for each part of the model. In sensitivity analysis, a plausible range of values is determined for each portion of the model. Variables that have the most influence on the model are determined. Different time horizons or perspectives may be considered. The objective is to see whether conclusions change when possibilities within a reasonable range are included.

**Cost-Effectiveness Analysis Using Decision Analysis**

Cost-effectiveness analysis is the use of decision analysis to compare strategies in terms of their cost per unit of output. Output is an outcome such as years of life, utility, or cases of disease prevented. Cost-effectiveness ratios are interpreted by comparing them to ratios for other strategies. An incremental cost-effectiveness ratio indicates how much additional money needs to be spent for a better, but more expensive strategy, to generate one additional unit of outcome.

Of practical importance, there usually is a limit to the amount of money a policy-maker is willing to spend to gain one QALY; this is termed the willingness-to-pay threshold. Cost–utility analysis is a specific type of cost-effectiveness analysis that uses QALYs (or other measures of utility) as the effectiveness end-point. By convention, cost–utility analyses are often called cost-effectiveness analyses. However, not all cost-effectiveness studies use the cost–utility methodology. Because they use QALYs as an end-point, cost–utility analyses generate information that may be compared across disease states. It is important to note that although they are useful in providing a common metric among outcomes, a number of stringent assumptions must be made to compare cost-effectiveness analyses. Principles for assessing decision analysis have been developed by the evidence-based medicine (EBM) group and are shown in Table 3-2. Representative decision analyses related to endocrine disorders are shown in Table 3-3.

**OTHER ASPECTS OF CLINICAL EPIDEMIOLOGY**

The methods of clinical epidemiology have been applied to risk, prognosis, the assessment of studies of different designs, and many other issues in clinical medicine. Readers are referred to standard texts.

**EVIDENCE-BASED ENDOCRINOLOGY**

The definition of evidence-based medicine (EBM) has evolved over time. A 2005 definition states that EBM requires the integration

of the best research evidence with clinical expertise and patient's unique values and circumstances. The best research evidence refers to valid and clinically relevant research, often from the basic sciences of medicine, but especially from patient-centered clinical research. Clinical expertise refers to the ability to use physicians' clinical skills and past experience to rapidly identify each patient's unique health state and diagnosis, their individual risks and benefits of potential interventions, and their personal circumstances.

and expectations. Patient values consist of the unique preferences, concerns, and expectations each patient brings to a clinical encounter that must be integrated into clinical decisions if they are to serve the patient. Patient circumstances refer to the patient's individual clinical state and the clinical setting.

The five steps of EBM as defined in 1997 are discussed below. Entire textbooks are devoted to the principles of EBM. In this chapter, we will briefly review these five steps and focus on how EBM views evidence and review some of the limitations.

**Step One: Translation of the Clinical Problem into Answerable Questions**

One of the fundamental skills required for practicing EBM is the asking of well-built clinical questions. To benefit patients and clinicians, such questions need to be both directly relevant to patients’ problems and phrased in ways that direct a literature search to relevant and precise answers. In practice, well-built clinical questions usually contain four elements: patient, intervention, comparison, and outcome. The patient refers to the individual to whom the evidence will be applied (eg, a hypertensive patient with diabetes). (The evidence-based approach can also be applied to a group to inform policy.) The intervention is the diagnostic test or therapy being considered for application to the particular patient (or group) (eg, tight control of blood pressure). The comparison is that intervention to which a new intervention being considered is to be compared (eg, less tight control of blood pressure). The outcome is the end point of interest to the physician or patient (eg, stroke, myocardial infarction, or death from diabetes). Background questions relate to general information or basic facts about a disease, and this information can usually be found in reliable textbooks, whether published in book form or on-line. However, more involved clinical questions, especially those that require the most up-to-date information about diagnosis, prognosis, or treatment, have been termed foreground questions and require a different approach.

**Step Two: Finding the Best Evidence**

The finding of best research evidence from the medical literature is a critical feature of the EBM approach and is an iterative process that involves medical informatics. Given the enormous breadth and depth of the medical literature, with more than two million articles published each year in about 20,000 biomedical journals (with more being established each year), efficient strategies must be used to take advantage of the best original journal articles, reviews and synopses of primary studies, and practice guidelines, along with textbooks, both traditional and innovative. Among the useful sources of information are PubMed, which allows sophisticated search strategies of the MEDLINE database. A variety of tools have been developed to facilitate this process. However, these are beyond the scope of this chapter, and readers are referred to references on the subject. Certain journals are specifically devoted to critically appraised articles (eg, ACP Journal Club, BMJ Evidence-Based Medicine). It is important to remember, however, that the presence of the label *evidence based* does not ensure that the information meets the highest standards. Systematic reviews are another useful source for evidence. In addition to the professional journals, such reviews are available from both governmental agencies (eg, Agency for Healthcare Research and Quality) and nongovernmental agencies (eg, the Cochrane Collaboration). Standards have been developed for reporting systematic reviews: preferred reporting items for systematic reviews and meta-analyses (PRISMA). Among the issues addressed specifically is that of publication bias and its potential effects on the results. Publication bias reflects, among other things, the tendency to not publish studies with negative findings.

**Step Three: Appraising the Evidence for its Validity and Usefulness**

Critical appraisal is the process of systematically examining research evidence to assess its validity, results, and relevance before using it to inform a decision. There are three basic questions to be addressed in evaluating any kind of research: (1) Is it valid? (2) Is it important? and (3) Is it applicable to my patient? This involves assessment of the study's methods in order to assess the internal validity of the conclusions. Once criteria for internal validity are satisfied, then the importance of the finding can be assessed. It is critical that statistical significance not be equated with clinical significance. Assuming the finding is important, it is necessary to consider the study's relevance to the patient (ie, the external validity of the study). A series of guides has been developed to help the clinician to critically appraise different types of studies. An example is shown in Table 3-4. Underlying this appraisal process is the EBM model of the hierarchy of evidence.

A. Hierarchies of evidence  Any empirical observation about the apparent relation between events constitutes evidence. This includes the thoughtful observations of an experienced clinician, the observations derived from physiologic experiments, and the results of large, randomized clinical trials. Methodological safeguards to protect against systematic error (bias) are inherent in experimental design. In this way, experiments differ from clinical observations. Different study designs lend themselves to different safeguards, and these safeguards vary in their efficacy both in theory and in practice.

The EBM approach uses a hierarchy of study designs based on their inherent safeguards. A hierarchy is shown in Table 3–5. In this hierarchy, randomized controlled trials (RCTs) are given the highest weight, followed by quasi-experimental studies (ie, non-RCTs), followed by other study designs, and finally opinions of authorities and unsystematic clinical observations. Evidence from the top of the hierarchy should have greater impact in clinical decision-making than observations from the lower levels. There is disagreement about what the hierarchy should be. Some have an N of 1 randomized trial (the equivalent of an RCT with one subject) at the top of the hierarchy, whereas others place meta-analyses of randomized trials at the top. However, the term evidence is not synonymous with evidence from RCTs (or whatever study design occupies at the preferred level of the hierarchy). Rather, it is preferred to use that sort of evidence when it is available. Evidence from other sources is still evidence and may be more than sufficient. For example, the introduction of thyroid replacement therapy for hypothyroidism or insulin therapy for type 1 diabetes has never been subjected to RCTs.

While recognizing the central role of evaluating the quality of the evidence in decision-making, the U.S. Preventive Services Task Force (USPSTF) has developed a different approach to address some of the shortcomings of the EBM approach. The USPSTF adopted three major changes to the process. First, a rating of internal validity was added to the study criterion for judging individual studies. A well-designed cohort or case-control study could be more compelling than an inadequately powered or poorly conducted RCT. Second, evidence was explicitly assessed at three different levels—the level of the individual study, both in terms of internal and external validity; the body of evidence supporting a given linkage in the analytic framework; and, because of the focus of the USPSTF, the level of evidence for the entire preventive service. Third, the magnitude of effect was separated from the assessment of quality. Both benefit and harm are considered in assessing the magnitude of the effect(s). Overall, the USPSTF grades the quality of the overall evidence for a service on a three-point scale (good, fair, poor) and grades its recommendations according to one of five classifications (A, B, C, D, I) reflecting the strength of evidence and magnitude of net benefit (benefits minus harms) (Table 3–6). This approach of assessing both the quality of evidence and strength of recommendations has been expanded to include practice guidelines: grading of recommendations, assessment, development, and evaluation (GRADE) system. Although a discussion of practice guidelines is beyond the scope of this chapter, it is important to recognize that they vary widely in quality, strength of evidence, and bias. Before a practitioner bases a decision on a practice guideline, the basis of that guideline must be clear.

B. Other evidence-related issues  Notwithstanding these improvements, there are three other major issues concerning the evidence. First, it is important to recognize that all of this evidence is essentially quantitative in nature. Thus, the EBM definition of evidence is relatively narrow and excludes information important to clinicians; many qualitative factors are involved in clinical decision-making concerning individual patients. Second, there are problems in the evidence in terms of the quality and scope of the data (eg, the soft data that clinicians usually use); the scope of the topics (average patients, gray zones of practice, lack of RCTs); sources of authority, which however explicit, require judgment; and potential abuses (eg, key findings could be ignored). Third, there is the issue of applying results in populations (ie, average results) to individuals.

Steps Four and Five: Applying the Results in Practice and Evaluating Performance

Knowledge of the best available evidence of treatment is not enough to recommend a particular course of action. Underlying this issue is heterogeneity of treatment effects. Treatment effect heterogeneity is the term given to the phenomenon in which the same treatment produces different results in different patients. For the average effect observed in a clinical trial to occur with certainty in one patient, all patients in the trial must have had that average response. Yet average response may also reflect a large response in some and small or no response or even harm in others. Part of clinical decision-making involves addressing this phenomenon to individualize therapy in the most effective way. To do so, four major factors about the patient must be taken into account: (1) baseline probability of incurring a disease-related adverse event (risk without treatment or susceptibility/prognosis), (2) responsiveness to the treatment, (3) vulnerability to the adverse side-effects of the treatment, and (4) utilities for different outcomes. When lacking good data on a patient’s individual level of risk, responsiveness, and vulnerability, the average treatment effect as reported in good clinical trials provides the most reasonable guide for decision-making. However, it is important that physicians evaluate the results in their own patients so that the course can be modified when necessary.

</tbody>
</table>

Levels of Certainty Regarding Net Benefit

<table>
<thead>
<tr>
<th>Level of Certainty*</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>High</strong></td>
<td>The available evidence usually includes consistent results from well-designed, well-conducted studies in representative primary care populations. These studies assess the effects of the preventive service on health outcomes. This conclusion is therefore unlikely to be strongly affected by the results of future studies.</td>
</tr>
</tbody>
</table>
| **Moderate**        | The available evidence is sufficient to determine the effects of the preventive service on health outcomes, but confidence in the estimate is constrained by such factors as:  
  • The number, size, or quality of individual studies.  
  • Inconsistency of findings across individual studies.  
  • Limited generalizability of findings to routine primary care practice.  
  • Lack of coherence in the chain of evidence.  
  As more information becomes available, the magnitude or direction of the observed effect could change, and this change may be large enough to alter the conclusion. |
| **Low**             | The available evidence is insufficient to assess effects on health outcomes. Evidence is insufficient because of:  
  • The limited number or size of studies.  
  • Important flaws in study design or methods.  
  • Inconsistency of findings across individual studies.  
  • Gaps in the chain of evidence.  
  • Findings not generalizable to routine primary care practice.  
  • Lack of information on important health outcomes.  
  More information may allow estimation of effects on health outcomes. |

*The USPSTF defines certainty as "likelihood that the USPSTF assessment of the net benefit of a preventive service is correct." The net benefit is defined as benefit minus harm of the preventive service as implemented in a general, primary care population. The USPSTF assigns a certainty level based on the nature of the overall evidence available to assess the net benefit of a preventive service.

Practicing and perfecting the art of medicine demands recognition that uncertainty permeates all clinical decisions. How clinicians make decisions, whether diagnostic or therapeutic, by combining the art and the science is a complicated matter replete with unknowns. There is a variety of modes of clinical problem-solving ranging from automatic decisions in which a clinician makes a decision without consciously considering alternatives or even specific features of the problem to rational decision-making using simplified strategies to take into account probabilities and values of outcomes to formal decision analysis. The potential deficiencies of automatic decisions (nondecisions one might say) are obvious. Formal decision analyses, even if accepted as gold standards (which they are not), are beyond practical use for the vast majority of clinicians, so that we are left with simplified processes to combine likelihoods and values. However, even in striving to reduce uncertainty and coming up with the best course of action for the patient, it is critical to recognize that uncertainty will always be with us. In using a quantitative approach, we can only become more certain about the probability of the outcome. We cannot guarantee the desired outcome.

The hypothalamus and pituitary gland form a unit that exerts control over the function of several endocrine glands—thyroid, adrenals, and gonads—as well as a wide range of physiologic activities. This unit is highly conserved across vertebrate species and constitutes a paradigm of neuroendocrinology—brain-endocrine interactions. The actions and interactions of the endocrine and nervous systems, whereby the nervous system regulates the endocrine system and endocrine activity modulates the activity of the central nervous system, constitute the major regulatory mechanisms for virtually all physiologic activities. These neuroendocrine interactions are also important in pathogenesis. This chapter will review the normal functions of the pituitary gland, the neuroendocrine control mechanisms of the hypothalamus, and the disorders of those mechanisms.

Nerve cells and endocrine cells, which are both involved in cell-to-cell communication, share certain characteristic features—secretion of chemical messengers (neurotransmitters or hormones) and electrical activity. A single chemical messenger—peptide or amine—can be secreted by neurons as a neurotransmitter or neural hormone and by endocrine cells as a classic hormone. Examples of such multifunctional chemical messengers are shown in Table 4–1. The cell-to-cell communication may occur by four

mechanisms: (1) autocrine communication via messengers that diffuse in the interstitial fluid and act on the cells that secreted them, (2) neural communication via synaptic junctions, (3) paracrine communication via messengers that diffuse in the interstitial fluid to adjacent target cells (without entering the bloodstream), and (4) endocrine communication via circulating hormones (Figure 4-1). The two major mechanisms of neural regulation of endocrine function are direct innervation and neurosecretion (neural secretion of hormones). The adrenal medulla, kidney, parathyroid gland, and pancreatic islets are endocrine tissues that receive direct autonomic innervation (see Chapters 9, 10, 11). An example of neurosecretory regulation is the hormonal secretion of certain hypothalamic nuclei into the portal hypophysial vessels, which regulate the hormone-secreting cells of the anterior lobe of the pituitary. Another example of neurosecretory regulation is the posterior lobe of the pituitary gland, which is made up of the endings of neurons whose cell bodies reside in hypothalamic nuclei. These neurons secrete vasopressin and oxytocin into the general circulation.

**Anatomy and Embryology**

The anatomic relationships between the pituitary and the main nuclei of the hypothalamus are shown in Figure 4-2. The posterior lobe of the pituitary (neurohypophysis) is of neural origin, arising embryologically as an evagination of the ventral hypothalamus and the third ventricle. The neurohypophysis consists of the axons and

**FIGURE 4-1** Intercellular communication by chemical mediators.
nerve endings of neurons whose cell bodies reside in the supraoptic and paraventricular nuclei of the hypothalamus and supporting tissues. This hypothalamic-neurohypophysial nerve tract contains approximately 100,000 nerve fibers. Repeated swellings along the nerve fibers ranging in thickness from 1 to 50 μm constitute the nerve terminals.

The human fetal anterior pituitary anlage is initially recognizable at 4 to 5 weeks of gestation, and rapid cytologic differentiation leads to a mature hypothalamic-pituitary unit at 20 weeks. The anterior pituitary (adenohypophysis) originates from Rathke pouch, an ectodermal evagination of the oropharynx, and migrates to join the neurohypophysis. The portion of Rathke pouch in contact with the neurohypophysis develops less extensively and forms the intermediate lobe. This lobe remains intact in some species, but in humans its cells become interspersed with those of the anterior lobe and develop the capacity to synthesize and secrete pro-opiomelanocortin (POMC) and adrenocorticotropic hormone (ACTH). Remnants of Rathke pouch may persist at the boundary of the neurohypophysis, resulting in small colloid cysts.

In addition, cells may persist in the lower portion of Rathke pouch beneath the sphenoid bone, the pharyngeal pituitary. These cells have the potential to secrete hormones and have been reported to undergo adenomatous change.

The pituitary gland itself lies at the base of the skull in a portion of the sphenoid bone called the sella turcica (Turkish saddle). The anterior portion, the tuberculum sellae, is flanked by posterior projections of the sphenoid wings, the anterior clinoid processes. The dorsum sellae forms the posterior wall, and its upper corners project into the posterior clinoid processes. The gland is surrounded by dura, and the roof is formed by a reflection of the dura attached to the clinoid processes, the diaphragma sellae. The arachnoid membrane and, therefore, cerebrospinal fluid are prevented from entering the sella turcica by the diaphragma sellae. The pituitary stalk and its blood vessels pass through an opening in this diaphragm. The lateral walls of the gland are in direct apposition to the cavernous sinuses and separated from them by dural membranes. The optic chiasm lies 5 to 10 mm above the diaphragma sellae and anterior to the stalk (Figure 4–3).
The size of the pituitary gland, of which the anterior lobe constitutes two-thirds, varies considerably. It measures approximately $15 \times 10 \times 6$ mm and weighs 500 to 900 mg; it may double in size during pregnancy. The sella turcica tends to conform to the shape and size of the gland, and for that reason there is considerable variability in its contour.

**Blood Supply**

The anterior pituitary is the most richly vascularized of all mammalian tissues, receiving 0.8 mL/g/min from a portal circulation connecting the median eminence of the hypothalamus and the anterior pituitary. Arterial blood is supplied from the internal carotid arteries via the superior, middle, and inferior hypophysial arteries. The superior hypophysial arteries form a capillary network in the median eminence of the hypothalamus that recombines in long portal veins draining down the pituitary stalk to the anterior lobe, where they break up into another capillary network and re-form into venous channels. The pituitary stalk and the posterior pituitary are supplied directly from branches of the middle and inferior hypophysial arteries (see Figures 4–2 and 4–3).

Venous drainage of the pituitary, the route through which anterior pituitary hormones reach the systemic circulation, is variable, but venous channels eventually drain via the cavernous sinuses posteriorly into the superior and inferior petrosal sinuses to the jugular bulb and vein (Figure 4–4). The axons of the neurohypophysis terminate on capillaries that drain via the posterior lobe veins and the cavernous sinuses to the general circulation. The hypophysial portal system of capillaries allows control of anterior pituitary function by the hypothalamic hypophysiotropic hormones secreted into the portal hypophysial vessels. This provides a short, direct connection to the anterior pituitary from the ventral hypothalamus and the median eminence (Figure 4–5). There may also be retrograde blood flow between the pituitary and hypothalamus, providing a possible means of direct feedback between pituitary hormones and their neuroendocrine control centers.

**Pituitary Development and Histology**

Anterior pituitary cells were originally classified as acidophils, basophils, and chromophobe cells based on staining with hematoxylin and eosin. Immunocytochemical and electron microscopic techniques now permit classification of cells by their specific secretory products: somatotrophs (growth hormone [GH]-secreting cells), lactotrophs (prolactin [PRL]-secreting cells), thyrotrophs (cells secreting thyroid-stimulating hormone [thyrotropin; TSH]), corticotrophs (cells-secreting ACTH [corticotropin] and related peptides), and gonadotrophs (luteinizing hormone [LH]– and follicle-stimulating hormone [FSH]-secreting cells). The development of the pituitary gland and the emergence of the distinct cell types from common primordial cells are controlled by a limited set of transcription factors, most notably Prop1 and Pit1.
CHAPTER 4 Hypothalamus and Pituitary Gland

FIGURE 4-4 Venous drainage of the pituitary gland—the route by which adenohypophysial hormones reach the systemic circulation.

FIGURE 4-5 Secretion of hypothalamic hormones. The hormones of the posterior lobe (PL) are released into the general circulation from the endings of supraoptic and paraventricular neurons, whereas hypophysiotropic hormones are secreted into the portal hypophysial circulation from the endings of arcuate and other hypothalamic neurons (AL, anterior lobe; ARC, arcuate and other nuclei; MB, mamillary bodies; OC, optic chiasm; PV, paraventricular nucleus; SO, supraoptic nucleus).

A. Somatotrophs The GH-secreting cells are acidophilic and usually located in the lateral portions of the anterior lobe. Granule size by electron microscopy is 150 to 600 nm in diameter. These cells account for about 50% of the adenohypophysial cells.

B. Lactotrophs The PRL-secreting cell is a second but distinct acidophil-staining cell randomly distributed in the anterior pituitary. These cells account for 10% to 25% of anterior pituitary cells. Granule size averages approximately 550 nm on electron microscopy. There are two types of lactotrophs: sparsely granulated and densely granulated. These cells proliferate during pregnancy as a result of elevated estrogen levels and account for the twofold increase in gland size.

C. Thyrotrophs These TSH-secreting cells, because of their glycoprotein product, are basophilic and also show a positive reaction with periodic acid-Schiff stain. Thyrotrophs are the least common pituitary cell type, making up less than 10% of adenohypophysial cells. The thyrotroph granules are small (50-100 nm), and these cells...
FIGURE 4-6 Transcription factors involved in the early development of mouse pituitary, including Tpit.

Tpit is expressed on embryonic day E 11.5, followed by expression of POMC-producing cells by E 12.5 (DAX1, dosage sensitive sex-reversal-adrenal hypoplasia congenital critical region on the X chromosome 1; GATA2, GATA-binding protein 2, zinc-finger transcription factor; α-GSU, alpha subunit of pituitary glycoprotein hormones; Hesx1, homeobox gene expressed in embryonic stem cells 1; Isl1, islet 1 transcription factor; LH/FSH, luteinizing hormone/follicle-stimulating hormone; Lhx3/4, LIM-domain transcription factor 3/4; LIF, leukemia inhibiting factor; NE, neural epithelium; Neuro01, neurogenic basic helix-loop-helix transcription factor 01; OE, oral ectoderm; Pax6, paired box containing transcription factor 1; Pit1, pituitary transcription factor 1; Prop1, prophet of Pit1; Ptx1, pituitary homeobox 1; RP, Rathke pouch; SF1, steroidogenic factor 1; Six3, sine oculis-like homeobox transcription factor 3; Tpit, T-box pituitary transcription factor; VH, ventral hypothalamus). (From Asteria C. T-Box and isolated ACTH deficiency. Eur J Endocrinol. 2002;146:463).

are usually located in the anteromedial and anterolateral portions of the gland. During states of primary thyroid failure, the cells demonstrate marked hypertrophy, increasing overall gland size.

D. Corticotrophs ACTH and its related peptides (see below) are secreted by basophilic cells that are embryologically of intermediate lobe origin and usually located in the anteromedial portion of the gland. Corticotrophs represent 15% to 20% of adenohypophysial cells. Electron microscopy shows that these secretory granules are about 360 nm in diameter. In states of glucocorticoid excess, corticotrophs undergo degranulation and a microtubular hyalinization known as Crooke hyaline degeneration.

E. Gonadotrophs LH and FSH originate from basophil-staining cells, whose secretory granules are about 200 nm in diameter. These cells constitute 10% to 15% of anterior pituitary cells, and they are located throughout the entire anterior lobe. They become hypertrophied and cause the gland to enlarge during states of primary gonadal failure such as menopause, Klinefelter syndrome, and Turner syndrome.

F. Other cell types Some cells, usually chromophobes, contain secretory granules but do not exhibit immunocytochemical staining for the major known anterior pituitary hormones. These cells have been called null cells; they may give rise to (apparently) nonfunctioning adenomas. Some may represent undifferentiated primitive secretory cells, and others (e.g., glia-like or folliculostellate cells) may produce one or more of the many paracrine factors that have been described in the pituitary. Mammosomatotrophs contain both GH and PRL; these bihormonal cells are most often seen in pituitary tumors. Human chorionic gonadotropin is also secreted by the anterior pituitary gland, but its cell of origin and physiologic significance are uncertain. The six known major anterior pituitary hormones are listed in Table 4–2.

HYPOTHALAMIC HORMONES

The hypothalamic hormones can be divided into those secreted into hypophysial portal blood vessels and those secreted by the neurohypophysis directly into the general circulation. The hypothalamic nuclei, their neurohormones, and their main functions are shown in Table 4–3. The structures of the eight major hypothalamic hormones are shown in Table 4–4.

Hypophysiotropic Hormones

The hypophysiotropic hormones that regulate the secretion of anterior pituitary hormones include growth hormone–releasing

hormone (GHRH), somatostatin, dopamine, thyrotropin-releasing hormone (TRH), corticotropin-releasing hormone (CRH), and gonadotropin-releasing hormone (GnRH). The location of the cell bodies of the hypothalamic hormone-secreting neurons is depicted in Figure 4–7. Most of the anterior pituitary hormones are controlled by stimulatory hormones, but GH and especially PRL are also regulated by inhibitory hormones. Some hypothalamic hormones are multifunctional. The hormones of the hypothalamus are secreted episodically and not continuously, and in some cases there is an underlying circadian rhythm.

A. GHRH  GHRH stimulates GH secretion by, and is trophic for, somatotrophs. GHRH-secreting neurons are located in the arcuate nuclei (see Figure 4–2), and axons terminate in the external layer of the median eminence. The major isoform of GHRH is 44 amino acids in length. It was isolated from a pancreatic tumor in a patient with clinical manifestations of GH excess (acromegaly) associated with somatotroph hyperplasia (see discussion later in the chapter). GHRH is synthesized from a larger precursor of 108 amino acids. Other secretory products derived from this precursor have also been found. Full biologic activity of these releasing factors appears to reside in the 1 to 29 amino acid sequence of the amino terminal portion of the molecule. Human GHRH is a member of a homologous family of peptides that includes secretin, glucagon, vasoactive intestinal peptide (VIP), and others. The half-life of GHRH is approximately 3 to 7 minutes.

B. Somatostatin  Somatostatin inhibits the secretion of GH and TSH. Somatostatin-secreting cells are located in the periventricular region immediately above the optic chiasm (see Figure 4–2) with nerve endings found diffusely in the external layer of the median eminence.

Somatostatin, a tetradecapeptide, has been found not only in the hypothalamus but also in the D cells of the pancreatic islets, the gastrointestinal mucosa, and the C cells (parafollicular cells) of the thyroid. The somatostatin precursor has 116 amino acids.

Processing of the carboxyl terminal region of preprosomatostatin results in the generation of the tetradecapeptide somatostatin 14 and an amino terminal extended form containing 28 amino acid residues (somatostatin 28). Somatostatin 14 is the major species in the hypothalamus, whereas somatostatin 28 is found in the gut. In addition to its profound inhibitory effect on GH secretion, somatostatin also has important inhibitory influences on many other hormones, including insulin, glucagon, gastrin, secretin, and VIP. This inhibitory hypothalamic peptide plays a role in the physiologic secretion of TSH by augmenting the direct inhibitory effect of thyroid hormone on the thyrotrophs; administration of anti-somatostatin antibodies results in a rise in circulating TSH level. Somatostatin has a half-life of 2 to 3 minutes.

C. Dopamine  Dopamine, the primary PRL-inhibitory hormone, is found in the portal circulation and binds to dopamine receptors on lactotrophs. It has a short half-life, on the order of 1 to 2 minutes. The hypothalamic control of PRL secretion, unlike that of the other pituitary hormones, is predominantly inhibitory. Thus, disruption of the hypothalamic-pituitary connection by stalk section, hypothalamic lesions, or pituitary autotransplantation increases PRL secretion. Dopamine-secreting neurons (teberoinfundibular dopaminergic system) are located in the arcuate nuclei, and their axons terminate in the external layer of the median eminence, primarily in the same area as the GnRH endings (laterally) and to a lesser extent medially (see Figure 4-2). The neurotransmitter gamma-aminobutyric acid (GABA) and cholinergic pathways also appear to inhibit PRL release.

D. Prolactin-releasing factors  The best-studied factor with PRL-releasing activity is TRH (see discussion later), but there is little evidence for a physiologic role. PRL increase associated with sleep, during stress, and after nipple stimulation or suckling is not accompanied by an increase in TRH or TSH. Another hypothalamic peptide, VIP, stimulates PRL release in humans. Serotonergic pathways may also stimulate PRL secretion, as demonstrated by the increased PRL secretion after the administration of serotonin precursors and by the reduction of secretion following treatment with serotonin antagonists.

<sup>3</sup>In addition to the tetradecapeptide shown here (somatostatin 14), an amino terminal-extended molecule (somatostatin 28), and a 12-amino-acid form (somatostatin 28 [1-12]) are found in most tissues.

E. Thyrotropin-releasing hormone  TRH, a tripeptide, is the major hypothalamic factor regulating TSH secretion. Human TRH is synthesized from a large precursor of 242 amino acids that contains six copies of TRH. TRH-secreting neurons are located in the medial portions of the paraventricular nuclei (see Figure 4–2), and their axons terminate in the medial portion of the external layer of the median eminence. The half-life of TRH is approximately 6 minutes.

F. Corticotropin-releasing hormone  CRH, a 41-amino-acid peptide, stimulates the secretion of ACTH and other products of its precursor molecule, POMC. CRH is synthesized from a precursor of 196 amino acids. The half-life of CRH follows a biphasic pattern in plasma lasting approximately 6 to 10 minutes and 40 to 50 minutes. Both antidiuretic hormone (ADH) and angiotensin II potentiate CRH-mediated secretion of ACTH. In contrast, oxytocin inhibits CRH-mediated ACTH secretion. CRH-secreting neurons are found in the anterior portion of the paraventricular nuclei just lateral to the TRH-secreting neurons; their nerve endings are found in all parts of the external layer of the median eminence. CRH is also secreted from human placenta. The level of this hormone increases significantly during late pregnancy and delivery. In addition, a specific CRH-binding protein (CRHBP) has been described in both serum and in intracellular locations within a variety of cells. It is likely that CRHBP modulate the actions and plasma half-life of CRH. Since the 1990s, three proteins homologous to CRH, termed urocortins, and two different receptors, have been identified. In addition to the role of CRH in the physiologic response to stress, this family of peptides appears to play a significant role in energy balance.

G. Gonadotropin-releasing hormone  The secretion of LH and FSH is controlled by a single stimulatory hypothalamic hormone, GnRH. This is achieved through differences in the size and frequency of GnRH release as well as feedback from estrogens and androgens; low-frequency pulses favor FSH release while high-frequency pulses result in LH release. GnRH is a linear decapeptide that stimulates only LH and FSH; it has no effect on other pituitary hormones except in some patients with acromegaly and Cushing disease (see discussion later). The precursor of GnRH—proGnRH—contains 92 amino acids. ProGnRH also contains the sequence of a 56-amino-acid polypeptide called GnRH-associated peptide. This secretory product exhibits PRL-inhibiting activity, but its physiologic role is unknown. GnRH-secreting neurons are located primarily in the preoptic area of the anterior hypothalamus, and their nerve terminals are found in the lateral portions of the external layer of the median eminence adjacent to the pituitary stalk (see Figure 4–2). GnRH has a half-life of 2 to 4 minutes.

Neuroendocrinology: The Hypothalamus as Part of a Larger System

The hypothalamus is involved in many nonendocrine functions such as regulation of body temperature, thirst, and food intake...
CHAPTER 4 Hypothalamus and Pituitary Gland

and is connected with many other parts of the nervous system. The brain itself is influenced by both direct and indirect hormonal effects. Steroid and thyroid hormones cross the blood–brain barrier and produce specific receptor-mediated actions (see Chapters 1, 7, and 9). Peptides in the general circulation, which do not cross the blood–brain barrier, elicit their effects indirectly (eg, insulin-mediated changes in blood–glucose concentration). In addition, communication between the general circulation and the brain may take place via the circumventricular organs, which are located outside the blood–brain barrier (see later). Moreover, hypothalamic hormones in extrahypothalamic brain function as neurotransmitters or neurohormones. They are also found in other tissues where they function as hormones (endocrine, paracrine, or autocrine). For example, somatostatin-containing neurons are widely distributed in the nervous system. They are also found in the pancreatic islets (D cells), the gastrointestinal mucosa, and the C cells of the thyroid gland (parafollicular cells). Somatostatin is not only secreted into the general circulation as well as locally—it is also secreted into the lumen of the gut, where it may affect gut secretion. A hormone with this activity has been called a lumone. Hormones common to the brain, pituitary, and gastrointestinal tract include not only TRH and somatostatin but also VIP and peptides derived from POMC.

Hypothalamic function is regulated both by hormone-mediated signals (eg, negative feedback) and by neural inputs from a wide variety of sources. These nerve signals are mediated by neurotransmitters including acetylcholine, dopamine, norepinephrine, epinephrine, serotonin, GABA, and opioids. The hypothalamus can be considered a final common pathway by which signals from multiple systems reach the anterior pituitary. For example, cytokines that play a role in the response to infection, such as the interleukins, are also involved in regulation of the hypothalamic-pituitary-adrenal axis. This system of immunoneuroendocrine interactions is important in the organism’s response to a variety of stresses.

The hypothalamus also sends signals to other parts of the nervous system. For example, while the major nerve tracts of the magnocellular neurons containing vasopressin and oxytocin terminate in the posterior pituitary, nerve fibers from the paraventricular and supraoptic nuclei project toward many other parts of the nervous system. In the brain stem, vasopressinergic neurons are involved in the autonomic regulation of blood pressure. Similar neurons project to the gray matter and are implicated in higher cortical functions. Fibers terminating in the median eminence permit release of ADH into the hypophysial-portal system; delivery of ADH in high concentrations to the anterior pituitary may facilitate its involvement in the regulation of ACTH secretion. Magnocellular neurons also project to the choroid plexus, where they may release ADH into the cerebrospinal fluid. In addition to magnocellular neurons, the paraventricular nuclei contain cells with smaller cell bodies—parvicellular neurons. Such neurons are also found in other regions of the nervous system and may contain other peptides such as CRH and TRH.

The Hypothalamus and the Control of Appetite

With the growing appreciation of adipose tissue as an endocrine organ, as well as the increasing problem of obesity and its associated health risks, understanding how energy balance and appetite are regulated has become a major topic of study. In 1901, Frohlich observed that some tumors affecting the pituitary and hypothalamus were associated with excess subcutaneous fat and hypogonadism. Subsequent lesioning experiments by Hetherington and Ranson in the 1940s established the hypothalamus as a fundamental site in the regulation of appetite. These experiments introduced the classic dual center model of food intake where the ventromedial hypothalamic nucleus functions as a satiety center and the lateral hypothalamic area serves as a feeding center. Subsequent studies have led to refinements of this model.
Growing evidence points to the pivotal role of the arcuate nucleus in the integration of feeding signals and energy reserves. It has special access to circulating hormones via the underlying median eminence, an area rich with fenestrated capillaries, that is, it is not protected by the blood–brain barrier (see Figure 4-2). Two populations of neurons involved in the regulation of feeding are located within the arcuate nucleus: one that inhibits food intake via the expression of neuropeptides POMC and cocaine-/amphetamine-regulated transcript, and one that stimulates food intake via expression of neuropeptide Y and agouti-related peptide. The arcuate nucleus projects to second-order neuronal populations including the paraventricular nucleus, dorsomedial nucleus, ventromedial nucleus, and lateral hypothalamic area, which then activate downstream pathways controlling appetite and energy expenditure.

Circulating markers of adiposity (leptin, adiponectin, insulin), and hormones from the gastrointestinal tract (ghrelin, peptide YY, glucagon-like peptide 1, cholecystokinin, oxyntomodulin, pancreatic polypeptide) converge on the hypothalamus and brain stem to signal adequacy of short- and long-term energy stores. Alterations in the levels or tissue sensitivity of these hormones may underlie disorders of weight regulation such as obesity, and could prove useful as therapeutic targets (see also Chapter 20).

The Pineal Gland and the Circumventricular Organs

The circumventricular organs are secretory midline brain structures that arise from the ependymal cell lining of the ventricular system (Figure 4–8). These organs are located adjacent to the third ventricle—subfornical organ, subcommissural organ, organum vasculosum of the lamina terminalis, pineal, and part of the median eminence—and at the roof of the fourth ventricle—area postrema (see Figure 4–8). The tissues of these organs have relatively large interstitial spaces and have fenestrated capillaries which, being highly permeable, permit diffusion of large molecules from the general circulation; elsewhere in the brain tight capillary endothelial junctions prevent such diffusion—the blood–brain barrier. For example, angiotensin II (see Chapter 10) is involved in the regulation of water intake, blood pressure, and secretion of vasopressin. In addition to its peripheral effects, circulating angiotensin II acts on the subfornical organ resulting in an increase in water intake.

The pineal gland, considered by the 17th century French philosopher Rene Descartes to be the seat of the soul, is located at the roof of the posterior portion of the third ventricle. The pineal gland in humans and other mammals has no direct neural connections with the brain except for sympathetic innervation via the superior cervical ganglion. The pineal gland secretes melatonin, an indole synthesized from serotonin by 5-methoxylation and N-acetylation (Figure 4–9). The pineal releases melatonin into the general circulation and into the cerebrospinal fluid. Melatonin secretion is regulated by the sympathetic nervous system and is increased in response to hypoglycemia and darkness. The pineal also contains other bioactive peptides and amines including TRH, somatostatin, GnRH, and norepinephrine. The physiologic roles of the pineal remain to be elucidated, but they appear to involve regulation of gonadal function and development and circadian rhythms.

The pineal gland may be the site of origin of pineal cell tumors (pinealomas) or germ cell tumors (germinomas). Neurologic signs and symptoms are the predominant clinical manifestations; examples include increased intracranial pressure, visual abnormalities, ataxia, and Parinaud syndrome—upward gaze palsy, absent pupillary light reflex, paralysis of convergence, and wide-based gait. Endocrine manifestations result primarily from deficiency of hypothalamic hormones (diabetes insipidus, hypopituitarism, or disorders of gonadal development). Treatment involves surgical removal or decompression, radiation therapy, and hormone replacement (discussed later).

Anterior Pituitary Hormones

The six major anterior pituitary hormones—ACTH, GH, PRL, TSH, LH, and FSH—may be classified into three groups: ACTH-related peptides (ACTH itself, lipotropin [LPH], melanocyte-stimulating hormone [MSH], and endorphins); the somatomammotropin proteins (GH and PRL); and the glycoproteins (LH, FSH, and TSH). The chemical features of these hormones are set forth in Table 4–2.
ADRENOCORTICOTROPIC HORMONE AND RELATED PEPTIDES

**Biosynthesis**

ACTH is a 39-amino-acid peptide hormone (MW 4500) processed from a large precursor molecule, POMC (MW 28,500). Within the corticotroph, a single mRNA directs the synthesis and processing of POMC into smaller, biologically active fragments (Figure 4–10), which include β-LPH, α-MSH, β-MSH, β-endorphin, and the amino terminal fragment of POMC. Most of these peptides are glycosylated, which accounts for differences in the reporting of molecular weights. These carbohydrate moieties are responsible for the basophilic staining of corticotrophs.

Two of these fragments are contained within the structure of ACTH: α-MSH is identical to ACTH 1 to 13, and corticotropin-like intermediate lobe peptide (CLIP) represents ACTH 18 to 39 (see Figure 4–10). Although these fragments are found in species with developed intermediate lobes (eg, the rat), they are not secreted as separate hormones in humans. β-LPH, a fragment with 91 amino acids (1-91), is secreted by the corticotroph in equimolar quantities with ACTH. Within the β-LPH molecule exists the amino acid sequence for β-MSH (41-58), γ-LPH (1-58), and β-endorphin (61-91).

**Function**

ACTH stimulates the secretion of glucocorticoids, mineralocorticoids, and androgens—all steroids from the adrenal cortex (see Chapters 9 and 10). The amino terminal end (residues 1-18) is responsible for this biologic activity. ACTH binds to receptors on the adrenal cortex and induces steroidogenesis through a cAMP-dependent mechanism.

The hyperpigmentation observed in states of ACTH hypersecretion (eg, Addison disease, Nelson syndrome) appears to be primarily due to ACTH binding to the MSH receptor, because...
α-MSH and β-MSH do not exist as separate hormones in humans.

The physiologic function of β-LPH and its family of peptide hormones, including β-endorphin, is not completely understood. However, both β-LPH and β-endorphin have the same secretory dynamics as ACTH.

**Measurement**

The development of immunoradiometric and immunochemiluminescent assays (IRMAs and ICMAs, respectively) has provided a sensitive and practical clinical ACTH assay for the evaluation of pituitary-adrenal disorders. The basal morning concentration ranges from 9 to 52 pg/mL (2-11 pmol/L). Its short plasma half-life (7-12 minutes) and episodic secretion cause wide and rapid fluctuations both in its plasma concentration and in that of cortisol.

Although β-LPH has a longer half-life than ACTH and is more stable in plasma, its measurement has not been extensively utilized. Current data suggest that the normal concentration of β-LPH is 10 to 40 pg/mL (1-4 pmol/L).

**Secretion**

The physiologic secretion of ACTH is mediated through neural influences by means of a complex of hormones, the most important of which is CRH (Figure 4–11).

CRH stimulates ACTH in a pulsatile manner: diurnal rhythmicity causes a peak before awakening and a decline as the day progresses. The diurnal rhythm is a reflection of neural control and provokes concordant diurnal secretion of cortisol from the adrenal cortex (Figure 4–12). This episodic release of ACTH is

**FIGURE 4–11** The hypothalamic-pituitary-adrenal axis, illustrating negative feedback by cortisol (F) at the hypothalamic and pituitary levels. A short negative feedback loop of ACTH on the secretion of corticotropin-releasing hormone (CRH) also exists. (Reproduced, with permission, from Gwinup G, Johnson B. Clinical testing of the hypothalamic-pituitary-adrenocortical system in states of hypo- and hypercortisolism. *Metabolism.* 1975;24:777).

**FIGURE 4–12** The episodic, pulsatile pattern of ACTH secretion and its concordance with cortisol secretion in a healthy human subject during a 24-hour period. (Previously unpublished, used with permission, from Johannes D. Veldhuis, MD.)
independent of circulating cortisol levels (i.e., the magnitude of an ACTH impulse is not related to preceding plasma cortisol levels). An example is the persistence of diurnal rhythm in patients with primary adrenal failure (Addison disease). ACTH secretion also increases in response to feeding in both humans and animals.

Many stresses stimulate ACTH, often supersed ing the normal diurnal rhythmicity. Physical, emotional, and chemical stresses such as pain, trauma, hypoxia, acute hypoglycemia, cold exposure, surgery, depression, and interleukin-1 and vasopressin administration have all been shown to stimulate ACTH and cortisol secretion. The increase in ACTH levels during stress is mediated by vasopressin as well as CRH. Although physiologic cortisol levels do not blunt the ACTH response to stress, exogenous corticosteroids in high doses suppress it.

Negative feedback of cortisol and synthetic glucocorticoids on ACTH secretion occurs at both the hypothalamic and pituitary levels via two mechanisms: fast feedback is sensitive to the rate of change in cortisol levels, whereas slow feedback is sensitive to the absolute cortisol level. The first mechanism is probably nonnuclear; that is, this phenomenon occurs too rapidly to be explained by the influence of corticosteroids on nuclear transcription of the specific mRNA responsible for ACTH. Recent studies suggest fast feedback is mediated by a novel membrane-associated glucocorticoid receptor that stimulates a rapid synthesis and retrograde release of endocannabinoids, thereby suppressing synaptic excitation. Slow feedback, occurring later, may be explained by a nuclear-mediated mechanism and a subsequent decrease in synthesis of ACTH. This latter form of negative feedback is the type probed by the clinical dexamethasone suppression test. In addition to the negative feedback of corticosteroids, ACTH also inhibits its own secretion (short-loop feedback).

### GROWTH HORMONE

#### Biosynthesis

GH or somatotropin is a 191-amino-acid polypeptide hormone (MW 21,500) synthesized and secreted by the somatotrophs of the anterior pituitary. Its larger precursor peptide, pre-GH (MW 28,000), is also secreted but has no physiologic significance.

#### Function

The primary function of GH is promotion of linear growth. Its basic metabolic effects serve to achieve this result, but most of the growth-promoting effects are mediated by insulin-like growth factor 1 (IGF-1; previously known as somatomedin C). The metabolic and biologic effects of GH and IGF-1 are shown in Tables 4–5 and 4–6 (see also Chapter 6).

GH, via IGF-1, increases protein synthesis by enhancing amino acid uptake and directly accelerating the transcription and translation of mRNA. In addition, GH tends to decrease protein catabolism by mobilizing fat as a more efficient fuel source; it directly causes the release of fatty acids from adipose tissue and enhances their conversion to acetyl-CoA, from which energy is derived. This protein-sparing effect is an important mechanism by which GH promotes growth and development.

GH also affects carbohydrate metabolism. In excess, it decreases carbohydrate utilization and impairs glucose uptake into cells. This GH-induced insulin resistance appears to be due to a postreceptor impairment in insulin action. These events result in glucose intolerance and secondary hyperinsulinism.

#### Measurement

GH has a plasma half-life of 10 to 20 minutes. The healthy adult secretes approximately 400 μg/d (18.6 nmol/d); in contrast, young adolescents secrete about 700 μg/d (32.5 nmol/d). The early morning GH concentration in fasting unstressed adults is less than 2 ng/mL (90 pmol/L). There are no significant sex differences.

About half of circulating GH is bound to specific GH-binding proteins (GHBP) that function to reduce oscillations in GH levels (due to its pulsatile secretion) and prolong plasma GH half-life. GHBP includes a high-affinity GHBP (corresponding to the extracellular portion of the GH receptor formed through proteolytic cleavage) and a low-affinity species. Measurement of serum concentrations of the high-affinity GHBP provides an index of GH receptor concentrations. For example, individuals with Laron dwarfism, a form of GH insensitivity characterized by mutations in the GH receptor, usually have abnormally low levels of GHBP.

Concentrations of IGF-I are determined by radioreceptor assays or radioimmunoassays. Determining the levels of these mediators of GH action may result in more accurate assessment of the biologic activity of GH (see Chapter 6).

**Secretion**

The secretion of GH is predominantly mediated by two hypothalamic hormones: GHRH and somatostatin (GH-inhibiting hormone), both of which contribute to the episodic pattern of GH secretion. These hypothalamic influences are tightly regulated by an integrated system of neural, metabolic, and hormonal factors. Table 4–7 summarizes the many factors that affect GH secretion in physiologic, pharmacologic, and pathologic states.

**A. Growth hormone-releasing hormone**

GHRH binds to specific receptors, stimulating cAMP production by somatotrophs and stimulating both GH synthesis and secretion. The effects of GHRH are partially blocked by somatostatin. The administration of GHRH to normal humans leads to rapid release of GH (within minutes); levels peak at 30 minutes and are sustained for 60 to 120 minutes.

Other peptide hormones such as ADH, ACTH, and α-MSH may act as GH-releasing factors when present in pharmacologic amounts. Even TSH and GnRH often cause GH secretion in patients with acromegaly; however, it is not certain whether any of these effects are mediated by the hypothalamus or represent direct effects on the somatotroph. Regulation of GHRH is primarily under neural control (see discussion later), but there is also short-loop negative feedback by GHRH itself.

**B. Somatostatin**

Somatostatin, a tetradecapeptide, is a potent inhibitor of GH secretion. It decreases cAMP production in GH-secreting cells and inhibits both basal and stimulated GH secretion. Somatostatin secretion is increased by elevated levels of GH and IGF-I. Long-acting analogs of somatostatin have been used therapeutically in the management of GH excess and in conditions such as pancreatic and carcinoid tumors that cause diarrhea.

**C. Growth hormone secretagogues**

Non-GHRH secretagogues act to release GH, not through the GHRH receptor, but through a separate receptor, the growth hormone secretagogue receptor (GHS-R). A number of synthetic secretagogues, both peptides and nonpeptides, have been described. Ghrelin, a circulating peptide made by endocrine cells in the stomach, was identified in 1999 as the endogenous ligand for GHS-R. Its location in the stomach suggests a new mechanism for regulation of GH secretion.

**D. Neural control**

The neural control of basal GH secretion results in irregular and intermittent release associated with sleep and varying with age. Peak levels occur 1 to 4 hours after the onset of sleep (during stages 3 and 4) (Figure 4–13). These nocturnal sleep bursts, which account for nearly 70% of daily GH secretion, are greater in children and tend to decrease with age. Glucose infusion does not suppress this episodic release. Emotional, physical, and chemical stress, including surgery, trauma, exercise, electroshock therapy, and pyrogen administration, provoke GH release. In addition, impairment of secretion leading to growth failure has been well documented in children with severe emotional deprivation (see Chapter 6).

**E. Metabolic control**

The metabolic factors affecting GH secretion include all fuel substrates: carbohydrate, protein, and fat. Glucose administration, orally or intravenously, lowers GH in

*Suppressive effects of some factors can be demonstrated only in the presence of a stimulus.

Healthy subjects and provides a simple physiologic maneuver useful in the diagnosis of acromegaly (see discussed below). In contrast, hypoglycemia stimulates GH release. This effect depends on intracellular glycopenia, because the administration of 2-deoxyglucose (a glucose analog that causes intracellular glucose deficiency) also increases GH. This response to hypoglycemia depends on both the rate of change in blood glucose and the absolute level attained.

A protein meal or intravenous infusion of amino acids (eg, arginine) causes GH release. Paradoxically, states of protein-calorie malnutrition also increase GH, possibly as a result of decreased IGF-I production and lack of inhibitory feedback.

Fatty acids suppress GH responses to certain stimuli, including arginine and hypoglycemia. Fasting stimulates GH secretion, possibly as a means of mobilizing fat as an energy source and preventing protein loss.

F. Effects of other hormones Responses to stimuli are blunted in states of cortisol excess and during hypoglycemia. Estrogen enhances GH secretion in response to stimulation.

G. Effects of neuropharmacologic agents Many neurotransmitters and neuropharmacologic agents affect GH secretion. Biogenic amine agonists and antagonists act at the hypothalamic level and alter GHRH or somatostatin release. Dopaminergic, alpha-adrenergic, and serotonergic agents all stimulate GH release.

Dopamine agonists such as levodopa, apomorphine, and bromocriptine increase GH secretion, whereas dopaminergic antagonists such as phenothiazines inhibit GH. The effect of levodopa, a precursor of both norepinephrine and dopamine, may be mediated by its conversion to norepinephrine, because its effect is blocked by the alpha-adrenergic antagonist phentolamine. Moreover, phentolamine suppresses GH release in response to other stimuli such as hypoglycemia, exercise, and arginine, emphasizing the importance of alpha-adrenergic mechanisms in modulating GH secretion.

Beta-adrenergic agonists inhibit GH, and beta-adrenergic antagonists such as propranolol enhance secretion in response to provocative stimuli.

PROLACTIN

Biosynthesis

PRL is a 198-amino-acid polypeptide hormone (MW 22,000) synthesized and secreted from the lactotrophs of the anterior pituitary. Despite evolution from an ancestral hormone common to GH and human placental lactogen (hPL), PRL shares only 16% of its residues with the former and 13% with hPL. A precursor molecule (MW 40,000-50,000) is also secreted and may constitute 8% to 20% of the PRL plasma immunoreactivity in healthy persons and in patients with PRL-secreting pituitary tumors. PRL and GH are structurally related to members of the cytokine-hematopoietin family that include erythropoietin, granulocyte-macrophage colony stimulating factor (GM-CSF), and interleukins IL-2 to IL-7.

Function

PRL stimulates lactation in the postpartum period (see Chapter 16). During pregnancy, PRL secretion increases and, in concert with many other hormones (estrogen, progesterone, hPL, insulin, and cortisol), promotes additional breast development in preparation for milk production. Despite its importance during pregnancy, PRL has not been demonstrated to play a role in the development of normal breast tissue in humans. During pregnancy, estrogen enhances breast development but blunts the effect of PRL on lactation; the decrease in both estrogen and progesterone after parturition allows initiation of lactation. Accordingly, galactorrhea may accompany the discontinuance of oral contraceptives or
FIGURE 4-13 Sleep-associated changes in prolactin (PRL) and growth hormone (GH) secretion in humans. Peak levels of GH occur during sleep stages 3 or 4; the increase in PRL is observed 1 to 2 hours after sleep begins and is not associated with a specific sleep phase. (Reproduced, with permission, from Sassin JF, et al. Human prolactin: 24-hour pattern with increased release during sleep. Science. 1972;177:1205).

Measurement

The PRL secretory rate is approximately 400 µg/d (18.6 nmol/d). The hormone is cleared by the liver (75%) and the kidney (25%), and its half-time of disappearance from plasma is about 25 to 50 minutes.

Basal levels of PRL in adults vary considerably, with a mean of 13 ng/mL (0.6 nmol/L) in women and 5 ng/mL (0.23 nmol/L) in men. The upper range of normal in most laboratories is 15 to 20 ng/mL (0.7-0.9 nmol/L).

PRL is measured using a highly specific immunoradiometric assay. However, when PRL levels are extremely high, which can occur with some PRL-secreting tumors, this assay may be susceptible to the "hook effect." PRL levels are erroneously reported as normal or modestly elevated due to saturation of available assay antibodies. Appropriate sample dilutions (ie, 1:100) will avoid this artifact.

In some patients a form of PRL with molecular mass greater than 150 kDa predominates. This is termed macroprolactinemia and consists of aggregates of monomeric PRL as well as PRL-immunoglobulin G complexes. These complexes may have reduced biological activity and can be measured using polyethylene glycol precipitation of serum samples.

Secretion

The hypothalamic control of PRL secretion is predominantly inhibitory, and dopamine is the most important inhibitory factor. The physiologic, pathologic, and pharmacologic factors influencing PRL secretion are listed in Table 4–8.

A. Prolactin-releasing factors TRH is a potent PRL-releasing factor that evokes release of PRL at a threshold dose similar to that which stimulates release of TSH. An exaggerated response of both TSH and PRL to TRH is observed in primary hypothyroidism, and their responses are blunted in hyperthyroidism. In addition, PRL secretion is also stimulated by VIP and serotoninergic pathways.

B. Episodic and sleep-related secretion PRL secretion is episodic. An increase is observed 60 to 90 minutes after sleep.
begins but—in contrast to GH—is not associated with a specific sleep phase. Peak levels are usually attained between 4 and 7 AM (see Figure 4–13). This sleep-associated augmentation of PRL release is not part of a circadian rhythm, like that of ACTH; it is related strictly to the sleeping period regardless of when it occurs during the day.

C. Other stimuli Stresses, including surgery, exercise, hypoglycemia, and acute myocardial infarction, cause significant elevation of PRL levels. Nipple stimulation in nonpregnant women also increases PRL. This neurogenic reflex may also occur from chest wall injury such as mechanical trauma, burns, surgery, and herpes zoster of thoracic dermatomes. This reflex discharge of PRL is abolished by denervation of the nipple or by spinal cord or brain stem lesions.

D. Effects of other hormones Many hormones influence PRL release. Estrogens augment basal and stimulated PRL secretion after 2 to 3 days of use (an effect that is of special clinical importance in patients with PRL-secreting pituitary adenomas); glucocorticoids tend to suppress TRH-induced PRL secretion; and thyroid hormone administration may blunt the PRL response to TRH.

E. Effects of pharmacologic agents (Table 4–8) Many pharmacologic agents alter PRL secretion. Dopamine agonists (eg, bromocriptine) decrease secretion, forming the basis for their use in states of PRL excess. Dopamine antagonists (eg, receptor blockers such as phenothiazines and metoclopramide) and dopamine depletors (eg, reserpine) augment PRL release. Serotonin agonists enhance PRL secretion; serotonin receptor blockers suppress PRL release associated with stress and with nursing.

### THYROTROPIN

**Biosynthesis**

TSH is a glycoprotein (MW 28,000) composed of two noncovalently linked alpha and beta subunits. The structure of the alpha subunit of TSH is identical to that of the other glycoprotein molecules—FSH, LH, and human chorionic gonadotropin (hCG)—but the beta subunits differ in these glycoproteins and is responsible for their biologic and immunologic specificity. The peptides of these subunits appear to be synthesized separately and united before the carbohydrate groups are attached. The intact molecule is then secreted, as are small amounts of nonlinked subunits.

**Function**

The beta subunit of TSH attaches to high-affinity receptors in the thyroid, stimulating iodide uptake, hormonogenesis, and release of T4 and T3. This occurs through activation of adenylyl cyclase and the generation of cAMP. TSH secretion also causes an increase in gland size and vascularity by promoting mRNA and protein synthesis. (For a more detailed description, see Chapter 7.)

**Measurement**

TSH circulates unbound in the blood with a half-life of 35 to 50 minutes. With ultrasensitive IRMAs for measuring TSH concentration, the normal range is usually 0.5 to 4.7 μU/mL (0.5-4.7 mU/L). These new assays are helpful in the diagnosis of primary hypothyroidism and hyperthyroidism; however, TSH levels alone cannot be used to evaluate pituitary or hypothalamic hypothyroidism.

The alpha subunit can be detected in about 80% of normals, with a range of 0.5 to 2 ng/mL. Plasma alpha subunit levels increase after administration of TRH in normal subjects, and basal levels are elevated in primary hypothyroidism, primary hypogonadism, and in patients with TSH-secreting, gonadotropin-secreting, or pure alpha subunit-secreting pituitary adenomas.

**Secretion**

The secretion of TSH is controlled by both stimulatory (TRH) and inhibitory (somatostatin) influences from the hypothalamus and in addition is modulated by the feedback inhibition of thyroid hormone on the hypothalamic-pituitary axis.

**A. TRH** The response of TSH to TRH is modulated by the circulating concentration of thyroid hormones. Small changes in serum levels (even within the physiologic range) cause substantial

alterations in the TSH response to TRH. As shown in Figure 4–14, the administration of T3 (15 μg) and T4 (60 μg) to healthy persons for 3 to 4 weeks suppresses the TSH response to TRH despite only small increases in circulating T3 and T4 levels. Thus, the secretion of TSH is inversely proportional to the concentration of thyroid hormone.

The set point (the level at which TSH secretion is maintained) is determined by TRH. Deviations from this set point result in appropriate changes in TSH release. Administration of TRH increases TSH within 2 minutes, and this response is blocked by previous T3 administration; however, larger doses of TRH may overcome this blockade—suggesting that both T3 and TRH act at the pituitary level to influence TSH secretion. In addition, T3 and T4 inhibit mRNA for TRH synthesis in the hypothalamus, indicating that a negative feedback mechanism operates at this level also.

B. Somatostatin This inhibitory hypothalamic peptide augments the direct inhibitory effect of thyroid hormone on the thyrotrophs. Infusion of somatostatin blunts the early morning TSH surge and suppresses high levels of TSH in primary hypothyroidism. Octreotide acetate, a somatostatin analog, has been used successfully to inhibit TSH secretion in patients with TSH-secreting pituitary tumors.

C. Neural control In addition to these hypothalamic influences on TSH secretion, neurally mediated factors may be important. Dopamine physiologically inhibits TSH secretion. Intravenous dopamine administration decreases TSH in both healthy and hypothyroid subjects as well as blunts the TSH response to TRH. Thus, as expected, dopaminergic agonists such as bromocriptine inhibit TSH secretion and dopaminergic antagonists such as metoclopramide increase TSH secretion in euthyroid subjects.

D. Effects of cortisol and estrogens Glucocorticoid excess has been shown to impair the sensitivity of the pituitary to TRH and may lower serum TSH to undetectable levels. However, estrogens increase the sensitivity of the thyrotroph to TRH; women have a greater TSH response to TRH than men do, and pretreatment of men with estradiol increases their TRH-induced TSH response. (See also Chapter 7.)

GONADOTROPINS: LUTEINIZING HORMONE AND FOLLICLE-STIMULATING HORMONE

Biosynthesis

LH and FSH are glycoprotein gonadotropins composed of alpha and beta subunits and secreted by the same cell. The specific beta subunit confers on these hormones their unique biologic activity, as it does with TSH and hCG. The biologic activity of hCG, a placental glycoprotein, closely resembles that of LH. Human
menopausal gonadotropin (hMG, menotropins)—an altered mixture of pituitary gonadotropins recovered from the urine of postmenopausal women—is a preparation with FSH-like activity. Menotropins and hCG are used clinically for induction of spermatogenesis or ovulation (see Chapters 12 and 13).

**Function**

LH and FSH bind to receptors in the ovary and testis and regulate gonadal function by promoting sex steroid production and gametogenesis.

In men, LH stimulates testosterone production from the interstitial cells of the testes (Leydig cells). Maturation of spermatozoa, however, requires both LH and FSH. FSH stimulates testicular growth and enhances the production of an androgen-binding protein by the Sertoli cells, which are a component of the testicular tubule necessary for sustaining the maturing sperm cell. This androgen-binding protein promotes high local concentrations of testosterone within the testis, an essential factor in the development of normal spermatogenesis (see Chapter 12).

In women, LH stimulates estrogen and progesterone production from the ovary. A surge of LH in the midmenstrual cycle is responsible for ovulation, and continued LH secretion subsequently stimulates the corpus luteum to produce progesterone by enhancing the conversion of cholesterol to pregnenolone. Development of the ovarian follicle is largely under FSH control, and the secretion of estrogen from this follicle is dependent on both FSH and LH.

**Measurement**

The normal levels of LH and FSH vary with the age of the subject (see Appendix). They are low before puberty and elevated in postmenopausal women. A nocturnal rise of LH in boys and the cyclic secretion of FSH and LH in girls usually herald the onset of puberty before clinical signs are apparent. In women, LH and FSH vary during the menstrual cycle; during the initial phase of the cycle (follicular), LH steadily increases, with a midcycle surge that initiates ovulation. FSH, on the other hand, initially rises and then decreases during the later follicular phase until the midcycle surge, which is concordant with LH. Both LH and FSH levels fall steadily after ovulation (see Chapter 13).

LH and FSH levels in men are similar to those in women during the follicular phase. The alpha subunit, shared by all the pituitary glycoprotein hormones, can also be measured (see TSH) and will rise following GnRH administration.

**Secretion**

The secretion of LH and FSH is controlled by GnRH, which maintains basal gonadotropin secretion, generates the phasic release of gonadotropins for ovulation, and determines the onset of puberty. As noted above, the size and frequency of GnRH pulses determine the ratio of gonadotropin secretion: low-frequency pulses favor FSH release while high-frequency pulses result in LH release. Many other factors are involved in regulation of this axis. For example, activins and follistatins are paracrine factors that exert opposing effects on gonadotrophs. Leptin, a hormone made in adipocytes in proportion to fat stores, is involved in regulation of this axis and may help to explain the suppression of gonadotropin secretion that accompanies caloric restriction.

**A. Episodic secretion**

In both males and females, secretion of LH and FSH is episodic, with secretory bursts that occur each hour and are mediated by a concordant episodic release of GnRH. The amplitude of these secretory surges is greater in patients with primary hypogonadism. The pulsatile nature of GnRH release is critical for sustaining gonadotropin secretion. A continuous, prolonged infusion of GnRH in women evokes an initial increase in LH and FSH followed by prolonged suppression of gonadotropin secretion. This phenomenon may be explained by downregulation of GnRH receptors on the pituitary gonadotrophs. Consequently, long-acting synthetic analogs of GnRH may be used clinically to suppress LH and FSH secretion in conditions such as precocious puberty.

**B. Positive feedback**

Circulating sex steroids affect GnRH secretion and thus LH and FSH secretion by both positive and negative (inhibitory) feedback mechanisms. During the menstrual cycle, estrogens provide a positive influence on GnRH effects on LH and FSH secretion, and the rise in estrogen during the follicular phase is the stimulus for the LH and FSH ovulatory surge. This phenomenon suggests that the secretion of estrogen is to some extent influenced by an intrinsic ovarian cycle. Progesterone amplifies the duration of the LH and FSH surge and augments the effect of estrogen. After this midcycle surge, the developed egg leaves the ovary. Ovulation occurs approximately 10 to 12 hours after the LH peak and 24 to 36 hours after the estradiol peak. The remaining follicular cells in the ovary are converted, under the influence of LH, to a progesterone-secreting structure, the corpus luteum. After about 12 days, the corpus luteum involutes, resulting in decreased estrogen and progesterone levels and then uterine bleeding (see Chapter 13).

**C. Negative feedback**

Negative feedback effects of sex steroids on gonadotropin secretion also occur. In women, primary gonadal failure or menopause results in elevations of LH and FSH, which can be suppressed with long-term, high-dose estrogen therapy. However, a shorter duration of low-dose estrogen may enhance the LH response to GnRH. In men, primary gonadal failure with low circulating testosterone levels is also associated with elevated gonadotropins. However, testosterone is not the sole inhibitor of gonadotropin secretion in men, since selective destruction of the tubules (eg, by cyclophosphamide therapy) results in azoospermia and elevation of only FSH.

Inhibin, a polypeptide (MW 32,000) secreted by the Sertoli cells of the seminiferous tubules, is the major factor that inhibits FSH secretion by negative feedback. Inhibin consists of separate alpha and beta subunits connected by a disulfide bridge. Androgens stimulate inhibin production; this peptide may help to locally regulate spermatogenesis (see Chapter 12).
ENDOCRINOLOGIC EVALUATION OF THE HYPOTHALAMIC-PITUITARY AXIS

The precise assessment of the hypothalamic-pituitary axis has been made possible by radioimmunoassays of the major anterior pituitary hormones and their specific target gland hormones. In addition, provocative testing using synthetic or purified hormones (eg, ACTH, ovine CRH, glucagon, insulin) can be used to assess hypothalamic-pituitary reserve and excess.

This section describes the principles involved in testing each pituitary hormone as well as special situations (eg, drugs, obesity) that may interfere with pituitary function or pituitary testing. Specific protocols for performing and interpreting diagnostic procedures are outlined at the end of this section and in Table 4-9. The clinical manifestations of either hypo- or hypersecretion of anterior pituitary hormones are discussed in subsequent sections.

EVALUATION OF ADRENOCORTICOTROPIC HORMONE

ACTH deficiency leads to secondary adrenocortical insufficiency, characterized by decreased secretion of cortisol and the adrenal androgens; aldosterone secretion, controlled primarily by the renin-angiotensin axis, is usually maintained. In contrast, excessive ACTH secretion leads to adrenal hyperfunction (Cushing syndrome, discussed in a later section of this chapter and in Chapter 9).

Plasma ACTH Levels

Basal ACTH measurements are usually unreliable indicators of pituitary function, because its short plasma half-life and episodic secretion result in wide fluctuations in plasma levels (see Figure 4–12). Therefore, the interpretation of plasma ACTH levels requires the simultaneous assessment of cortisol secretion by the adrenal cortex. These measurements are of greatest utility in differentiating primary and secondary adrenocortical insufficiency and in establishing the etiology of Cushing syndrome (see the later section on Cushing disease and also Chapter 9).

Evaluation of ACTH Deficiency

In evaluating ACTH deficiency, measurement of basal cortisol levels is also generally unreliable. Because plasma cortisol levels are usually low in the late afternoon and evening, reflecting the normal diurnal rhythm, samples drawn at these times are of virtually no value for this diagnosis. Plasma cortisol levels are usually highest in the early morning; however, there is considerable overlap between adrenal insufficiency and normal subjects. A plasma cortisol level less than 5 μg/dL (138 nmol/L) at 8 AM strongly suggests the diagnosis—and the lower the level, the more likely the diagnosis. Conversely, a plasma cortisol greater than 20 μg/dL (552 nmol/L) virtually excludes the diagnosis. Similarly, salivary cortisol levels less than 1.8 ng/mL (5 nmol/L) at 8 AM strongly suggest adrenal insufficiency, while levels in excess of 5.8 ng/mL (16 nmol/L) greatly reduce the probability of the diagnosis. Consequently, the diagnosis of ACTH hyposcretion (secondary adrenal insufficiency) must be established by provocative testing of the reserve capacity of the hypothalamic-pituitary axis.

Adrenal Stimulation

Because adrenal atrophy develops as a consequence of prolonged ACTH deficiency, the initial and most convenient approach to evaluation of the hypothalamic-pituitary-adrenal axis is assessment of the plasma cortisol response to synthetic ACTH (cosyntropin). In normal individuals, injection of cosyntropin (250 μg) causes a rapid increase (within 30 minutes) of cortisol to at least 18 to 20 μg/dL (496-552 nmol/L), and this response usually correlates with the cortisol response to insulin-induced hypoglycemia. A subnormal cortisol response to ACTH confirms adrenocortical insufficiency. However, a normal response does not directly evaluate the ability of the hypothalamic-pituitary axis to respond to stress (see Chapter 9). Thus, patients withdrawn from long-term glucocorticoid therapy may have an adequate increase in cortisol following exogenous ACTH that precedes complete recovery of the hypothalamic-pituitary-adrenal axis. Therefore, such patients should receive glucocorticoids during periods of stress for at least 1 year after steroids are discontinued, unless the hypothalamic-pituitary axis is shown to be responsive to stress as described below.

The more physiologic dose administered in the 1 μg ACTH test is designed to improve its sensitivity in detection of secondary adrenal insufficiency. The cortisol response to 1 μg of synthetic ACTH correlates better with the cortisol response to insulin-induced hypoglycemia in patients with complete chronic secondary adrenal insufficiency. However, the results in partial secondary adrenal insufficiency are less reliable and technical difficulties make the test impractical for routine use. Thus, the standard 250 μg ACTH test remains the procedure of choice (see discussion later and Chapter 9).

Pituitary Stimulation

Direct evaluation of pituitary ACTH reserve can be performed by means of insulin-induced hypoglycemia, metyrapone administration, or CRH stimulation. These studies are unnecessary if the cortisol response to rapid ACTH stimulation is subnormal.

A. Insulin-induced hypoglycemia The stimulus of neuroglycopenia associated with hypoglycemia (blood glucose <40 mg/dL) evokes a stress-mediated activation of the hypothalamic-pituitary-adrenal axis. Subjects should experience adrenergic symptoms (diaphoresis, tachycardia, weakness, headache) associated with the fall in blood sugar. In normal persons, plasma cortisol increases to more than 18 to 20 μg/dL (496-552 nmol/L), indicating normal ACTH reserve. Although plasma ACTH also rises, its determination has not proved to be as useful, because pulsatile secretion requires frequent sampling, and the normal response is not well standardized. Although insulin-induced hypoglycemia most reliably predicts ACTH secretory capacity in times of stress, it is rarely performed at present, because the procedure

<tr>
<td>GnRH test</td>
<td>The patient should be at rest but need not be fasting. Give GnRH (gonadorelin), 100 μg intravenously, over 15 s. Blood samples for LH and FSH determinations are taken at 0, 30, and 60 min. Since the FSH response is somewhat delayed, a 90-min specimen may be necessary.</td>
<td>Side effects are rare, and no contraindications have been reported.</td>
<td>This response is dependent on sex and the time of the menstrual cycle. Table 4-9 illustrates the mean maximal change in LH and FSH after GnRH administration. An increase of LH of 1.3-2.6 μg/L (12-23 IU/L) is considered to be normal; FSH usually responds more slowly and less markedly. FSH may not increase even in healthy subjects.</td>
</tr>
<tr>
<td>Clomiphene test</td>
<td>Clomiphene is administered orally. For women, give 100 mg daily for 5 d (beginning on day 5 of the cycle if the patient is menstruating); for men, give 100 mg daily for 7-10 d. Blood for LH and FSH determinations is drawn before and after clomiphene is given.</td>
<td>This drug may stimulate ovulation, and women should be advised accordingly.</td>
<td>In women, LH and FSH levels peak on the fifth day to a level above the normal range. After the fifth day, LH and FSH levels decline. In men, LH should double after 1 wk; FSH will also increase, but to a lesser extent.</td>
</tr>
<tr>
<td>CRH test</td>
<td>CRH (1 μg/kg) is given intravenously as a bolus injection. Blood samples for ACTH and cortisol are taken at 0, 15, 30, and 60 min.</td>
<td>Flushing often occurs. Transient tachycardia and hypotension have also been reported.</td>
<td>The ACTH response is dependent on the assay utilized and occurs 15 min after CRH is administered. The peak cortisol response occurs at 30-60 min and is usually &gt;10 μg/dL (276 nmol/L).</td>
</tr>
<tr>
<td>Low-dose dexamethasone suppression test</td>
<td>Dexamethasone (1 mg) is given between 11 PM and midnight. Blood samples for cortisol and dexamethasone are taken at 8 AM the next morning.</td>
<td>Side effects are rare. Compliance is sometimes an issue. Some medications and patient variability can affect dexamethasone metabolism.</td>
<td>Cortisol should suppress to &lt;1.8 μg/dl in normal individuals. This cutoff has a high sensitivity, but specificity is compromised.</td>
</tr>

</table>

requires a physician’s presence and is contraindicated in elderly patients, patients with cerebrovascular or cardiovascular disease, and those with seizure disorders. It should be used with caution in patients in whom diminished adrenal reserve is suspected, because severe hypoglycemia may occur; in these patients, the test should always be preceded by the ACTH adrenal stimulation test.

B. Metyrapone stimulation  Metyrapone administration is an alternative method for assessing ACTH secretory reserve. Metyrapone inhibits P450c11 (11β-hydroxylase), the enzyme that catalyzes the final step in cortisol biosynthesis (see Chapter 9). The inhibition of cortisol secretion interrupts negative feedback on the hypothalamic-pituitary axis, resulting in a compensatory increase in ACTH. The increase in ACTH secretion stimulates increased steroid biosynthesis proximal to P450c11, and the increase can be detected as an increase in the precursor steroid (11-deoxycortisol) in plasma. The overnight test is preferred because of its simplicity; it is performed by administering 30 mg/kg of metyrapone orally at midnight. Plasma 11-deoxycortisol is determined the following morning and rises to more than 7 μg/dL (0.2 nmol/L) in healthy individuals. Again the test should be used cautiously in patients with suspected adrenal insufficiency and should be preceded by a rapid ACTH stimulation test (see discussion earlier). The traditional 3-day metyrapone test should not be used at present because of the risk of precipitating adrenal insufficiency. The overnight metyrapone test is most useful in patients with partial secondary adrenal insufficiency in whom the rapid ACTH stimulation test is normal or borderline. It has been shown to correlate well with the response to insulin-induced hypoglycemia. Metyrapone may be obtained directly from the Novartis Pharmaceutical Corporation, East Hanover, New Jersey.

C. CRH stimulation  Ovine CRH administered intravenously is used to assess ACTH secretory dynamics. In healthy subjects,
CRH (1 μg/kg) provokes a peak ACTH response within 15 minutes and a peak cortisol response within 30 to 60 minutes. This dose may be associated with mild flushing, occasional shortness of breath, tachycardia, and hypotension. Patients with primary adrenal insufficiency have elevated basal ACTH levels and exaggerated ACTH responses to CRH. Secondary adrenal insufficiency results in an absent ACTH response to CRH in patients with pituitary corticotroph destruction; however, in patients with hypothalamic dysfunction, there is a prolonged and augmented ACTH response to CRH with a delayed peak. Because of overlap between the responses of normal individuals and those with partial secondary adrenal insufficiency, the CRH test is less useful than the procedures described above.

ACTH Hypersecretion

ACTH hypersecretion is manifested by adrenocortical hyperfunction (Cushing syndrome). The diagnosis and differential diagnosis of ACTH hypersecretion and hypercortisolism are outlined in a later section on Cushing disease and also in Chapter 9. The low-dose dexamethasone suppression test is used to establish the presence of hypercortisolism regardless of its cause. Dexamethasone 1 mg is taken orally between 11 PM and midnight. The following morning at 8 AM, a blood sample is obtained for cortisol (and dexamethasone level if available or cortisol does not suppress). Cortisol values less than 1.8 μg/dL are normal. Sensitivity using this cutoff is good though specificity is compromised. Patient compliance, individual differences in dexamethasone metabolism, drugs that affect metabolism of dexamethasone, and medical conditions that alter cortisol secretion (acute illness, anxiety, depression, alcoholism) may influence the accuracy of this test.

Insulin-Induced Hypoglycemia

The most reliable stimulus of GH secretion is insulin-induced hypoglycemia. In normal individuals, GH levels increase to more than 5 ng/mL after adequate hypoglycemia is achieved. Because 10% of normal individuals fail to respond to hypoglycemia, other stimulatory tests may be necessary.

GHRH-Arginine Test

Both forms of human GHRH (GHRH-40 and GHRH-44) have been used to evaluate GH secretory capacity. A dose of GHRH (1 μg/kg) combined with a 30-minute infusion of arginine (0.5 g/kg to a maximum of 20 g) promptly stimulates GH; the mean peak is 10 to 15 ng/mL (460-700 pmol/L) at 30 to 60 minutes in healthy subjects. The results are comparable to those achieved with insulin-induced hypoglycemia. Unfortunately, GHRH is no longer available in the United States.

Glucagon Stimulation Test

Glucagon can also be used to evaluate GH secretory capacity. A dose of glucagon (1 mg) is given intramuscularly and GH levels are measured every 30 minutes for 3 to 4 hours. In adults with GH deficiency, peak GH levels fail to rise above 3 ng/mL.

Tests with Levodopa, Arginine, and Other Stimuli

Stimulation testing with levodopa, arginine infusion alone, or propranolol, is less reliable in the diagnosis of GH deficiency.

GH Hypersecretion

The evaluation of GH hypersecretion is discussed in the section on acromegaly and is most conveniently assessed by GH suppression testing with oral glucose and measurement of IGF-I levels.

EVALUATION OF THYROID-STIMULATING HORMONE

Basal Measurements

The laboratory evaluation of TSH secretory reserve begins with an assessment of target gland secretion; thyroid function tests (free thyroxine [FT₄]) should be obtained. Normal thyroid function studies in a clinically euthyroid patient indicate adequate TSH secretion, and no further studies are warranted. Laboratory evidence of hypothyroidism requires measurement of a TSH level. With primary thyroid gland failure, the TSH level is elevated; low or normal TSH in the presence of hypothyroidism suggests hypothalamic-pituitary dysfunction (see Chapter 7).
EVALUATION OF LH AND FSH

Testosterone and Estrogen Levels
The evaluation of gonadotropin function also requires assessment of target gland secretory function, and measurement of gonadal steroids (testosterone in men, estradiol in women) is useful in the diagnosis of hypogonadism. In women, the presence of regular menstrual cycles is strong evidence that the hypothalamic-pituitary-gonadal axis is intact. Estradiol levels rarely fall below 50 pg/mL (180 pmol/L), even during the early follicular phase. A level of less than 30 pg/mL (110 pmol/L) in the presence of oligomenorrhea or amenorrhea is indicative of gonadal failure. In men, serum testosterone (normal range, 300-1000 ng/dL; 10-35 nmol/L) is a sensitive index of gonadal function (see Chapters 12 and 13).

LH and FSH Levels
In the presence of gonadal insufficiency, high LH and FSH levels are a sign of primary gonadal failure; low or normal LH and FSH suggest hypothalamic-pituitary dysfunction (hypogonadotropic hypogonadism).

GnRH Test
LH and FSH secretory reserves may be assessed with the use of synthetic GnRH (gonadorelin). Administration of GnRH causes a prompt increase in plasma LH and a lesser and slower increase in FSH. However, in most patients, the GnRH test provides no more useful information than is obtained by measurement of basal gonadotropin and gonadal steroid levels. Thus, this test is uncommonly performed.

PROBLEMS IN EVALUATION OF THE HYPOTHALAMIC-PITUITARY AXIS

This section briefly outlines some of the disorders and conditions that may cause confusion and lead to misinterpretation of pituitary function tests. The effects of drugs are described in the next section.

Obesity
GH dynamics are impaired in many severely obese patients; all provocative stimuli, including insulin-induced hypoglycemia, arginine, levodopa, and glucagon plus propranolol, often fail to provoke GH secretion. The GH response to GHRH is also impaired in obesity and improves with weight loss. Obesity is also a common cause of hypogonadotropic hypogonadism in adult men.

Diabetes Mellitus
Although glucose normally suppresses GH secretion, most individuals with type 1 diabetes have normal or elevated GH levels that often do not rise further in response to hypoglycemia or arginine. Levodopa increases GH in some diabetic patients, and even a dopamine infusion (which produces no GH change in nondiabetic subjects, because it does not cross the blood–brain barrier), stimulates GH in diabetic patients. Despite the increased GH secretion in patients with inadequately controlled diabetes, the GH response to GHRH in insulin-dependent diabetic patients is similar to that of nondiabetic subjects. IGF-I levels are low in insulin-deficient diabetes despite the elevated GH levels.

Uremia
Basal levels of GH, PRL, LH, FSH, TSH, and free cortisol tend to be elevated, for the most part owing to prolongation of their plasma half-life. GH may paradoxically increase following glucose administration and is often hyperresponsive to a hypoglycemic stimulus. Although the administration of TRH (protirelin) has no effect on GH secretion in healthy subjects, the drug may increase GH in patients with chronic renal failure. The response of PRL to TRH is blunted and prolonged. Gonadotropin response to synthetic GnRH usually remains intact. Dexamethasone suppression of cortisol may be impaired.

Starvation and Anorexia Nervosa
GH secretion increases with fasting and malnutrition, and such conditions may cause a paradoxical increase in GH following glucose administration. Severe starvation, such as occurs in patients with anorexia nervosa, may result in low levels of gonadal steroids. LH and FSH responses to GnRH may be intact despite a state of functional hypogonadotropic hypogonadism. Cortisol levels may be increased and fail to suppress adequately with dexamethasone. PRL and TSH dynamics are usually normal despite a marked decrease in circulating total thyroid hormones (see Chapter 7).

Depression
Depression may alter the ability of dexamethasone to suppress plasma cortisol and may elevate cortisol secretion; the response to insulin-induced hypoglycemia usually remains intact. In addition, late-evening salivary cortisol levels usually remain normal and are not elevated as seen in patients with Cushing syndrome. The ACTH response to CRH is blunted in endogenous depression. Some depressed patients also have abnormal GH dynamics: TRH may increase GH, and hypoglycemia or levodopa may fail to increase GH. These patients may also show blunted TSH responses to TRH.

EFFECTS OF PHARMACOLOGIC AGENTS ON HYPOTHALAMIC-PITUITARY FUNCTION

Glucocorticoid excess impairs the GH response to hypoglycemia, the TSH response to TRH, and the LH response to GnRH. Estrogens tend to augment GH dynamics as well as the PRL and TSH response to TRH. Estrogens increase plasma cortisol secondary to a rise in corticosteroid-binding globulin and may result in inadequate suppression with dexamethasone.
Phenytoin enhances the metabolism of dexamethasone, making clinical testing in patients of this agent difficult to interpret. Phenothiazines may blunt the GH response to hypoglycemia and levodopa and frequently cause hyperprolactinemia. The many other pharmacologic agents that increase PRL secretion are listed in Table 4-8.

Narcotics, including heroin, morphine, and methadone, may all raise PRL levels and suppress GH and cortisol response to hypoglycemia.

In chronic alcoholics, alcohol excess or withdrawal may increase cortisol levels and cause inadequate dexamethasone suppression and an impaired cortisol increase after hypoglycemia.

ENDOCRINE TESTS OF HYPOTHALAMIC-PITUITARY FUNCTION

Methods for performing endocrine tests and their normal responses are summarized in Table 4-9. The indications for and the clinical utility of these procedures are described in the preceding section and will be mentioned again in the section on pituitary and hypothalamic disorders.

NEURORADIOLOGIC EVALUATION

Symptoms of pituitary hormone excess or deficiency, headache, or visual disturbance lead the clinician to consider a hypothalamic-pituitary disorder. In this setting, accurate neuroradiologic assessment of the hypothalamus and pituitary is essential in confirming the existence and defining the extent of hypothalamic-pituitary lesions. However, the diagnosis of such lesions should be based on both endocrine and radiologic criteria, because variability of pituitary anatomy in the normal population may lead to false-positive interpretations. Furthermore, patients with pituitary microadenomas may have normal neuroradiologic studies. Imaging studies must be interpreted in light of the fact that 10% to 20% of the general population harbor nonfunctional and asymptomatic pituitary microadenomas.

Magnetic Resonance Imaging

MRI is the current procedure of choice for imaging the hypothalamus and pituitary. It has superseded the use of computed tomography (CT) because it allows better definition of normal structures and has better resolution in defining tumors. Arteriography is rarely utilized at present except in patients with intrasellar or parasellar aneurysms.

Imaging is performed in sagittal and coronal planes at 1.5 to 2 mm intervals. This allows clear definition of hypothalamic and pituitary anatomy and can accurately visualize lesions as small as 3 to 5 mm. The use of the heavy-metal contrast agent gadolinium allows even more precise differentiation of small pituitary adenomas from normal anterior pituitary tissue and other adjacent structures as shown in Figure 4–15.

A. Normal anatomy

The normal anterior pituitary is 5 to 7 mm in height and approximately 10 mm in its lateral dimensions. The superior margin is flat or concave but may be upwardly convex with a height of 10 to 12 mm in healthy menstruating young women. The floor of the sella turcica is formed by the bony roof of the sphenoid sinus, and its lateral margins are formed by the dural membranes of the cavernous sinuses, which contain the carotid arteries and the third, fourth, and sixth cranial nerves. The posterior pituitary appears on MRI as a high-signal-intensity structure, the "posterior pituitary bright spot," which is absent in patients with diabetes insipidus. The pituitary stalk, which is normally in the midline, is 2 to 3 mm in diameter and 5 to 7 mm in length. The pituitary stalk joins the inferior hypothalamus below the third ventricle and posterior to the optic chiasm. All of these normal structures are readily visualized with MRI; the normal pituitary and the pituitary stalk show increased signal intensity with gadolinium.

B. Microadenomas

These lesions, which range from 2 to 10 mm in diameter, appear as low-signal-intensity lesions on MRI and do not usually enhance with gadolinium. Adenomas less than 5 mm in diameter may not be visualized and do not usually alter the normal pituitary contour. Lesions greater than 5 mm in diameter create a unilateral convex superior gland margin and usually cause deviation of the pituitary stalk toward the side opposite the adenoma.

MRI scans must be interpreted with caution, because minor abnormalities occur in 10% of patients who have had incidental high-resolution scans but no clinical pituitary disease. These abnormalities may represent the clinically insignificant pituitary abnormalities that occur in 10% to 20% of the general population, and they may also be due to small intrapituitary cysts, which usually occur in the pars intermedia. Artifacts within the sella turcica associated with the bones of the skull base may also result in misinterpretation of imaging studies. Finally, many patients with pituitary microadenomas have normal high-resolution MRI scans. Therefore, despite increased accuracy of neuroradiologic diagnosis, the presence or absence of a small pituitary tumor and the decision concerning its treatment must be based on the entire clinical picture.

C. Macroadenomas

Pituitary adenomas greater than 10 mm in diameter are readily visualized with MRI scans, and the scan also defines the adjacent structures and degree of extension of the lesion. Thus, larger tumors show compression of the normal pituitary and distortion of the pituitary stalk. Adenomas larger than 1.5 cm frequently have suprasellar extension, and MRI scans show compression and upward displacement of the optic chiasm. Less commonly, there is lateral extension and invasion of the cavernous sinus.

D. Other uses

High-resolution MRI scanning is also a valuable tool in the diagnosis of empty sella syndrome, hypothalamic tumors, and other parasellar lesions.
CHAPTER 4 Hypothalamus and Pituitary Gland

FIGURE 4-15 Upper panel: A: The coronal magnetic resonance (MR) image shows a large nonfunctioning pituitary adenoma (arrows) with pronounced suprasellar extension and chiasmal compression. B: A sagittal MR image of another large pituitary adenoma shows spontaneous hemorrhage within the suprasellar portion of the adenoma (arrows). (Photographs courtesy of David Norman, MD. Reproduced, with permission, from West J Med. 1995;162:342, 350.)

Lower panel: Gadolinium-enhanced MR images are shown of the pituitary gland. A and B: Coronal and sagittal images show the normal, uniformly enhancing pituitary stalk and pituitary gland. C: A pituitary microadenoma appears as a low-intensity lesion in the inferior aspect of the right lobe of the gland (arrow). D: The pituitary microadenoma appears as a low-intensity lesion between the left lobe of the pituitary and the left cavernous sinus (arrow). (Photographs courtesy of David Norman, MD.)

PITUITARY AND HYPOTHALAMIC DISORDERS

Hypothalamic-pituitary lesions present with a variety of manifestations, including pituitary hormone hypersecretion and hyposecretion, sellar enlargement, and visual loss. The approach to evaluation should be designed to ensure early diagnosis at a stage when the lesions are amenable to therapy.

Etiology and Early Manifestations

In adults, the most common cause of hypothalamic-pituitary dysfunction is a pituitary adenoma, of which the great majority are hypersecreting. Thus, the earliest symptoms of such tumors are due to endocrinologic abnormalities—hypogonadism is the most frequent manifestation—and these precede sellar enlargement and local manifestations such as headache and visual loss, which are late manifestations seen only in patients with larger tumors or suprasellar extension.
In children, pituitary adenomas are uncommon; the most frequent structural lesions causing hypothalamic-pituitary dysfunction are craniopharyngiomas and other hypothalamic tumors. These also usually manifest as endocrine disturbances (low GH levels, delayed puberty, diabetes insipidus) prior to the development of headache, visual loss, or other central nervous system symptoms.

Common and Later Manifestations

A. Pituitary hypersecretion  PRL is the hormone most commonly secreted in excess amounts by pituitary adenomas, and it is usually elevated in patients with hypothalamic disorders and pituitary stalk compression as well. Thus, PRL measurement is essential in evaluating patients with suspected pituitary disorders and should be performed in patients presenting with galactorrhea, gonadal dysfunction, secondary gonadotropin deficiency, or enlargement of the sella turcica. Hypersecretion of GH or ACTH leads to the more characteristic syndromes of acromegaly and Cushing disease (see discussion later).

B. Pituitary insufficiency  Although panhypopituitarism is a classic manifestation of pituitary adenomas, it is present in less than 20% of patients in current large series because of earlier diagnosis of these lesions.

The earliest clinical manifestation of a pituitary adenoma in adults is hypogonadism secondary to elevated levels of PRL, GH, or ACTH and cortisol. The hypogonadism in these patients is due to interference with the secretion of GnRH rather than to destruction of anterior pituitary tissue. Thus, patients with hypogonadism should first be screened with FSH and LH measurements to exclude primary gonadal failure (elevated FSH or LH) and those with hypogonadotropic hypogonadism should have serum PRL levels measured and be examined for clinical evidence of GH or ACTH and cortisol excess.

In children, short stature is the most frequent clinical presentation of hypothalamic-pituitary dysfunction; in these patients, GH deficiency should be considered (see Chapter 6).

TSH or ACTH deficiency is relatively unusual and, if present, usually indicates panhypopituitarism. Thus, patients with secondary hypothyroidism or hypoadrenalism should undergo a complete assessment of pituitary function and neuroradiologic studies, because panhypopituitarism and large pituitary tumors are common in this setting. PRL measurement is again essential, because prolactinomas are the most frequent pituitary tumors in adults.

C. Enlarged sella turcica  Patients may present with enlargement of the sella turcica, which may be noted on radiographs performed for head trauma or on sinus series. These patients usually have either a pituitary adenoma or empty sella syndrome. Other less common causes include craniopharyngioma, lymphocytic hypophysitis, and carotid artery aneurysm. Evaluation should include clinical assessment of pituitary dysfunction and measurements of PRL and thyroid and adrenal function. Pituitary function is usually normal in the empty sella syndrome; this diagnosis can be confirmed by MRI. Patients with clinical or laboratory evidence of pituitary dysfunction usually have a pituitary adenoma.

D. Visual field defects  Patients presenting with bitemporal hemianopia or unexplained visual field defects or visual loss should be considered to have a pituitary or hypothalamic disorder until proven otherwise. The initial steps in diagnosis should be neuro-ophthalmologic evaluation and neuroradiologic studies with MRI, which will reveal the tumor if one is present. These patients should also have PRL measurements and be assessed for anterior pituitary insufficiency, which is especially common with large pituitary adenomas.

In addition to causing visual field defects, large pituitary lesions may extend laterally into the cavernous sinus, compromising the function of the third, fourth, or sixth cranial nerve, leading to diplopia.

E. Diabetes insipidus  Diabetes insipidus is a common manifestation of hypothalamic lesions and metastases to the pituitary, but is rare in primary pituitary lesions. Diagnostic evaluation is described in Chapter 5. In addition, all patients should undergo radiologic evaluation and assessment of anterior pituitary function.

EMPTY SELLA SYNDROME

Etiology and Incidence

Empty sella syndrome occurs when the subarachnoid space extends into the sella turcica, partially filling it with cerebrospinal fluid. This process causes remodeling and enlargement of the sella turcica and flattening of the pituitary gland.

Primary empty sella syndrome resulting from congenital incompetence of the diaphragma sellae (Figure 4-16) is common, with an incidence in autopsy series ranging from 5% to 23%. It is the most frequent cause of enlarged sella turcica. An empty sella is also commonly seen after pituitary surgery or radiation therapy and may also occur following postpartum pituitary infarction (Sheehan syndrome). In addition, both PRL-secreting and GH-secreting pituitary adenomas may undergo subclinical hemorrhagic infarction and cause contraction of the overlying suprasellar cistern downward into the sella. Therefore, the presence of an empty sella does not exclude the possibility of a coexisting pituitary tumor.

Clinical Features

A. Symptoms and signs  Most patients are middle-aged obese women. Many have systemic hypertension; benign intracranial hypertension may also occur. Although 48% of patients complain of headache, this feature may have only initiated the evaluation (ie, skull x-rays), and its relationship to the empty sella is probably coincidental. Serious clinical manifestations are uncommon. Spontaneous cerebrospinal fluid rhinorrhea and visual field impairment may occur rarely.
B. Laboratory findings  Tests of anterior pituitary function are almost always normal, although some patients have hyperprolactinemia. Endocrine function studies should be performed to exclude pituitary hormone insufficiency or a hypersecretory pituitary microadenoma.

Diagnosis

The diagnosis of empty sella syndrome can be readily confirmed by MRI, which demonstrates the herniation of the diaphragma sellae and the presence of cerebrospinal fluid in the sella turcica.

HYPOTHALAMIC DYSFUNCTION

Hypothalamic dysfunction is most often caused by tumors, of which craniopharyngioma is the most common in children, adolescents, and young adults. In older adults, primary central nervous system tumors and those arising from hypothalamic (epidermoid and dermoid tumors) and pineal structures (pinealomas) are more common. Other causes of hypothalamic-pituitary dysfunction are discussed below in the section on hypopituitarism.

Clinical Features

A. Craniopharyngioma  Craniopharyngiomas are thought to originate from metaplasia of remnant epithelial cell rests in Rathke pouch and the craniopharyngeal duct during development. The differential diagnosis includes Rathke cleft cysts and arachnoid cysts. Rathke cleft cysts are a common incidental finding within the pituitary, but may present with symptoms similar to craniopharyngiomas. Although Rathke cleft cysts and craniopharyngiomas are both thought to arise from Rathke pouch during development, craniopharyngiomas tend to be more aggressive and are more likely to recur after resection.

The initial symptoms of craniopharyngioma in children and adolescents are predominantly endocrinologic; however, these manifestations are frequently unrecognized, and at diagnosis more than 80% of patients have hypothalamic-pituitary endocrine deficiencies. These endocrine abnormalities may precede presenting symptoms by months or years; GH deficiency is most common, with about 50% of patients having growth retardation and approximately 70% decreased GH responses to stimulation at diagnosis. Gonadotropin deficiency leading to absent or arrested puberty is usual in older children and adolescents; TSH and ACTH deficiencies are less common, and diabetes insipidus is present in about 15%.

Symptoms leading to the diagnosis are frequently neurologic and due to the mass effect of the expanding tumor. Symptoms of increased intracranial pressure such as headache and vomiting are present in about 40% of patients; decreased visual acuity or visual field defects are the presenting symptoms in another 35%. MRI confirms the tumor in virtually all patients; in 95%, the tumor is suprasellar.

In adults, craniopharyngiomas have similar presentations; that is, the diagnosis is usually reached as a result of investigation of complaints of headache or visual loss. However, endocrine manifestations—especially hypogonadism, diabetes insipidus, or other deficiencies of anterior pituitary hormones—usually precede these late manifestations. MRI readily demonstrates the tumors, which in adults are almost always both intrasellar and suprasellar. The appearance is typically of a heterogeneous, cystic mass that enhances with contrast. Calcifications may also be present.

B. Other tumors  Other hypothalamic or pineal tumors and primary central nervous system tumors involving the hypothalamus have variable presentations in both children and adults. Thus, presentation is with headache, visual loss, symptoms of increased intracranial pressure, growth failure, various degrees of
hypopituitarism, or diabetes insipidus. Endocrine deficiencies usually precede neurologic manifestations. Hypothalamic tumors in childhood may present with precocious puberty.

C. Other manifestations of hypothalamic dysfunction

Lesions in the hypothalamus can cause many other abnormalities, including disorders of consciousness, behavior, thirst, appetite, and temperature regulation. These abnormalities are usually accompanied by hypopituitarism and diabetes insipidus.

Somnolence can occur with hypothalamic lesions, as can a variety of changes in emotional behavior. Decreased or absent thirst may occur and predispose these patients to dehydration. When diminished thirst accompanies diabetes insipidus, fluid balance is difficult to control. Hypothalamic dysfunction may also cause increased thirst, leading to polydipsia and polyuria that may mimic diabetes insipidus. Obesity is common in patients with hypothalamic tumors because of hyperphagia, decreased satiety, and decreased activity. Frohlich syndrome, or adiposogenital dystrophy, is characterized by obesity, growth retardation, and delayed development of sexual organs. Anorexia and weight loss are unusual manifestations of these tumors.

Temperature regulation can also be disordered in these patients. Sustained, or less commonly, paroxysmal hyperthermia can occur following acute injury due to trauma, hemorrhage, or craniotomy. This problem usually lasts less than 2 weeks. Poikilothermia, the inability to adjust to changes in ambient temperature, can occur in patients with bilateral hypothalamic lesions. These patients most frequently exhibit hyperthermia but can also develop hypothermia during hot weather. A few patients manifest sustained hypothermia due to anterior hypothalamic lesions.

Diagnosis

Patients with suspected hypothalamic tumors should undergo MRI to determine the extent and nature of the tumor. Complete assessment of anterior pituitary function is necessary in these patients, because deficiencies are present in the great majority (see section on Hypopituitarism below), and the evaluation will establish the requirements for replacement therapy. PRL levels should also be determined, because most hypothalamic lesions cause hyperprolactinemia either by hypothalamic injury or by damage to the pituitary stalk.

Treatment

Treatment depends on the type of tumor. Because complete resection of craniopharyngioma is usually not feasible, this tumor is best managed by limited neurosurgical removal of accessible tumor and decompression of cysts, followed by radiotherapy. Patients treated by this method have a recurrence rate of approximately 20%; with surgery alone, the recurrence rate approximates 80%.

Other hypothalamic tumors are usually not completely resectable; however, biopsy is indicated to arrive at a histologic diagnosis.

HYPOPITUITARISM

Hypopituitarism is manifested by diminished or absent secretion of one or more pituitary hormones. The development of signs and symptoms is often slow and insidious, depending on the rate of onset and the magnitude of hypothalamic-pituitary damage—factors that are influenced by the underlying pathogenesis. Hypopituitarism is either a primary event caused by destruction of the anterior pituitary gland or a secondary phenomenon resulting from deficiency of hypothalamic stimulatory factors normally acting on the pituitary. In general, acquired loss of anterior pituitary function follows the sequence of GH, LH/FSH, TSH, ACTH, and PRL. Treatment and prognosis depend on the extent of hypopituitarism, the underlying cause, and the location of the lesion in the hypothalamic-pituitary axis.

Etiology

The etiologic considerations in hypopituitarism are diverse. As shown below, a helpful mnemonic device is the phrase "nine Is": invasive, infarction, infiltrative, injury, immunologic, iatrogenic, infectious, idiopathic, and isolated. Most of these lesions may cause pituitary or hypothalamic failure (or both). Establishing the precise cause of hypopituitarism is helpful in determining treatment and prognosis.

A. Invasive

Space-occupying lesions cause hypopituitarism by destroying the pituitary gland or hypothalamic nuclei or by disrupting the hypothalamic-hypophysial portal venous system. Large pituitary adenomas cause hypopituitarism by these mechanisms, and pituitary function may improve after their removal. Small pituitary tumors—microadenomas (<10 mm in diameter)—characteristically seen in the hypersecreatory states (excess PRL, GH, ACTH) do not directly cause pituitary insufficiency. Craniopharyngioma, the most common tumor of the hypothalamic-pituitary region in children, frequently impairs pituitary function by its compressive effects. Primary central nervous system tumors, including meningioma, chordoma, optic glioma, epidermoid tumors, and dermoid tumors, may decrease hypothalamic-pituitary secretion by their mass effects. Metastatic lesions to this area are common (especially breast carcinoma) but rarely result in clinically obvious hypopituitarism. Anatomic malformations such as basal encephalocele and parasellar aneurysms cause hypopituitarism and may enlarge the sella turcica and mimic pituitary tumors.

B. Infarction

Ischemic damage to the pituitary has long been recognized as a cause of hypopituitarism. In 1914, Simmonds reported pituitary necrosis in a woman with severe puerperal sepsis and in 1937 Sheehan published his classic description of its occurrence following postpartum hemorrhage and vascular collapse. The mechanism for the ischemia in such cases is not certain. Hypotension along with vasospasm of the hypophysial arteries is currently believed to compromise arterial perfusion of the anterior pituitary. During pregnancy, the pituitary gland may be more sensitive to hypoxemia because of its increased metabolic needs or
more susceptible to the prothrombotic effects of the hyperestrogenic state. Some investigators have noted that the hypopituitarism does not always correlate with the degree of hemorrhage but that there is good correlation between the pituitary lesion and severe disturbances of the clotting mechanism (as in patients with placenta previa). Ischemic pituitary necrosis has also been reported to occur with greater frequency in patients with diabetes mellitus.

The extent of pituitary damage determines the rapidity of onset as well as the magnitude of pituitary hypofunction. The gland has a great secretory reserve, and more than 75% must be destroyed before clinical manifestations are evident. The initial clinical feature in postpartum necrosis may be failure to lactate after parturition; failure to resume normal menstrual periods is another clue to the diagnosis. However, the clinical features of hypopituitarism are often subtle, and years may pass before pituitary insufficiency is recognized following an ischemic insult.

Spontaneous hemorrhagic infarction of a pituitary tumor (pituitary apoplexy) frequently results in partial or total pituitary insufficiency. Pituitary apoplexy is often a fulminating clinical syndrome manifested by severe headache, visual impairment, ophthalmoplegias, meningismus, and an altered level of consciousness. Pituitary apoplexy is usually associated with a pituitary tumor; it may also be related to diabetes mellitus, radiotherapy, or open heart surgery. Acute pituitary failure with hypotension may result, and rapid mental deterioration, coma, and death may ensue. Emergency treatment with corticosteroids (see Chapter 24) and transsphenoidal decompression of the intrasellar contents may be lifesaving and may prevent permanent visual loss. Most patients who have survived pituitary apoplexy have developed multiple adenohypophysial deficits, but infarction of the tumor in some patients may cure the hypersecretory pituitary adenoma and its accompanying endocrinopathy. Pituitary infarction may also be a subclinical event (silent pituitary apoplexy), resulting in improvement of pituitary hormone hypersecretion without impairing the secretion of other anterior pituitary hormones.

C. Infiltrative  
Hypopituitarism may be the initial clinical manifestation of infiltrative disease processes such as sarcoidosis, hemochromatosis, and Langerhan histiocytosis.

1. Sarcoidosis—The most common intracranial sites of involvement of sarcoidosis are the hypothalamus and pituitary gland. At one time, the most common endocrine abnormality in patients with sarcoidosis was thought to be diabetes insipidus; however, many of these patients actually have centrally mediated disorders of thirst that results in polydipsia and polyuria, which in some cases explains the abnormal water metabolism. Deficiencies of multiple anterior pituitary hormones have been well documented in sarcoidosis and are usually secondary to hypothalamic insufficiency. Granulomatous involvement of the hypothalamic-pituitary unit is occasionally extensive, resulting in visual impairment, and therefore, may simulate the clinical presentation of a pituitary or hypothalamic tumor.

2. Hemochromatosis—Hypopituitarism, particularly hypogonadotropic hypogonadism, is a prominent manifestation of iron storage disease—either primary (hereditary) hemochromatosis or transfusional iron overload. Hypogonadism occurs in most such cases and is often the initial clinical feature of iron excess; complete iron studies should be considered in any patient presenting with unexplained hypogonadotropic hypogonadism. If the diagnosis is established early, hypogonadism in hemochromatosis may be reversible with iron depletion. Pituitary deficiencies of TSH, GH, and ACTH may occur later in the course of the disease and are not reversible by iron chelation therapy.

3. Langerhan histiocytosis—In this disorder, the infiltration of multiple organs by well-differentiated histiocytes, is often heralded by the onset of diabetes insipidus and anterior pituitary hormone deficiencies. Most histologic and biochemical studies have indicated that this infiltrative process involves chiefly the hypothalamus, and hypopituitarism occurs only as a result of hypothalamic damage.

D. Injury  
Severe head trauma may cause anterior pituitary insufficiency and diabetes insipidus. Posttraumatic anterior hypopituitarism may be due to injury to the anterior pituitary, the pituitary stalk, or the hypophysial stalk. Pituitary insufficiency with growth retardation has been described in battered children who suffer closed head trauma with subdural hematoma.

E. Immunologic  
Lymphocytic hypophysitis resulting in anterior hypopituitarism is a distinct entity, occurring most often in women during pregnancy or in the postpartum period. It may present as a mass lesion of the sella turcica with visual field disturbances simulating pituitary adenoma. An autoimmune process with extensive infiltration of the gland by lymphocytes and plasma cells destroys the anterior pituitary cells. These morphologic features are similar to those of other autoimmune endocrinopathies (eg, thyroiditis, adrenalitis, and oophoritis). About 50% of patients with lymphocytic hypophysitis have other endocrine autoimmune diseases, and circulating pituitary autoantibodies have been found in several cases. It is presently uncertain how this disorder should be diagnosed and treated. It must be considered in the differential diagnosis of women with pituitary gland enlargement and hypopituitarism during pregnancy or the postpartum period.

Lymphocytic hypophysitis may result in isolated hormone deficiencies (especially ACTH or prolactin). Consequently, women with this type of hypopituitarism may continue to menstruate while suffering from secondary hypothyroidism or hypoadrenalism.

F. Iatrogenic  
Both surgical and radiation therapy to the pituitary gland may compromise its function. The anterior pituitary is quite resilient during transphenoidal microsurgery, and despite extensive manipulation during the search for microadenomas, anterior pituitary function is usually preserved. The dose of conventional radiation therapy presently employed to treat pituitary tumors is 4500 to 5000 cGy and results in a 50% to 60% incidence of hypothalamic and pituitary insufficiency. Such patients most frequently have modest hyperprolactinemia (PRL 30-100 ng/mL [1.3-4.5 nmol/L]) with GH and gonadotropin failure; TSH and ACTH deficiencies are less common. Heavy particle (proton beam) irradiation and gamma knife radiosurgery for
pituitary tumors results in a 15% to 55% incidence of hypopituitarism. Irradiation of tumors of the head and neck (nasopharyngeal cancer, brain tumors) and prophylactic cranial irradiation in leukemia may also cause hypopituitarism. The clinical onset of pituitary failure in such patients is usually insidious and results from both pituitary and hypothalamic injury.

G. Infectious Although many infectious diseases, including tuberculosis, syphilis, and mycotic infections, have been implicated as causative agents in pituitary hypofunction, antimicrobial drugs have now made them rare causes of hypopituitarism.

H. Idiopathic In some patients with hypopituitarism, no underlying cause is found. These may be isolated (see discussion later) or multiple deficiencies. Familial forms of hypopituitarism characterized by a small, normal, or enlarged sella turcica have been described. Both autosomal recessive and X-linked recessive inheritance patterns have been reported. A variety of complex congenital disorders may include deficiency of one or more pituitary hormones (eg, Prader-Willi syndrome, septo-optic dysplasia). Although progress has been made into understanding the genetic basis for some of these disorders, the pathogenesis remains uncertain.

I. Isolated Isolated (monotropic) deficiencies of the anterior pituitary hormones have been described. Some of these have been associated with mutations in the genes coding for the specific hormones. Others, particularly GH deficiency, have been associated with mutations in genes necessary for normal pituitary development as noted.

1. GH deficiency—In children, congenital monotropic GH deficiency may be sporadic or familial. These children, who may experience fasting hypoglycemia, have a gradual deceleration in growth velocity after 6 to 12 months of age. Diagnosis must be based on failure of GH responsiveness to provocative stimuli and the demonstration of normal responsiveness of other anterior pituitary hormones. Monotropic GH deficiency and growth retardation have also been observed in children suffering severe emotional deprivation. This disorder is reversed by placing the child in a supportive psychosocial milieu. A more detailed description of GH deficiency and growth failure is provided in Chapter 6.

2. ACTH deficiency—Monotropic ACTH deficiency is rare and is manifest by the signs and symptoms of adrenocortical insufficiency. LPH deficiency has also been noted in such patients. The defect in these patients may be due to primary failure of the corticotrophs to release ACTH and its related peptide hormones or may be secondary to impaired secretion of CRH by the hypothalamus. Most acquired cases of monotropic ACTH deficiency are presumed to be due to lymphocytic hypophysitis.

3. Gonadotropin deficiency—Isolated deficiency of gonadotropins is not uncommon. Kallmann syndrome initially described in the 1940s, is characterized by an isolated defect in GnRH secretion associated with maldevelopment of the olfactory center with hyposmia or anosmia; X-linked recessive, autosomal dominant, and autosomal recessive patterns of inheritance are seen. Sporadic cases occur, and other neurologic defects such as color blindness and nerve deafness have been reported. At least five Kallmann syndrome genes have been identified: KAL1, FGF1, FGF8, PROKR2, and PROK2. KAL1 mutations are responsible for the X-linked form of the disease and result in decreased expression of the extracellular glycoprotein anosmin-1. This in turn interferes with the normal embryonic development and migration of GnRH-secreting neurons. Because anterior pituitary function is otherwise intact, young men with isolated hypogonadotropic hypogonadism develop a eunuchoid appearance, since testosterone deficiency results in failure of epiphyseal closure (see Chapter 12). In women, a state of hypogonadotropic hypogonadism manifested by oligomenorrhea or amenorrhea often accompanies weight loss, emotional or physical stress, and athletic training. Anorexia nervosa and marked obesity both result in hypothalamic dysfunction and impaired gonadotropin secretion. Hypothalamic hypogonadism has also been observed in overtrained male athletes. Sickle cell anemia also causes hypogonadotropic hypogonadism due to hypothalamic dysfunction and results in delayed puberty. Clomiphene treatment has been effective in some cases. Isolated gonadotropin deficiency may also be seen in the polyglandular autoimmune syndrome; this deficiency is related to selective pituitary gonadotrope failure from autoimmune hypophysitis. Other chronic illnesses (eg, poorly controlled diabetes, malnutrition) may result in gonadotropin deficiency. Isolated deficiencies of both LH and FSH without an obvious cause such as those described have been reported but are rare. In addition, acquired partial gonadotropin deficiency may occur in middle-aged men. The cause and exact frequency of this disorder are unknown.

4. TSH deficiency—Monotropic TSH deficiency is rare and can be caused by a reduction in either hypothalamic TRH secretion (tertiary hypothyroidism) or pituitary TSH secretion (secondary hypothyroidism). These defects have been reported in association with gene mutations, empty sella, lymphocytic hypophysitis, and pituitary tumors. Some patients with chronic renal failure also appear to have impaired TSH secretion.

5. Prolactin deficiency—PRL deficiency almost always indicates severe intrinsic pituitary damage, and panhypopituitarism is usually present. However, isolated PRL deficiency has been reported after lymphocytic hypophysitis. Deficiencies of TSH and PRL have been noted in patients with pseudohypoparathyroidism.

6. Multiple hormone deficiencies isolated from other pituitary damage—Multiple hormone deficiencies result from abnormal pituitary development related to abnormalities of the genes encoding the transcription factors, PIT-1 (TSH, GH, and PRL) and PROP-1 (TSH, GH, PRL, LH, FSH, and ACTH).

Clinical Features

The onset of pituitary insufficiency is usually gradual, and the classic course of progressive hypopituitarism is an initial loss of GH and gonadotropin secretion followed by deficiencies of TSH, then ACTH, and finally PRL.

A. Symptoms Impairment of GH secretion causes decreased growth in children but may be clinically occult in adult patients. GH deficiency is associated with a decreased sense of well-being and a lower health-related quality of life. Decreased muscle mass
and increased fat mass can also be seen, although this may be difficult to discern in any given individual.

Hypogonadism, manifested by amenorrhea in women and decreased libido or erectile dysfunction in men, may antedate the clinical appearance of a hypothalamic-pituitary lesion. The only symptom of PRL deficiency is failure of postpartum lactation.

Hypothyroidism caused by TSH deficiency generally simulates the clinical changes observed in primary thyroid failure; however, it is usually less severe, and goiter is absent. Cold intolerance, dry skin, mental dullness, bradycardia, constipation, hoarseness, and anemia have all been observed; gross myxedematous changes are uncommon.

ACTH deficiency causes adrenocortical insufficiency, and its clinical features resemble those of primary adrenal failure. Weakness, nausea, vomiting, anorexia, weight loss, fever, and hypotension may occur. The zona glomerulosa and the renin-angiotensin system are usually intact; therefore, the dehydration and sodium depletion seen in Addison disease are uncommon. However, these patients are susceptible to hypotension, shock, and cardiovascular collapse, because glucocorticoids are necessary to maintain vascular reactivity, especially during stress. In addition, because of their gradual onset, the symptoms of secondary adrenal insufficiency may go undetected for prolonged periods, becoming manifest only during periods of stress. Hypoglycemia aggravated by GH deficiency may occur with fasting and has been the initial presenting feature of some patients with isolated ACTH deficiency. In contrast to the hyperpigmentation that occurs during states of ACTH excess (Addison disease, Nelson syndrome), depigmentation and diminished tanning have been described as a result of ACTH insufficiency. In addition, lack of ACTH-stimulated adrenal androgen secretion will cause a decrease in body hair if gonadotropin deficiency is also present.

B. Signs Abnormal findings on physical examination may be subtle and require careful observation. Patients with hypopituitarism are not cachectic. A photograph of a cachectic patient with “Simmonds syndrome” that appeared in some older textbooks of endocrinology caused confusion. That particular patient probably suffered from anorexia nervosa and was found to have a normal pituitary gland at postmortem examination.

Patients with pituitary failure are usually slightly overweight. The skin is fine, pale, and smooth, with fine wrinkling of the face. Body and pubic hair may be deficient or absent, and atrophy of the genitalia may occur. Postural hypotension, bradycardia, decreased muscle strength, and delayed deep tendon reflexes occur in more severe cases. Neuro-ophthalmologic abnormalities depend on the presence of a large intrasellar or parasellar lesion.

C. Laboratory and other findings These may include anemia (related to thyroid and androgen deficiency and chronic disease), hypoglycemia, hyponatremia (related to hypothryroidism and hypoadrenalism, which cause inappropriate water retention, not sodium loss), and low-voltage bradycardia on electrocardiographic testing. Hyperkalemia, which is common in primary adrenal failure, is not present. Adult GH deficiency is associated with decreased red blood cell mass, increased LDL cholesterol, and decreased bone mass.

Diagnosis

A. Assessment of target gland function (Figure 4–17) If endocrine hypofunction is suspected, pituitary hormone deficiencies must be distinguished from primary failure of the thyroid, adrenals, or gonads. Basal determinations of each anterior pituitary hormone are useful only if compared to target gland secretion. Baseline laboratory studies should include thyroid function tests (free T₄) and determination of serum testosterone secretion. Testosterone is a sensitive indicator of hypopituitarism in women as well as in men. In women, a substantial decrease in testosterone is commonly observed in pituitary failure related to hypofunction of the two endocrine glands responsible for its production—the ovary and the adrenal. Adrenocortical reserve should initially be evaluated by a rapid ACTH stimulation test.

B. Evaluation of prolactin Because hyperprolactinemia (discussed later), regardless of its cause, leads to gonadal dysfunction, serum PRL should be measured early in the evaluation of hypogonadism.

C. Differentiation of primary and secondary hypofunction Subnormal thyroid function as shown by appropriate tests, a low serum testosterone level, or an impaired cortisol response to the rapid ACTH stimulation test requires measurement of basal levels of specific pituitary hormones. In primary target gland hypofunction, such as autoimmune polyglandular syndromes types 1 and 2 (APS 1 and 2), TSH, LH, FSH, or ACTH will be elevated. Low or normal values for these pituitary hormones suggest hypothalamic-pituitary dysfunction.

D. Stimulation tests Provocative endocrine testing may then be employed to confirm the diagnosis and to assess the extent of hypofunction. At present, these tests are not required in most patients.

Treatment

A. ACTH Treatment of secondary adrenal insufficiency, like that of primary adrenal failure, must include glucocorticoid support (see Chapter 9). Hydrocortisone (15–25 mg/d orally) or prednisone (5–7.5 mg/d orally) in two or three divided doses provides adequate glucocorticoid replacement for most patients. The minimum effective dosage should be given in order to avoid iatrogenic hypercortisolism. Increased dosage is required during periods of stress such as illness, surgery, or trauma. Patients with only partial ACTH deficiency may need steroid treatment only during stress. A two- to threefold increase in steroid dosage during the stressful situation should be recommended, followed by gradual tapering as the stress resolves. Unlike primary adrenal insufficiency, ACTH deficiency does not usually require mineralocorticoid therapy. Patients with adrenal insufficiency should wear...
medical alert bracelets so they may receive prompt treatment in case of emergency.

B. TSH The management of patients with secondary hypothyroidism must be based on clinical grounds and the circulating concentration of serum thyroxine (see Chapter 7). The treatment of secondary and tertiary hypothyroidism is identical to that for primary thyroid failure. Full oral replacement dose of levothyroxine sodium is 1.6 μg/kg daily (0.1-0.15 mg/d is usually adequate). Response to therapy is monitored clinically and with measurement of serum free thyroxine levels, which should be maintained in the mid to upper range of normal. Measurement
of TSH levels is obviously of no value in the management of these patients.

**Caution:** Because thyroid hormone replacement in patients with hypopituitarism may aggravate even partial adrenal insufficiency, the adrenal hormone deficiency should be treated first.

### C. Gonadotropins

The object of treatment of secondary hypogonadism is to replace sex steroids and restore fertility (see Chapters 12 and 13).

1. **Estrogens and progesterone**—In premenopausal women, estrogen replacement is essential. Adequate estrogen treatment maintains secondary sex characteristics (e.g., vulvar and vaginal lubrication), prevents osteoporosis, and abolishes vasomotor symptoms, with an improvement in sense of well-being. Many estrogen preparations are available (e.g., oral estradiol, 1-2 mg daily; conjugated estrogens, 0.3-1.25 mg orally daily; or transdermal estradiol, 0.05-0.1 mg daily). Estrogens should be cycled with a progestin compound (e.g., medroxyprogesterone, 5-10 mg orally daily during the last 10 days of estrogen therapy each month) to induce withdrawal bleeding and prevent endometrial hyperplasia. Many oral contraceptive pill combinations are also clinically available.

2. **Ovulation induction**—Ovulation can often be restored in women with hypothalamic-pituitary dysfunction (see Chapter 13). In patients with gonadal failure of hypothalamic origin, clomiphene citrate may cause a surge of gonadotropin secretion resulting in ovulation. Pulsatile subcutaneous injections of GnRH with an infusion pump can also be used to induce ovulation and fertility in women with hypothalamic dysfunction. Combined treatment with FSH (human menopausal gonadotropins; menotropins) and LH (chorionic gonadotropin) can be utilized to provoke ovulation in women with intrinsic pituitary failure. This form of therapy is expensive, and multiple births are a risk (see Chapter 13).

3. **Androgens in women**—Because of a deficiency of both ovarian and adrenal androgens, some women with hypopituitarism have diminished libido despite adequate estrogen therapy. Although experience is limited, small doses of long-acting androgens (testosterone enanthate, 25-50 mg intramuscularly every 4-8 weeks) may be helpful in restoring sexual activity without causing hirsutism. In addition, some reports have suggested that oral dehydroepiandrosterone (DHEA) in doses of 25 to 50 mg/d may reverse plasma testosterone levels to normal. A transdermal delivery system is being evaluated for use in women, but efficacy appears to be modest and the long-term safety is unknown.

4. **Androgens in men**—The treatment of male hypogonadism is discussed in Chapter 12. Testosterone gels (available in packets in doses of 2.5, 5, or 10 g, or from a metered-dose pump in 1.25 g increments) and testosterone patches (in doses of 2.5 or 5 mg) are applied daily. A transbuccal formulation is administered at a dose of 30 mg twice daily. Other therapeutic preparations include intramuscular testosterone enanthate or cypionate in doses of 100 mg every week or 200 mg every 2 weeks. Testosterone undecanoate is an intramuscular preparation available in several countries that can be given every 3 months. Oral testosterone preparations available in the United States are rarely used out of concern for hepatic side effects.

5. **Spermatogenesis**—Spermatogenesis can be achieved in many patients with the combined use of hCG and recombinant FSH. If pituitary insufficiency is of recent onset, therapy with hCG alone may restore both fertility and adequate gonadal steroid production. Pulsatile GnRH infusion pumps have also been used to restore fertility in male patients with secondary hypogonadism.

### D. Growth hormone (also see chapter 6)

Human GH (hGH) produced by recombinant DNA technology is available for use in children with hypopituitarism and for adults with GH deficiency and known pituitary disease. Some studies indicate improvement in body composition, bone density, psychologic well-being, and functional status with GH therapy. However, the long-term benefits and risks remain to be established. In adults, GH is usually administered subcutaneously, once per day in a dosage of 2 to 5 μg/kg. Monitoring of effectiveness is accomplished by measurement of IGF-I, and the dosage of GH is adjusted accordingly (up to about 10 μg/kg/d). Side effects (e.g., edema, paresthesias, arrhythmias, glucose intolerance, diabetes) should be assessed. Contraindications to GH therapy include the presence of diabetic retinopathy, active malignancy, intracranial hypertension, or airway obstruction in individuals with Prader-Willi syndrome.

### PITUITARY ADENOMAS

Advances in endocrinologic and neuroradiologic research in recent years have allowed earlier recognition and more successful therapy of pituitary adenomas. Prolactinomas are the most common type, accounting for about 60% of primary pituitary tumors; GH hypersecretion occurs in approximately 20%; and ACTH excess in 10%. Hypersecretion of TSH, the gonadotropins, or alpha subunits is unusual. Nonfunctional tumors currently represent only 10% of all pituitary adenomas, and some of these may in fact be gonadotropin-secreting or alpha subunit-secreting adenomas. The differential diagnosis of nonpituitary sellar and parasellar masses is listed in Table 4–10.

Early clinical recognition of the endocrine effects of excessive pituitary secretion, especially the observation that PRL excess causes secondary hypogonadism, has led to early diagnosis of pituitary tumors before the appearance of late manifestations such as sellar enlargement, panhypopituitarism, and suprasellar extension with visual impairment.

Pituitary microadenomas are defined as intrasellar adenomas less than 1 cm in diameter that present with manifestations of hormonal excess without sellar enlargement or extrassellar extension. Panhypopituitarism does not occur, and such tumors can usually be treated successfully.

Pituitary macroadenomas are those larger than 1 cm in diameter and cause generalized sellar enlargement. Tumors 1 to 2 cm in diameter confined to the sella turcica can usually be successfully treated; however, larger tumors—especially those with suprasellar, sphenoid sinus, or lateral extensions—are much more difficult to manage. Panhypopituitarism and visual loss increase in frequency with tumor size and suprasellar extension.

Insights into the pathogenesis and biologic behavior of pituitary tumors have been gained from studies of pituitary tumors.

clonality and somatic mutations. Analyses of allelic X inactivation of specific genes has shown that most pituitary adenomas are monoclonal, a finding most consistent with a somatic mutation model of tumorigenesis; polyclonality of tumors would be expected if tonic stimulation by hypothalamic-releasing factors were the mechanism underlying neoplastic transformation. In fact, transgenic animals expressing GHRH have exhibited pituitary hyperplasia but not pituitary adenomas. One somatic mutation has been found in 30% to 40% of GH-secreting tumors (but not in leukocytes from the same patients). Point mutations in the alpha subunit of the GTP-binding protein responsible for activation of adenylyl cyclase result in constitutive stimulation of pituitary cell growth and function. In studies of anterior pituitary cell ontogeny, PIT-1 has been identified as a transcription factor important in pituitary differentiation. The restriction of its expression to somatotrophs, lactotrophs, and thyrotrophs may account for the distinct hormonal expression seen in some tumors. A host of other candidate genes have been described, including the pituitary tumor transforming gene (PTTG). Overexpression of this gene has been found in all pituitary tumor types and may promote tumorigenesis through cell cycle disruption, stimulation of fibroblast growth factor secretion, and abnormal chromatin separation. Several genetic syndromes are associated with pituitary tumors including multiple endocrine neoplasia type 1, McCune-Albright syndrome, Carney syndrome, and familial acromegaly.

Treatment
Pituitary adenomas are treated with surgery, irradiation, or drugs to suppress hypersecretion by the adenoma or its growth. The aims of therapy are to correct hypersecretion of anterior pituitary hormones, to preserve normal secretion of other anterior pituitary hormones, and to remove or suppress the adenoma itself. These objectives are currently achievable in most patients with pituitary microadenomas; however, in the case of larger tumors, multiple therapies are frequently required and may be less successful.

A. Surgical treatment The transsphenoidal microsurgical approach to the sella turcica, now done endoscopically in most centers, is the procedure of choice; transfrontal craniotomy is required only in the rare patient with massive suprasellar extension of the adenoma. In the transsphenoidal procedure, the surgeon approaches the pituitary from the nasal cavity through the sphenoid sinus, removes the anterior-inferior sellar floor, and incises the dura. The adenoma is selectively removed; normal pituitary tissue is identified and preserved. Success rates approach 90% in patients with microadenomas. Major complications, including postoperative hemorrhage, cerebrospinal fluid leak, meningitis, and visual impairment, occur in less than 5% of patients and are most frequent in patients with large or massive tumors. Transient diabetes insipidus lasting a few days to 1 to 2 weeks occurs in approximately 15%; permanent diabetes insipidus is rare. A transient form of the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) with symptomatic hyponatremia occurs in 10% of patients within 5 to 14 days of transsphenoidal pituitary microsurgery. These abnormalities of water balance can occur within days of each other making medical management difficult. A triphasic response of diabetes insipidus, SIADH, and diabetes insipidus is occasionally encountered and thought to be due to early hypothalamic dysfunction, followed by release of ADH from the degenerating pituitary, and then depletion of ADH stores. Surgical hypopituitarism is rare in patients with microadenomas but approaches 5% to 10% in patients with larger tumors. The perioperative management of such patients should include glucocorticoid administration in stress doses (see Chapter 9) and postoperative assessment of daily weight, fluid balance, and electrolyte status to look for evidence of diabetes insipidus. Mild diabetes insipidus is managed by giving fluids orally; in more severe cases—urine output greater than 5 to 6 L/24 h—ADH therapy in the form of desmopressin, or DDAVP, can be administered intranasally, orally, subcutaneously, or parenterally (see Chapter 5). SIADH is managed by fluid restriction; however, in more severe cases, hypertonic saline may be required. ADH receptor antagonists (tolvaptan is given orally and conivaptan is administered intravenously) are also now available for use in some patients (see section on SIADH).

B. Radiotherapy Pituitary irradiation should be reserved for patients who have had incomplete resection of larger pituitary
adenomas and whose tumors are not amenable to, or have failed, medical therapy.

1. Conventional irradiation—Conventional irradiation using high-energy sources, in total doses of 4000 to 5000 cGy given in daily doses of 180 to 200 cGy, is most commonly employed. The response to radiation therapy is slow, and 5 to 10 years may be required to achieve the full effect (see section on Acromegaly). Treatment is ultimately successful in about 80% of patients with acromegaly but in only about 55% to 60% of patients with Cushing disease. The response rate in prolactinomas is not precisely known, but tumor progression is prevented in most patients. Morbidity during radiotherapy is minimal, although some patients experience malaise and nausea, and serous otitis media may occur. Hypopituitarism is common, and the incidence increases with time following radiotherapy—about 50% to 60% at 5 to 10 years. Rare late complications include damage to the optic nerves and chiasm, seizures, and radionecrosis of brain tissue. Recent studies from the United Kingdom have shown that conventional radiotherapy is a major risk factor for excess mortality in acromegaly.

2. Gamma knife radiosurgery—This form of radiotherapy utilizes stereotactic CT-guided cobalt-60 gamma radiation to deliver high radiation doses to a narrowly focused area. Remission rates have been reported in the range of 43% to 78%. An adequate distance of the pituitary tumor from the optic chiasm is needed to prevent radiation-induced damage. Repeat treatments put patients at higher risk of new visual or third, fourth, or sixth cranial nerve deficits.

3. Proton stereotactic radiotherapy—Experience with this modality is limited. In one study, 52% of patients with Cushing disease had clinical remission. A similar rate of new pituitary hormone deficiencies was seen, although no visual complications or brain injury was reported.

C. Medical treatment Medical management of pituitary adenomas became feasible with the availability of bromocriptine, a dopamine agonist that suppresses both PRL and tumor growth in patients with prolactinomas. Somatostatin analogs are useful in the therapy of acromegaly and some TSH-secreting adenomas. Specifics of the use of these and other medications are discussed later.

Posttreatment Follow-Up

Patients undergoing transsphenoidal microsurgery should be reevaluated 4 to 8 weeks postoperatively to document that complete removal of the adenoma and correction of endocrine hypersecretion has been achieved. Prolactinomas are assessed by basal PRL measurements, GH-secreting tumors by glucose suppression testing and IGF-I levels, and ACTH-secreting adenomas by measurement of urine-free cortisol and the response to low-dose dexamethasone suppression (see later). Other anterior pituitary hormones—TSH, ACTH, and LH/FSH—should also be assessed as described earlier in the section on endocrine evaluation. In patients with successful responses, yearly evaluation should be performed to watch for late recurrence; late hypopituitarism does not occur after microsurgery. MRI is not necessary in patients with normal postoperative pituitary function but should be utilized in patients with persistent or recurrent disease.

Follow-up of patients treated by pituitary irradiation is also essential, because the response to therapy may be delayed and the incidence of hypopituitarism increases with time. Yearly endocrinologic assessment of both the hypersecreted hormone and the other pituitary hormones is recommended.

1. PROLACTINOMAS

PRL hypersecretion is the most common endocrine abnormality due to hypothalamic-pituitary disorders, and PRL is the hormone most commonly secreted in excess by pituitary adenomas.

The understanding is that PRL hypersecretion causes not only galactorrhea but also gonadal dysfunction, and the use of PRL measurements in screening such patients has permitted recognition of these PRL-secreting tumors before the development of sellar enlargement, hypopituitarism, or visual impairment. Thus, plasma PRL should be measured in patients with galactorrhea, suspected hypothalamic-pituitary dysfunction, or sellar enlargement and in those with unexplained gonadal dysfunction, including amenorrhea, infertility, decreased libido, or impotence (Table 4-11).

Pathology

PRL-secreting pituitary adenomas arise most commonly from the lateral wings of the anterior pituitary, but with progression they fill the sella turcica and compress the normal anterior and posterior lobes. Tumor size varies greatly from microadenomas to large invasive tumors with extrasellar extension. Most patients have microadenomas (ie, tumors <1 cm in diameter at diagnosis).

Prolactinomas usually appear chromophobic on routine histologic study, reflecting the inadequacy of the techniques used. The cells are small and uniform, with round or oval nuclei and scanty cytoplasm, and secretory granules are usually not visible with routine stains. The stroma contains a diffuse capillary network.

Electron microscopic examination shows that prolactinoma cells characteristically contain secretory granules that usually range from 100 to 500 nm in diameter and are spherical. Larger granules (400-500 nm), which are irregular or crescent-shaped, are less commonly seen. The cells show evidence of secretory activity, with a large Golgi area, nucleolar enlargement, and a prominent endoplasmic reticulum. Immunocytochemical studies of these tumors have confirmed that the secretory granules indeed contain PRL.

Clinical Features

The clinical manifestations of PRL excess are the same regardless of the cause (see later). The classic features are galactorrhea and
ameenorrhea in women and decreased libido or impotence in men. Although the sex distribution of prolactinomas is approximately equal, microadenomas are much more common in women, presumably because of earlier recognition of the endocrine consequences of PRL excess.

**A. Galactorrhea**

Galactorrhea occurs in the majority of women with prolactinomas and is much less common in men. It is usually not spontaneous, or may be present only transiently or intermittently. The absence of galactorrhea despite markedly elevated PRL levels is probably due to concomitant deficiency of the gonadal hormones required to initiate lactation (see Chapter 16).

**B. Gonadal dysfunction**

1. **In women**—Amenorrhea, oligomenorrhea with anovulation, or infertility is present in approximately 90% of women with prolactinomas. These menstrual disorders usually present concurrently with galactorrhea if it is present but may either precede or follow it. The amenorrhea is usually secondary and may follow pregnancy or oral contraceptive use. Primary amenorrhea occurs in the minority of patients who have onset of hyperprolactinemia during adolescence. The necessity of measuring PRL in patients with unexplained primary or secondary amenorrhea is emphasized by several studies showing that hyperprolactinemia occurs in as many as 20% of patients with neither galactorrhea nor other manifestations of pituitary dysfunction. A number of these patients have been shown to have prolactinomas.

   Gonadal dysfunction in these women is due to interference with the hypothalamic-pituitary-gonadal axis by the hyperprolactinemia and except in patients with large or invasive adenomas is not due to destruction of the gonadotropin-secreting cells. This has been documented by the return of menstrual function following reduction of PRL levels to normal by drug treatment or surgical removal of the tumor. Although basal gonadotropin levels are frequently within the normal range despite reduction of sex steroid levels in hyperprolactinemic patients, PRL inhibits both the normal pulsatile secretion of LH and FSH and the midcycle LH surge, resulting in anovulation. The positive feedback effect of estrogen on gonadotropin secretion is also inhibited; in fact, patients with hyperprolactinemia are usually estrogen deficient.

   Estrogen deficiency in women with prolactinomas may be accompanied by decreased vaginal lubrication, other symptoms of estrogen deficiency, and low bone mass as assessed by bone densitometry. Other symptoms may include weight gain, fluid retention, and irritability. Hirsutism may also occur, accompanied by elevated plasma levels of dehydroepiandrosterone (DHEA) sulfate. Patients with hyperprolactinemia may also suffer from anxiety and depression. In small clinical trials, treatment with dopamine agonists has been shown to improve psychologic well-being in such patients.

2. **In men**—In men, PRL excess may also occasionally cause galactorrhea; however, the usual manifestations are those of hypogonadism. The initial symptom is decreased libido, which may be dismissed by both the patient and physician as due to psychosocial factors; thus, the recognition of prolactinomas in men is frequently delayed, and marked hyperprolactinemia (PRL >200 ng/mL [9.1 nmol/L]) and sellar enlargement are usual. Unfortunately, prolactinomas in men are often not diagnosed until late manifestations such as headache, visual impairment, or hypopituitarism appear; virtually all such patients have a history of sexual or gonadal dysfunction. Serum testosterone levels are low, and in the presence of normal or subnormal gonadotropin levels, PRL excess should be suspected as should other causes of hypothyroidic-pituitary-gonadal dysfunction (see section on Hypopituitarism). Impotence also occurs in hyperprolactinemic males. Its cause is unclear, because testosterone replacement may not reverse it if hyperprolactinemia is not corrected. Male infertility accompanied by reduction in sperm count is a less common initial complaint.

**C. Tumor progression**

In general, the growth of prolactinomas is slow; several studies have shown that most microadenomas do not change significantly in size, and macroadenomas tend to grow very slowly.

**Differential Diagnosis**

The many conditions associated with hyperprolactinemia are listed in Table 4-8. Pregnancy, hypothalamic-pituitary disorders, primary hypothyroidism, and drug ingestion are the most common causes.

Hypothalamic lesions frequently cause PRL hypersecretion by decreasing the secretion of dopamine that tonically inhibits PRL release; the lesions may be accompanied by panhypopituitarism. Similarly, traumatic or surgical section of the pituitary stalk leads to hyperprolactinemia and hypopituitarism. Nonfunctional pituitary macroadenomas frequently cause mild hyperprolactinemia by compression of the pituitary stalk or hypophalmus.

Pregnancy leads to a physiologic increase in PRL secretion; the levels increase as pregnancy continues and may reach 200 ng/mL (9.1 nmol/L) during the third trimester. Following delivery, basal PRL levels gradually fall to normal over several weeks but increase in response to breast feeding. Hyperprolactinemia persisting for 6 to 12 months or longer following delivery is an indication for evaluation. PRL levels are also high in normal neonates.

Several systemic disorders lead to hyperprolactinemia. Primary hypothyroidism is a common cause, and measurement of thyroid function, and especially TSH, should be part of the evaluation. In primary hypothyroidism, there is hyperplasia of both thyrotrrophs and lactotrophs, presumably due to TRH hypersecretion. This may result in significant pituitary gland enlargement, which may be mistaken for a PRL-secreting pituitary tumor. The PRL response to TRH is usually exaggerated in these patients. PRL may also be increased in liver disease, particularly in patients with severe cirrhosis, and in patients with chronic renal failure.

PRL excess and galactorrhea may also be caused by breast disease, nipple stimulation, disease or injury to the chest wall, and spinal cord lesions. These disorders increase PRL secretion by stimulation of afferent neural pathways. Artifactual elevations in PRL levels may be observed in the presence of anti-PRL antibodies or of macroprolactinemia. In the latter, a high-molecular-weight complex of PRL molecules maintains immunologic activity, but minimal or no bioactivity. Macroprolactinemia can be assessed with polyethylene glycol precipitation of serum samples.
The most common cause of hyperprolactinemia is drug ingestion, and a careful history of drug intake must be obtained. Elevated PRL levels, galactorrhea, and amenorrhea may occur following estrogen therapy or oral contraceptive use, but their persistence should suggest prolactinoma. Many other drugs also cause increased PRL secretion and elevated plasma levels (see Table 4-8). PRL levels are usually less than 200 ng/mL (9.1-13.7 nmoi/L), and the evaluation should focus on discontinuation of the drug or medication and reevaluation of the patient after several weeks. In patients in whom drug withdrawal is not feasible, neuroradiologic studies, if normal, usually exclude prolactinoma.

**Diagnosis**

**A. General evaluation** The evaluation of patients with galactorrhea or unexplained gonadal dysfunction with normal or low plasma gonadotropin levels should first include a history regarding menstrual status, pregnancy, fertility, sexual function, and symptoms of hypothyroidism or hypopituitarism. Current or previous use of medication, drugs, or estrogen therapy should be documented. Basal PRL levels, gonadotropins, thyroid function tests, and TSH levels should be established, as well as serum testosterone in men. Liver and kidney function should be assessed. A pregnancy test should be performed in women with amenorrhea.

Patients with galactorrhea but normal menses may not have hyperprolactinemia and usually do not have prolactinomas. If the PRL level is normal, they may be reassured and followed with sequential PRL measurements. Those with elevated levels require further evaluation as described later.

**B. Specific diagnosis** When other causes of hyperprolactinemia have been excluded, the most likely cause of persistent hyperprolactinemia is a prolactinoma, especially if there is associated hypogonadism. Because currently available suppression and stimulation tests do not distinguish PRL-secreting tumors from other causes of hyperprolactinemia, the diagnosis must be established by the assessment of both basal PRL levels and neuroradiologic studies. Patients with large tumors and marked hyperprolactinemia usually present little difficulty. With very rare exceptions, basal PRL levels greater than 200 to 300 ng/mL (9.1-13.7 nmoi/L) are virtually diagnostic of prolactinoma. In addition, because there is a general correlation between the PRL elevation and the size of the pituitary adenoma, these patients usually have sellar enlargement and obvious macroadenomas. Similarly, if the basal PRL level is between 100 and 200 ng/mL (4.5 and 9.1 nmol/L), the cause is usually prolactinoma. These patients may have either micro- or macroadenomas; however, with basal levels of PRL greater than 100 ng/mL (4.5 nmol/L), the PRL-secreting tumor is usually radiologically evident, and again the diagnosis is generally straightforward. Patients with mild to moderate hyperprolactinemia (20-100 ng/mL [0.9-4.5 nmol/L]) present the greatest difficulty in diagnosis, because both PRL-secreting microadenomas and the many other conditions causing hyperprolactinemia (see Table 4-8) cause PRL hypersecretion of this degree. In such patients, MRI frequently demonstrates a definite pituitary microadenoma. Scans showing only minor or equivocal abnormalities should be interpreted with caution, because of the high incidence of false-positive scans in the normal population (see Neuroradiologic Evaluation, above). Because the diagnosis cannot be either established or excluded in patients with normal or equivocal neuroradiologic studies, they require further evaluation or serial assessment (see later). Dilutions of prolactin samples can be performed in patients with modest prolactin elevation or macroadenomas to rule out interference from the high-dose hook effect; large quantities of antigen can impair antigen-antibody binding, resulting in erroneously low prolactin measurements in some immunoassays.

**Treatment**

Satisfactory control of PRL hypersecretion, cessation of galactorrhea, and return of normal gonadal function can be achieved in most patients with PRL-secreting microadenomas. In patients with hyperprolactinemia, ovulation should not be induced with ovulation induction agents, because of the risks of further tumor expansion, hypopituitarism, and visual impairment. Patients with persistent hyperprolactinemia and hypogonadism and normal neuroradiologic studies—that is, those in whom prolactinoma cannot be definitely established—may be managed by observation if hypogonadism is of short duration. However, in patients whose hypogonadism has persisted for more than 6 to 12 months, dopamine agonists should be used to suppress PRL secretion and restore normal gonadal function. In women with macroprolactinomas, replacement estrogen therapy should be initiated only after PRL hypersecretion has been controlled by dopamine agonist therapy since estrogen stimulates lactotroph hyperplasia and may increase tumor size. In this regard, periodic measurement of serum PRL should be performed in women with microadenomas on estrogen therapy who are not also receiving dopamine agonist therapy.

**A. Dopamine agonists** Bromocriptine became available in the United States more than 30 years ago and was the first effective medical therapy for pituitary adenomas; however, cabergoline is more potent, much longer acting, and better tolerated. Cabergoline has, therefore, become the dopamine agonist of choice in the therapy of prolactinomas.

1. **Bromocriptine**—Bromocriptine stimulates dopamine receptors and has effects at both the hypothalamic and pituitary levels. It is effective therapy for a PRL-secreting pituitary adenoma and directly inhibits PRL secretion by the tumor. Doses of 2.5 to 5 mg daily are often effective. However, at present, cabergoline is the therapy of choice.

2. **Cabergoline**—Cabergoline, a newer nonergot dopamine agonist, is administered once or twice a week and has a better side-effect profile than bromocriptine. It is as effective as
bromocriptine in reducing macroadenoma size and is more effective in reducing PRL levels. It has been used successfully in most patients previously intolerant or resistant to bromocriptine. Cabergoline should be started at a dosage of 0.25 mg twice per week and increased if necessary to 0.5 mg twice per week. Although several recent studies have demonstrated associations between cabergoline and cardiac valve disease in patients treated for Parkinson disease, clinically relevant valve disease in patients treated for prolactinoma appears to be rare, likely because doses used to manage symptoms of Parkinsonism are often 20 to 30 times higher and administered daily rather than twice weekly. The risk also appears to be related to the affinity of different dopamine agonists for valvular serotonin (5-HT2B) receptors. Until larger, prospective safety studies are available, some authorities recommend echocardiographic evaluation in patients who are expected to need long-term treatment, especially at high doses.

a. Microadenomas—Cabergoline is successful in about 90% of patients, and very few are intolerant or resistant. Correction of hyperprolactinemia allows recovery of normal gonadal function; ovulation and fertility are restored, so that mechanical contraception should be advised if pregnancy is not desired. Bromocriptine induces ovulation in most female patients who wish to become pregnant. In these patients with microadenomas, the risk of major expansion of adenoma during the pregnancy is less than 2%; however, both the patient and the physician must be aware of this potential complication. Current data do not indicate an increased risk of multiple pregnancy, abortion, or fetal malformations in pregnancies occurring in women taking dopamine agonists; however, patients should be instructed to discontinue these drugs at the first missed menstrual period and obtain a pregnancy test. Although no late toxicity has yet been reported other than the side effects noted above, questions about possible long-term risk are currently unanswered. Maternal hyperprolactinemia should not be harmful to the developing fetus; prolactin increases normally during pregnancy and does not appear to cross the placenta.

b. Macroadenomas—Dopamine agonists are effective in controlling hyperprolactinemia in patients with PRL-secreting macroadenomas even when basal PRL levels are markedly elevated. Dopamine agonists may be used either as initial therapy or to control residual hyperprolactinemia in patients unsuccessfully treated with surgery or radiotherapy. Dopamine agonists should not be used to induce ovulation and pregnancy in women with untreated macroadenomas, because the risk of tumor expansion and visual deficits in the later part of pregnancy is approximately 15% to 25%. These patients should first have tumor volume decreased with medical therapy or be treated with surgery prior to induction of ovulation.

Dopamine agonists normalize PRL secretion in about 60% to 70% of patients with macroadenomas and also reduce tumor size in about the same percentage of patients. Reduction of tumor size may occur within days to weeks following institution of therapy. The drugs have been used to restore vision in patients with major suprasellar extension and chiasmal compression.

c. Long-Term Remission—Current studies suggest that 30% to 40% of patients with micro- and macroadenomas will remain in long-term remission after withdrawal of cabergoline therapy of 2 to 3 years duration provided that they have normalization of PRL levels and tumor shrinkage. Larger macroadenomas (>2.0 cm) are likely to recur, and long-term dopamine agonist therapy should be continued in these patients.

B. Surgical treatment Transsphenoidal microsurgery is the surgical procedure of choice in patients with prolactinomas.

1. Microadenomas—In patients with microadenomas, remission, as measured by restitution of normal PRL levels, normal menorrhagia, and cessation of galactorrhea, is achieved in 85% to 90% of cases. Success is most likely in patients with basal PRL levels under 200 ng/mL (9.1 nmol/L) and duration of amenorrhea of less than 5 years. In these patients, the incidence of surgical complications is less than 2%, and hypopituitarism is a rare complication. Thus, in this group of patients with PRL-secreting microadenomas, PRL hypersecretion can be corrected, gonadal function restored, and secretion of TSH and ACTH preserved. Recurrence rates vary considerably in reported series. In our experience, approximately 85% of patients have had long-term remissions, and 15% have had recurrent hyperprolactinemia.

2. Macroadenomas—Transsphenoidal microsurgery is considerably less successful in restoring normal PRL secretion in patients with macroadenomas; many clinicians would treat these patients with dopamine agonists alone. The surgical outcome is directly related to tumor size and the basal PRL level. Thus, in patients with tumors 1 to 2 cm in diameter without extrasellar extension and with basal PRL levels less than 200 ng/mL (9.1 nmol/L), transsphenoidal surgery is successful in about 80% of cases. In patients with higher basal PRL levels and larger or invasive tumors, the success rate—defined as complete tumor resection and restoration of normal basal PRL secretion—is 25% to 50%. Although progressive visual loss or pituitary apoplexy is a clear indication for surgery, the great majority of these patients should be treated with dopamine agonists.

C. Radiotherapy Conventional radiation therapy is reserved for patients with PRL-secreting macroadenomas who have persistent hyperprolactinemia and who have not responded to attempts to control their pituitary adenomas with surgery or dopamine agonists. In this group of patients, radiotherapy with 4000 to 5000 cGy prevents further tumor expansion, although PRL levels usually do not fall into the normal range. Impairment of anterior pituitary function occurs in approximately 50% to 60% of patients. Experience with gamma knife radiosurgery in prolactinomas is limited and rates of remission and reduction in tumor volume have been reported with varying degrees of success.

Selection of Therapy for Prolactinomas

The selection of therapy for prolactinomas depends on the wishes of the patient, the patient's plans for pregnancy and tolerance of medical therapy, and the availability of a skilled neurosurgeon.

A. Microadenomas All patients should be treated to prevent the occasional tumor progression, loss of bone mass, and the other effects of prolonged hypogonadism. Medical therapy with
cabergoline effectively restores normal gonadal function and fertility, and pregnancy carries only a small risk of tumor expansion. Those patients who respond should be treated for 2 to 3 years, and then the drug should be withdrawn to determine if long-term remission will occur. Patients who have recurrence of hyperprolactinemia after cabergoline withdrawal may require surgical excision. Transsphenoidal adenectomy, either initially or after a trial of dopamine agonist therapy, carries little risk when performed by an experienced neurosurgeon and offers a high probability of long-term remission.

**B. Macroadenomas** Primary surgical therapy in these patients usually does not result in long-term remission, so medical therapy is the primary therapy of choice, particularly when the patient’s PRL levels are greater than 200 ng/mL (9.1 nmol/L) and the tumor is larger than 2 cm. Although transsphenoidal microsurgery rapidly decreases tumor size and decompresses the pituitary stalk, the optic chiasm, and the cavernous sinuses, there is usually residual tumor and hyperprolactinemia. Thus, these patients require additional therapy with dopamine agonists. Although tumor growth and PRL secretion can be controlled by medical therapy in most patients, therapeutic failure can result from drug intolerance, poor compliance, or resistance. Radiation therapy is reserved for postsurgical patients with residual adenomas who are not controlled with dopamine agonists.

## 2. ACROMEGALY AND GIGANTISM

GH-secreting pituitary adenomas are second in frequency to prolactinomas and cause the classic clinical syndromes of acromegaly and gigantism.

The characteristic clinical manifestations are the consequence of chronic GH hypersecretion, which in turn leads to excessive generation of IGF-I, the mediator of most of the effects of GH (see Chapter 6). Although overgrowth of bone is the classic feature, GH excess causes a generalized systemic disorder with deleterious effects and an increased mortality rate, although deaths are rarely due to the space-occupying or destructive effects of pituitary adenoma per se.

Acromegaly and gigantism are virtually always secondary to a pituitary adenoma. Ectopic GHRH secretion has been identified as another cause of GH hypersecretion and acromegaly in a few patients with carcinoid or islet cell tumors. Reports of intrapituitary GHRH-secreting gangliocytomas in direct contiguity with GH-secreting somatotroph adenomas and a report of a GHRH-secreting hypothalamic hamartoma in a patient with acromegaly provide a link between ectopic and eutopic GHRH production. Ectopic secretion of GH per se is very rare but has been documented in a few lung tumors.

In adults, GH excess leads to acromegaly, the syndrome characterized by local overgrowth of bone, particularly of the skull and mandible. Linear growth does not occur, because of prior fusion of the epiphyses of long bones. In childhood and adolescence, the onset of chronic GH excess leads to gigantism. Most of these patients have associated hypogonadism, which delays epiphyseal closure and the combination of IGF-I excess and hypogonadism leads to a striking acceleration of linear growth. Most patients with gigantism also have features of acromegaly if GH hypersecretion persists through adolescence and into adulthood.

### Pathology

Pituitary adenomas causing acromegaly are usually more than 1 cm in diameter when the diagnosis is established. These tumors arise from the lateral wings of the anterior pituitary; less than 10% are diagnosed as microadenomas.

GH-secreting adenomas are of two histologic types: densely and sparsely granulated. However, there appears to be no difference in the degree of GH secretion or clinical manifestations in these patients. About 15% of GH-secreting tumors also contain lactotrophs, and these tumors thus hypersecrete both GH and PRL.

### Etiology and Pathogenesis

In most cases, excessive pituitary GH secretion is a primary pituitary disorder. A somatic mutation in the G, protein leading to excessive cAMP production has been identified in 40% of GH-secreting adenomas. Pituitary adenomas are present in virtually all patients and are usually greater than 1 cm in diameter; hyperplasia alone is rare, and nonadenomatous anterior pituitary tissue does not exhibit somatotroph hyperplasia when examined histologically. In addition, there is a return of normal GH levels and dynamic control of GH secretion following selective removal of the pituitary adenoma.

### Pathophysiology

In acromegaly, GH secretion is increased and its dynamic control is abnormal. Secretion remains episodic; however, the number, duration, and amplitude of secretory episodes are increased, and they occur randomly throughout the 24-hour period. The characteristic nocturnal surge is absent, and there are abnormal responses to suppression and stimulation. Thus, glucose suppressibility is lost (see Diagnosis, later), and GH stimulation by hypoglycemia is usually absent. TRH and GnRH may cause GH release, whereas these substances do not normally stimulate GH secretion. Dopamine and dopamine agonists such as bromocriptine and apomorphine, which normally stimulate GH secretion, paradoxically cause GH suppression in about 70% to 80% of patients with acromegaly.

Most of the deleterious effects of chronic GH hypersecretion are caused by its stimulation of excessive amounts of IGF-I (see Chapter 6), and plasma levels of this protein are increased in acromegaly. The growth-promoting effects of IGF-I (DNA, RNA, and protein synthesis) lead to the characteristic proliferation of bone, cartilage, and soft tissues and increase in size of other organs to produce the classic clinical manifestations of acromegaly. The insulin resistance and carbohydrate intolerance seen in acromegaly appear to be direct effects of GH and not due to IGF-I excess.
Clinical Features

The sex incidence of acromegaly is approximately equal; the mean age at diagnosis is approximately 40 years; and the duration of symptoms is usually 5 to 10 years before the diagnosis is established.

Acromegaly is a chronic disabling and disfiguring disorder with increased late morbidity and mortality if untreated. Although spontaneous remissions have been described, the course is slowly progressive in the great majority of cases.

A. Symptoms and signs Early manifestations (Table 4-12) include soft tissue proliferation, with enlargement of the hands and feet and coarsening of the facial features. This is usually accompanied by increased sweating, heat intolerance, oiliness of the skin, fatigue, and weight gain.

At diagnosis, most patients have classic manifestations, and acral and soft tissue changes are always present. Bone and cartilage changes affect chiefly the face and skull. These changes include thickening of the calvarium; increased size of the frontal sinuses, which leads to prominence of the supraorbital ridges; enlargement of the nose; and downward and forward growth of the mandible, which leads to prognathism and widely spaced teeth. Soft tissue growth also contributes to the facial appearance, with coarsening of the features and facial and infraorbital puffiness. The hands and feet are predominantly affected by soft tissue growth; they are large, thickened, and bulky, with blunt, spade-like fingers (Figure 4-18) and toes. A bulky, sweaty handshake frequently suggests the diagnosis, and there are increases in ring, glove, and shoe sizes. There is generalized thickening of the skin, with increased oiliness and sweating. Acne, sebaceous cysts, and fibromata mollusca (skin tags and papillomas) are common, as is acanthosis nigricans of the axillae and neck and hypertrichosis in women.

These bony and soft tissue changes are accompanied by systemic manifestations, which include hyperhidrosis, heat intolerance, lethargy, fatigue, and increased sleep requirement. Sleep apnea, both obstructive and central, is very common in patients with acromegaly. This has particular importance for the anesthesiologist who must take special precautions to protect the airway during surgery. Moderate weight gain usually occurs. Paresthesias, usually due to carpal tunnel compression, occur in 70%; sensorimotor neuropathies occur uncommonly. Bone and cartilage overgrowth leads to arthralgias and in longstanding cases to degenerative arthritis of the spine, hips, and knees. Photophobia of unknown cause occurs in about half of cases and is most troublesome in bright sunlight and during night driving.

GH excess leads to generalized visceromegaly, clinically evident as thyromegaly and enlargement of the salivary glands. Enlargement of other organs is usually not clinically detectable.

Hypertension occurs in about 25% of patients and acromegaly in about 15%. Cardiac enlargement may be secondary to hypertension, atherosclerotic disease, or, rarely, to acromegalic cardiomyopathy. Renal calculi occur in 11% secondary to the hypercalciuria induced by GH excess.

Other endocrine and metabolic abnormalities are common and may be due either to GH excess or to mechanical effects of the pituitary adenoma. Glucose intolerance and hyperinsulinism occur in 50% and 70% of patients, respectively, owing to GH-induced insulin resistance. Overt clinical diabetes occurs in a minority, and diabetic ketoacidosis is rare. Hypogonadism occurs in 60% of female and 46% of male patients and is of multifactorial origin; tumor growth and compression may impair pituitary gonadotropin secretion, and associated hyperprolactinemia (see later) or the PRL-like effect of excessive GH secretion may impair gonadotropin and gonad al function. In men, low total plasma testosterone levels may be due to GH suppression of sex hormone–binding globulin (SHBG) levels; in these cases, plasma-free testosterone levels may be normal, with normal gonadal function. With earlier diagnosis, hypothyroidism and hypoadrenalism due to destruction of the normal anterior pituitary are unusual and are present in only 13% and 4% of patients, respectively. Galactorrhea occurs in about 15% and is usually caused by hyperprolactinemia from a pituitary adenoma with a mixed cell population of somatotrophs and lactotrophs. Gynecomastia of unknown cause occurs in about 10% of men. Although acromegaly may be a component of multiple endocrine neoplasia (MEN) type 1 syndrome, it is distinctly unusual, and concomitant parathyroid hyperfunction or pancreatic islet cell tumors are rare.

*Percentage of patients in whom these features were present.

When GH hypersecretion is present for many years, late complications occur, including progressive cosmetic deformity and disabling degenerative arthritis. In addition, the mortality rate is increased; after age 45, the death rate in acromegaly from cardiovascular and cerebrovascular atherosclerosis, respiratory diseases, and colon cancer is two to four times that of the normal population. Death rates tend to be higher in patients with hypertension, cardiovascular disease, or clinical diabetes mellitus.

Space-occupying manifestations of the pituitary adenoma are also common in acromegaly (eg, 65% of patients have headache). Although visual impairment was usually present in older series, it now occurs in only 15% to 20%, because most patients are now diagnosed because of the manifestations of GH excess.

B. Laboratory findings In addition to elevations in IGF-I and GH, postprandial plasma glucose may be elevated, and serum insulin is increased in 70% of cases. Elevated serum phosphate (due to increased renal tubular resorption) and hypercalciuria appear to be due to direct effects of GH or IGF-I.

C. Imaging studies Plain films (Figure 4–19) show sellar enlargement in 90% of cases. Thickening of the calvarium, enlargement of the frontal and maxillary sinuses, and enlargement of the jaw can also be seen. Radiographs of the hand show increased soft tissue bulk, "arrowhead" tufting of the distal phalanges, increased width of intra-articular cartilages, and cystic changes of the carpal bones. Radiographs of the feet show similar changes,
and there is increased thickness of the heel pad (normal, <22 mm).

**Diagnosis**

Acromegaly is usually clinically obvious and can be readily confirmed by assessment of GH secretion; basal fasting GH levels (normal, 1-5 ng/mL [46-232 pmol/L]) are greater than 10 ng/mL (465 pmol/L) in more than 90% of patients and range from 5 ng/mL (232 pmol/L) to greater than 500 ng/mL (23,000 pmol/L), with a mean of approximately 50 ng/mL (2300 pmol/L). However, single measurements are not entirely reliable, because GH secretion is episodic in acromegaly and because other conditions may increase GH secretion (see discussed later).

**A. Glucose suppression** Suppression with oral glucose is the simplest and most specific dynamic test for acromegaly. In healthy subjects, oral administration of 100 g of glucose causes a reduction of the GH level to less than 1 ng/mL (47 pmol/L) at 60 minutes. In acromegaly, GH levels may decrease, increase, or show no change; however, they do not decrease to less than 1 ng/mL (47 pmol/L), and this lack of response establishes the diagnosis.

Supersensitive GH assays have been developed and are becoming commercially available. With these assays, normal individuals may suppress GH levels to less than 0.1 ng/mL. Thus, the criteria expressed above may need to be adjusted in the near future.

**B. IGF-I measurement** Measurement of IGF-I (see Chapter 6) is a useful means of establishing the diagnosis of GH hypersecretion. IGF-I results must be interpreted according to age- and sex-adjusted normative data. IGF-I levels directly reflect GH activity. IGF-I has a long half-life, so that IGF-I levels fluctuate much less than GH levels. IGF-I levels are elevated in virtually all patients with acromegaly (normal ranges vary widely in different laboratories, and some commercial assays are not reliable).

**C. Tumor localization** Radiographic localization of the pituitary adenoma causing acromegaly is usually straightforward (see Neuroradiologic Evaluation, above). In virtually all patients, tumor location and size can be shown by MRI; 90% have tumors greater than 1 cm in diameter that are readily visualized. In the rare patient with normal neuroradiologic studies, an extrapituitary ectopic source of GH or GHRH should be considered. If scans suggest diffuse pituitary enlargement or hyperplasia, ectopic GHRH should also be suspected.

**Differential Diagnosis**

**A. Other causes of GH or IGF-I hypersecretion** The presence of clinical features of GH excess, elevated GH and IGF-I secretion, and abnormal GH dynamics, together with the demonstration of a pituitary tumor by neuroradiologic studies, are diagnostic of acromegaly. However, other conditions associated with GH hypersecretion must be considered in the differential diagnosis. These include anxiety, exercise, acute illness, chronic renal failure, cirrhosis, starvation, protein-calorie malnutrition, anorexia nervosa, and type I (insulin-dependent) diabetes mellitus. Estrogen therapy may increase GH responsiveness to various stimuli. These conditions may be associated with abnormal GH suppressibility by glucose and by abnormal GH responsiveness to TRH; however, patients with these conditions do not have clinical manifestations of GH excess and are thus readily differentiated from patients with acromegaly. In addition, the conditions listed above do not lead to elevation of IGF-I concentrations. Use of testosterone or the contraceptive depot medroxyprogesterone acetate has been associated with modest elevations in IGF-I.

**B. Ectopic GH or GHRH secretion** These rare patients with acromegaly due to ectopic secretion of GH or GHRH have typical clinical manifestations of acromegaly. This may occur in lung carcinoma, carcinoid tumors, and pancreatic islet cell tumors. These syndromes should be suspected in patients with a known extrapituitary tumor who have GH excess or in those with clinical and biochemical features of acromegaly who have radiologic procedures that show normal pituitary glands or that suggest diffuse pituitary enlargement or hyperplasia.

**Treatment**

All patients with acromegaly should undergo therapy to halt progression of the disorder and to prevent late complications and excess mortality. The objectives of therapy are removal or destruction of the pituitary tumor, reversal of GH hypersecretion, and maintenance of normal anterior and posterior pituitary function. These objectives are currently attainable in most patients, especially those with smaller tumors and only moderate GH hypersecretion. In patients with large tumors who have marked GH hypersecretion, several therapies are usually required to achieve normal GH secretion.

The criteria for an adequate response to therapy continue to evolve. Recent reports described increased late mortality in patients with GH levels by radioimmunoassay greater than 2.5 ng/mL (116 pmol/L) after therapy. Therefore, current guidelines for remission are a fasting GH of 1 ng/mL (47 pmol/L) or less and a glucose-suppressed GH of 1 ng/mL (47 pmol/L) or less accompanied by a normal level of IGF-I.

The initial therapy of choice is transsphenoidal microsurgery because of its high success rate, rapid reduction of GH levels, the low incidence of postoperative hypopituitarism, and the low surgical morbidity rate. Patients with persisting GH hypersecretion after surgery should currently be treated medically with somatostatin analogs, dopamine agonists, or a GH receptor antagonist. Radiation therapy should be reserved for those patients with inadequate responses to surgery and medical therapy.

**A. Surgical treatment** Transsphenoidal selective adenoma removal is the procedure of choice; craniotomy is necessary in the rare patient in whom major suprasellar extension precludes the transsphenoidal approach. Successful reduction of GH levels is achieved in approximately 60% to 80% of patients. In those with small or moderate-sized tumors (<2 cm), success is achieved in more than 80%, whereas in those with larger tumors and basal..
GH levels greater than 50 ng/mL (2325 pmol/L)—and particularly in those with major extracellular extension of the adenoma—successful responses occur in only 30% to 60%. Recurrence rates in those with a successful initial response are low (about 5% of patients at our institution). Surgical complications (discussed earlier) occur in less than 2%.

**B. Medical treatment**  
Octreotide acetate, a somatostatin analog, was the first effective medical therapy for patients with acromegaly. However, the drug required high doses (100-500 μg) given subcutaneously three times daily. Its use in acromegaly has been superseded by sustained-release somatostatin analogs with activities lasting up to 1 month. Preparations include octreotide LAR and lanreotide acetate given by injection every 4 weeks. Octreotide LAR normalizes GH and IGF-I levels in 75% of patients when used at doses of 20 to 40 mg/mo; however, tumor reduction occurs in a much smaller percentage. These long-acting agents have become the therapy of choice for patients with residual GH hypersecretion following surgery. Side effects of this class of agents consist mainly of gastrointestinal symptoms and the development of gallstones. Impaired glucose tolerance has been reported in some studies. The dopamine agonist cabergoline normalizes IGF-I levels in about 30% of acromegalics when used at doses of 1 to 2 mg/wk. However, it has not been commonly used as sole therapy. When cabergoline is added to somatostatin analog therapy, the number of patients with normalization of GH and IGF-I levels is increased.

Pegvisomant, the latest medical therapy for acromegaly, is a GH receptor antagonist. In doses of 10 to 20 mg/d given by subcutaneous injection, it reduces IGF-I levels to normal in more than 90% of patients. Although there are concerns regarding the continued excess GH secretion and possible tumor progression, serious problems have not arisen to date. Pegvisomant is effective, but its use is limited by cost and the need for daily injection. Therefore, it is currently used mainly in those patients who have failed therapy with surgery and somatostatin analogs.

**C. Radiotherapy**  
Conventional supervoltage irradiation in doses of 4500 to 5000 cGy, although ultimately successful in 60% to 80% of patients, should not be used, because GH levels may not return to normal until 10 to 15 years after therapy. In one series, GH levels were under 10 ng/mL (460 pmol/L) in only 38% of patients at 2 years posttreatment; however, at 5 and 10 years, 73% and 81% had achieved such levels. The incidence of hypopituitarism is appreciable, and in this series hypothyroidism occurred in 19%, hypoadrenalism in 38%, and hypogonadism in approximately 50% to 60% of patients as a consequence of radiotherapy. Gamma knife radiosurgery has also been used for tumors confined to the sella. Current series, although limited, suggest remission rates of about 50% to 70% at 2 years following therapy.

**Response to Treatment**  
In patients with successful reduction in GH hypersecretion, there is cessation of bone overgrowth. In addition, these patients experience considerable clinical improvement, including reduction in soft tissue bulk of the extremities, decreased facial puffiness, increased energy, and cessation of hyperhidrosis, heat intolerance, and oily skin. Bony changes typically do not regress. Headache, carpal tunnel syndrome, arthralgias, sleep apnea, and photophobia are also reversible with successful therapy. Glucose intolerance and hyperinsulinemia as well as hypercalcemia are also reversed in most cases.

Recent studies have also shown that the excess mortality associated with acromegaly can be reversed if GH levels are normalized.

**Posttreatment Follow-Up**  
Posttreatment assessment includes evaluation of GH secretion, anterior pituitary function, and tumor size. Patients undergoing surgery should be seen 4 to 8 weeks after the operation for assessment of GH secretion and pituitary function. Those with persistent GH hypersecretion (>1 ng/dL [47 pmol/L]) should receive further therapy with somatostatin analogs. Patients with postoperative GH levels under 1 ng/mL (47 pmol/L) should have follow-up GH and IGF-I determinations at 6-month intervals for 2 years and yearly thereafter to rule out recurrences. Recurrent elevations in IGF-I should prompt a repeat MRI of the sella. Late hypopituitarism after surgery alone does not occur. GH replacement therapy in patients with history of acromegaly and hypopituitarism is controversial and further studies are needed.

**3. ACTH-SECRETING PITUITARY ADENOMAS: CUSHING DISEASE**  
In 1932, Harvey Cushing documented the presence of small basophilic pituitary adenomas in six of eight patients with clinical features of adrenocortical hyperfunction. Years later, ACTH hypersecretion was identified from such tumors and found to be the cause of bilateral adrenal hyperplasia. Pituitary ACTH hypersecretion (Cushing disease) is now recognized as the most common cause of spontaneous hypercortisolism (Cushing syndrome) and must be distinguished from the other forms of adrenocortical excess—ectopic ACTH syndrome and adrenal tumors (see Chapter 9).

**Pathology**  
ACTH-secreting pituitary tumors exist in virtually all patients with Cushing disease. These tumors are usually benign microadenomas under 10 mm in diameter; 50% are 5 mm or less in diameter, and microadenomas as small as 1 mm have been described. These tumors in Cushing disease are either basophilic or chromophobic adenomas and may be found anywhere within the anterior pituitary. Rarely, ACTH-secreting tumors are large, with invasive tendencies, and malignant tumors have rarely been reported.

Histologically, the tumors are composed of compact sheets of uniform, well-granulated cells (granule size, 200-700 nm by electron microscopy) with a sinusoidal arrangement and a high content of ACTH and its related peptides (β-LPH, β-endorphin). A zone of perinuclear hyalinization (Crooke changes) is frequently
observed as a result of exposure of the corticotroph cells to prolonged hypercortisolism. A specific ultrastructural finding in these adenomas is the deposition of bundles of perinuclear microfilaments that encircle the nucleus; these are the ultrastructural equivalent of Crooke hyaline changes seen on light microscopy. In contrast to the adenoma’s cells, ACTH content in the portion of the anterior pituitary not involved with the tumor is decreased.

Diffuse hyperplasia of anterior pituitary corticotrophs or adenomatous hyperplasia, presumed to result from hypersecretion of CRH, occurs rarely.

The adrenal glands in Cushing disease are enlarged, weighing 12 to 24 g (normal, 8-10 g). Microscopic examination shows a thickened cortex due to hyperplasia of both the zona reticularis and zona fasciculata; the zona glomerulosa is normal. In some cases, ACTH-secreting pituitary adenomas cause bilateral nodular hyperplasia; the adenomas show diffuse bilateral cortical hyperplasia and the presence of one or more nodules that vary from microscopic to several centimeters in diameter, with multiple small nodules being the most common.

Pathogenesis

The weight of current evidence is that Cushing disease is a primary pituitary disorder and that hypothalamic abnormalities are secondary to hypercortisolism. The endocrine abnormalities in Cushing disease are as follows: (1) hypersecretion of ACTH, with bilateral adrenocortical hyperplasia and hypercortisolism; (2) absent circadian periodicity of ACTH and cortisol secretion; (3) absent responsiveness of ACTH and cortisol to stress (hypoglycemia or surgery); (4) abnormal negative feedback of ACTH secretion by glucocorticoids; and (5) subnormal responsiveness of GH, TSH, and gonadotropins to stimulation.

Evidence that Cushing disease is a primary pituitary disorder is based on the high frequency of pituitary adenomas, the response to their removal, and the interpretation of hypothalamic abnormalities as being secondary to hypercortisolism. In addition, molecular studies have found that nearly all corticotroph adenomas are monoclonal. These findings suggest that ACTH hypersecretion arises from a spontaneously developing pituitary adenoma and that the resulting hypercortisolism suppresses the normal hypothalamic-pituitary axis and CRH release, thereby abolishing the hypothalamic regulation of circadian variability and stress responsiveness.

Analysis of the response to therapy by pituitary microsurgery sheds some light on the pathogenesis of Cushing disease. Selective removal of pituitary microadenomas by transsphenoidal microsurgery corrects ACTH hypersecretion and hypercortisolism in most patients. After selective removal of the pituitary adenoma, the following return to normal: the circadian rhythmicity of ACTH and cortisol, the responsiveness of the hypothalamic-pituitary axis to hypoglycemic stress, and the dexamethasone suppressibility of cortisol secretion.

Clinical Features

Cushing disease presents with the signs and symptoms of hypercortisolism and adrenal androgen excess (see Chapter 9). The onset of these features is usually insidious, developing over months or years. Obesity (with predominantly central fat distribution), hypertension, glucose intolerance, and gonadal dysfunction (amenorrhea or impotence) are common features. Other common manifestations include moon (rounded) facies, plethora, osteopenia, proximal muscle weakness, easy bruisability, psychologic disturbances, violaceous striae, hirsutism, acne, poor wound healing, and superficial fungal infections. Unlike patients with the classic form of ectopic ACTH syndrome, patients with Cushing disease rarely have hypokalemia, weight loss, anemia, or hyperpigmentation. Virilization, observed occasionally in patients with adrenal carcinoma, is unusual in Cushing disease. Clinical symptoms related to the ACTH-secreting primary tumor itself, such as headache or visual impairment, are rare because of the small size of these adenomas.

The usual age range is 20 to 40 years, but Cushing disease has been reported in infants and in patients over 70. There is a female: male ratio of approximately 8:1. In contrast, the ectopic ACTH syndrome occurs more commonly in men (male:female ratio of 3:1).

Diagnosis

The initial step in the diagnosis of an ACTH-secreting pituitary adenoma is the documentation of endogenous hypercortisolism, which is confirmed by increased urine-free cortisol secretion, abnormal cortisol suppressibility to low-dose dexamethasone, and/or abnormal late night salivary cortisol measurement. The differentiation of an ACTH-secreting pituitary tumor from other causes of hypercortisolism must be based on biochemical studies, including the measurement of basal plasma ACTH levels and central venous sampling, to detect a central to peripheral gradient of ACTH levels (see Chapter 9). The diagnosis and differential diagnosis of Cushing syndrome are presented in Chapter 9.

Treatment

Transsphenoidal microsurgery is the procedure of choice in Cushing disease. A variety of other therapies—operative, radiologic, pharmacologic—are discussed below.

A. Surgical treatment Selective transsphenoidal resection of ACTH-secreting pituitary adenomas is the initial treatment of choice. At operation, meticulous exploration of the intrasellar contents by an experienced neurosurgeon is required. The tumor, which is usually found within the anterior lobe tissue, is selectively removed, and normal gland is left intact.

In about 85% of patients with microadenomas, selective microsurgery is successful in correcting hypercortisolism. Surgical damage to anterior pituitary function is rare, but most patients develop transient secondary adrenocortical insufficiency requiring postoperative glucocorticoid support until the hypothalamic-pituitary-adrenal axis recovers, usually in 2 to 18 months. The role of total hypophysectomy is currently unclear, however; hemihypophysectomy based on central venous sampling lateralization is successful in only about 50% to 70% of patients.
By contrast, transsphenoidal surgery is successful in only 25% of the 10% to 15% of patients with Cushing disease with pituitary macroadenomas or in those with extracellular extension of tumor.

Transient diabetes insipidus occurs in about 10% of patients, but other surgical complications (eg, hemorrhage, cerebrospinal fluid rhinorrhea, infection, visual impairment, permanent diabetes insipidus) are rare. Hypopituitarism occurs only in patients who undergo total hypophysectomy.

Before the introduction of pituitary microsurgery, bilateral total adrenalectomy was the preferred treatment of Cushing disease and may still be employed in patients in whom other therapies are unsuccessful. Total adrenalectomy, which can now be performed laparoscopically, corrects hypercortisolism but produces permanent hypoadrenalinism, requiring lifelong glucocorticoid and mineralocorticoid therapy. The ACTH-secreting pituitary adenoma persists and may progress, causing hyperpigmentation and invasive complications (Nelson syndrome; see below). Persistent hypercortisolism may occasionally follow total adrenalectomy as ACTH hypersecretion stimulates adrenal remnants or congenital rests.

**B. Radiotherapy** Conventional radiotherapy of the pituitary is of benefit in patients who have persistent or recurrent disease following pituitary microsurgery. In these patients, reported remission rates are 55% to 70% at 1 to 3 years after radiotherapy.

Gamma knife radiosurgery achieves remission rates of 65% to 75%. However, as noted above, both forms of radiotherapy cause late loss of pituitary function in more than 50% of patients and visual deficits can occur with damage to the optic chiasm or cranial nerves.

**C. Medical treatment** Drugs that inhibit adrenal cortisol secretion are useful in Cushing disease, often as adjunctive therapy (see Chapter 9). No drug currently available successfully suppresses pituitary ACTH secretion.

Ketoconazole, an imidazole derivative, has been found to inhibit adrenal steroid biosynthesis. It inhibits the cytochrome P450 enzymes P450scC and P450c11. In daily doses of 600 to 1200 mg, ketoconazole has been effective in the management of Cushing syndrome. Hepatotoxicity is common, however, but may be transient. Metyrapone, which inhibits P450c11, and aminoglutethimide, which inhibits P450scC, have also been utilized to reduce cortisol hypersecretion. Metyrapone is only available directly through the manufacturer and aminoglutethimide is no longer manufactured in the United States.

The use of these drugs is accompanied by increased ACTH levels that may overcome the enzyme inhibition. In addition, they cause gastrointestinal side effects that may limit their effectiveness. More effective control of hypercortisolism with fewer side effects is obtained by combined use of these agents. Adequate data are not available on the long-term use of these drugs as the sole treatment of Cushing disease. Thus, ketoconazole and aminoglutethimide ordinarily are used while awaiting a response to therapy or in the preparation of patients for surgery.

The adrenolytic drug mitotane results in adrenal atrophy predominantly of the zonae fasciculata and reticularis. Remission of hypercortisolism is achieved in approximately 80% of patients with Cushing disease, but most relapse after therapy is discontinued. Mitotane therapy is limited by the delayed response, which may take weeks or months, and by the frequent side effects, including severe nausea, vomiting, diarrhea, somnolence, and skin rash.

The anesthesia induction agent etomidate inhibits P450c11. It must be given intravenously and is generally reserved for life-threatening cases of hypercortisolism resistant to conventional therapy or when oral medications are contraindicated.

Pharmacologic inhibition of ACTH secretion in Cushing disease has also been attempted with cyproheptadine, bromocriptine, and cabergoline. However, few patients have had successful responses, and the use of these agents is not recommended.

### 4. Nelson Syndrome

The clinical appearance of an ACTH-secreting pituitary adenoma following bilateral adrenalectomy as initial therapy for Cushing disease was first described by Nelson and coworkers in 1958. However, with the evolution of pituitary microsurgery as the initial therapy for Cushing disease, the Nelson syndrome is now a rare occurrence.

**Pathogenesis**

It now seems likely that Nelson syndrome represents the clinical progression of a preexisting adenoma after the restraint of hypercortisolism on ACTH secretion and tumor growth is removed. Thus, following adrenalectomy, the suppressive effect of cortisol is no longer present, ACTH secretion increases, and the pituitary adenoma may progress.

**Incidence**

Prior to the development of transsphenoidal surgery, when bilateral adrenalectomy was the initial therapy for Cushing disease, the incidence of Nelson syndrome ranged from 10% to 78% depending on what criteria were used for diagnosis (see Chapter 9). In one series, approximately 30% of patients adrenalectomized for Cushing disease developed classic Nelson syndrome with progressive hyperpigmentation and an obvious ACTH-secreting tumor; another 50% developed evidence of a microadenoma without marked progression; and about 20% never developed a progressive tumor. The reasons for these differences in clinical behavior are uncertain. Prophylactic pituitary radiotherapy is controversial. At present, when adrenalectomy is utilized only in those patients who fail pituitary microsurgery, the incidence of Nelson syndrome is less than 10%. Nevertheless, continued examination, including plasma ACTH levels and MRI, is required following bilateral adrenalectomy in patients with Cushing disease.

**Clinical Features**

The pituitary tumors in patients with classic Nelson syndrome can be among the most aggressive and rapidly growing of all pituitary
tumors. These patients present with hyperpigmentation and with manifestations of an expanding intrasellar mass lesion. Visual field defects, headache, cavernous sinus invasion with extraocular muscle palsies, and even malignant changes with local or distant metastases may occur. Pituitary apoplexy may also complicate the course of these tumors.

**Diagnosis**

Plasma ACTH levels are markedly elevated, usually over 1000 pg/mL (222 pmol/L) and often as high as 10,000 pg/mL (2220 pmol/L). MRI defines the extent of the tumor.

**Treatment**

Pituitary surgery by the transsphenoidal approach is the initial mode of treatment. Complete resection is usually not possible, because of the large size of these tumors. Conventional radiotherapy or gamma knife radiosurgery is employed postoperatively in patients with residual tumor or extrasellar extension.

**5. THYROTROPIN-SECRETING PITUITARY ADENOMAS**

TSH-secreting pituitary adenomas are rare tumors manifested as hyperthyroidism with goiter in the presence of elevated TSH. Patients with TSH-secreting tumors are often resistant to routine ablative thyroid therapy, requiring large, often multiple doses of $^{131}$I and several operations for control of thyrotoxicosis. Histologically, the tumors are chromophobe adenomas. They are often very large and cause visual impairment, which alerts the physician to a pituitary abnormality. Patients with these tumors do not have extrathyroidal systemic manifestations of Graves disease such as ophthalmopathy or dermopathy.

The diagnosis is based on findings of hyperthyroidism (elevated $T_3$ or $T_4$) with elevated serum TSH and alpha subunit, and neuroradiologic studies consistent with pituitary tumor. The differential diagnosis includes those patients with primary hypothyroidism (thyroid failure) that develops major hyperplasia of pituitary thyrotrophs and lactotrophs with sellar enlargement and occasional suprasellar extension. These patients can be identified by symptoms of hypothyroidism and low thyroid hormone levels. Thyroid hormone resistance may be more difficult to exclude as $T_4$ and $T_3$ levels can also be elevated. These patients, however, tend to be clinically euthyroid or hypothyroid, have a family history of thyroid hormone resistance, and generally do not present with sellar masses. Alpha subunit levels in these patients are usually not elevated.

Treatment should be directed initially at the adenoma via the transsphenoidal microururgical approach. However, additional therapy is usually required because of the large size of these adenomas.

Somatostatin analogs normalize TSH and $T_4$ levels in more than 70% of these patients when given in doses similar to those used for the treatment of acromegaly (see discussion earlier). Shrinkage of the tumor has been observed in about 40% of patients.

If tumor growth and TSH hypersecretion cannot be controlled by surgery and somatostatin analogs, the next step is pituitary irradiation. In addition, such patients may also require ablative therapy of the thyroid with either $^{131}$I or surgery to control their thyrotoxicosis.

**6. GONADOTROPIN-SECRETING PITUITARY ADENOMAS**

Although many pituitary adenomas synthesize gonadotropins (especially FSH) and their subunits, only a minority of these patients have elevated serum levels of FSH or LH. The majority of these tumors produce FSH and the alpha subunit, but tumors secreting both FSH and LH and a tumor secreting only LH have been described.

Gonadotropin-secreting pituitary adenomas are usually large chromophobe adenomas presenting with visual impairment. Most patients have hypogonadism and many have panhypopituitarism. Hormonal evaluation reveals elevated FSH in some patients accompanied by normal LH values. Basal levels of the alpha subunit may also be elevated. The presence of elevation of both FSH and LH should suggest primary hypogonadism. TRH stimulation leads to an increase in FSH secretion in 33% and an increase in LH-$eta$ in 66% of patients.

Therapy for gonadotropin-secreting adenomas has been directed at surgical removal. Because of their large size, adequate control of the tumor is difficult to achieve, and radiotherapy is usually required.

**7. ALPHA SUBUNIT-SECRETING PITUITARY ADENOMAS**

Excessive quantities of the alpha subunit of the glycoprotein pituitary hormones have been observed in association with the hypersecretion of many anterior pituitary hormones (TSH, GH, PRL, LH, FSH). However, pure alpha subunit hypersecretion has been identified in several patients with large invasive chromophobe adenomas and partial panhypopituitarism. Thus, the determination of the alpha subunit may be a useful marker in patients with presumed ”nonfunctioning” pituitary adenomas.

**8. NONFUNCTIONAL PITUITARY ADENOMAS**

“Nonfunctional” chromophobe adenomas once represented approximately 80% of all primary pituitary tumors; however, with clinical application of radioimmunoassay of anterior pituitary hormones, these tumors currently account for only about 10% of all pituitary adenomas. Thus, the great majority of these chromophobe adenomas have now been documented to be PRL-secreting; a smaller number secrete TSH or the gonadotropins.

Nonfunctional tumors are usually large when the diagnosis is established; headache and visual field defects are the usual presenting symptoms. However, endocrine manifestations are usually present for months to years before the diagnosis is made, with gonadotropin deficiency being the most common initial symptom.
Hypothyroidism and hypoadrenalism are also common, but the symptoms are subtle and may be missed.

Evaluation should include MRI and visual field testing; endocrine studies should include assessment of pituitary hormones and end-organ function to determine whether the adenoma is hyper-secreting or whether hormonal replacement is needed.

Because these tumors are generally large, both surgery and radiation therapy are usually required to prevent tumor progression or recurrence. In the absence of an endocrine index of tumor hypersecretion such as PRL excess, serial scans at yearly intervals are required to assess the response to therapy and to detect possible recurrence.

9. PITUITARY CARCINOMA

Pituitary carcinomas are extremely rare with fewer than 200 cases reported and defined by the distant metastases of a pituitary tumor. Most present as hormone-producing invasive macroadenomas with symptoms of mass effect. ACTH- and PRL-secreting tumors are most common. Metastases may present many years after diagnosis of the primary pituitary tumor. Survival rates are low and treatment may include additional surgery, radiotherapy, or chemotherapy.

Hypopituitarism and Other Hypothalamic-Pituitary Disorders

The Posterior Pituitary (Neurohypophysis)

Alan G. Robinson, MD

Vasopressin is the water-retaining hormone in all mammals and along with thirst is the primary regulator of osmolality. Pressure and volume are primarily regulated by changes in sodium balance mediated via renin, angiotensin, and aldosterone. The relative importance of vasopressin in regulation of osmolality versus regulation of pressure is reflected in the sensitivity to changes in osmolality versus changes in pressure/volume. Figure 5-1 illustrates the exquisite sensitivity of the osmostat to as little as a 1% change in osmolality. The regulation of vasopressin secretion by baroreceptors, however, involves many concurrent and synergistic sympathetic inputs, and decrease in volume or pressure of 10% to 15% is necessary before there is a measurable increase in plasma vasopressin.

The exquisite sensitivity in the relation of plasma osmolality to urine osmolality and urine volume is illustrated in Figure 5–2. While the normal range of plasma osmolality encompasses a range of approximately 10 mOsm/L, for any individual, the set-point is much more narrow. Small changes in osmolality produce a corresponding and linear change in plasma vasopressin. As illustrated in Figure 5–2, the normal range of plasma osmolality and plasma vasopressin produces a corresponding linear increase in urine osmolality from maximally dilute to maximally concentrated. This entire range from maximally dilute urine to maximally concentrated urine is accomplished by a narrow range of plasma vasopressin (from approximately 1 to 5 pg/mL). In unusual circumstances, plasma osmolality can rise higher than the normal range, and there is a corresponding increase in plasma vasopressin, but urine osmolality plateaus at the concentration of the renal inner medulla. When urine in the collecting duct is iso-osmotic with the urine in the inner medulla, maximum urine concentration is achieved. While the relation of plasma osmolality, plasma vasopressin, and urine osmolality are linear, the relation of these to urine volume is not linear. Rather, there is a logarithmic relationship between urine volume and urine osmolality. The total urine volume required to excrete a fixed quantity of urine osmoles changes relatively little until plasma vasopressin and urine concentration are nearly absent, then urine volume increases dramatically from a few liters per day to 18 to 20 L/d.

In the kidney, fluid is conserved by reabsorption of sodium and fluid in the distal and the proximal tubules and then reabsorption of water in the collecting duct. The counter-current multiplier system in the loop of Henle generates a high osmolality in the renal medulla. Vasopressin acts on principal cells in the collecting duct by V_2 receptors that stimulate the expression of intracellular water channels, aquaporin-2. When vasopressin binds to the V_2 receptor, adenylate cyclase is activated to produce cyclic AMP which stimulates both the production of new aquaporin-2 protein and the transfer of existing aquaporin-2 from the cytoplasm into the cell membrane. In the cell membrane, aquaporins act as water channels in the hydrophobic lipid bilayer so that water moves down the osmotic gradient from the collecting duct into the principal cell. Aquaporins-3 and -4 are involved in moving water out of the principal cell into the medullary extracellular fluid and from there into the circulation. In response to changes in vasopressin,
aquaporin-2 can be quickly shuttled in and out of the membrane producing rapid changes in water reabsorption and concentration of urine.

Volume/pressure regulation by vasopressin operates through $V_1$ receptors on blood vessels. These receptors cause contraction of smooth muscle to raise blood pressure and, secondarily reduce intravascular volume.

$V_2$ receptors also stimulate antihemophilic and von Willebrand factors. There is a third type receptor ($V_3$) on anterior pituitary cells that stimulates ACTH. These functions are not further considered in this chapter.

In most physiologic situations, changes in osmolality and volume are additive or synergistic in producing the appropriate physiologic response. For example, most cases of dehydration result in greater loss of water than solute. This produces an increase in plasma osmolality and a decrease in volume that act together to stimulate thirst and the secretion of vasopressin, which promotes retention of water. Similarly, excess ingestion of hypotonic fluid produces a decrease in plasma osmolality and an increase in plasma volume, both of which decrease plasma vasopressin and result in excretion of dilute urine. The normal regulation of osmolality is an elegant and simple system. Fluid ingested and water produced from metabolized food is in excess of true need. The retained water causes a small decrease in plasma osmolality with a small decrease in vasopressin and an excretion of the ingested fluid. If the water intake is not sufficient to supply body needs, plasma osmolality rises, producing concentrated urine to reduce fluid loss, and stimulates thirst that induces drinking to replenish body fluid.

**FIGURE 5-2** Normal physiologic relationship between plasma osmolality (pOsm; mOsm/kg H$_2$O), plasma vasopressin (PAVP; pg/mL), urine osmolality (uOsm; mOsm/kg H$_2$O), and urine volume (L/d).

(A) Changes in osmolality induce linear changes in vasopressin with a normal physiologic range of osmolality producing vasopressin levels of 0.5 to 5 pg/mL. (B) The physiologic range of vasopressin produces linear changes in urine osmolality. At vasopressin levels above 5 to 6 pg/mL, urine osmolality is at the maximum, determined by the osmolality of the inner medulla of the kidney. (C) Assuming a constant osmolar load, the relationship of volume to urine osmolality is logarithmic. The urine volume to excrete a given osmolar load at the urine osmolality in (B) is indicated in C. (Calculated from formulas in Robertson GL, Shelton RL, Athar S. The osmoregulation of vasopressin. Kidney Int. 1976;10:25-37.) (Copyright 2003, A.G. Robinson, University of California at Los Angeles.)
Fluid and electrolyte balance is not well regulated in elderly people. By age 80, total body water declines to as low as 50% of the level in normal young adults. Older subjects may have a decrease in glomerular filtration rate, and the collecting duct is less responsive to vasopressin. Numerous studies have indicated a decreased thirst with dehydration in elderly subjects, but also a lessened ability to excrete a water load. These age-related changes in body fluid and renal function predispose elderly people to both hypernatremia and hyponatremia. Also, elderly people are more likely to have comorbid diseases which enhance their tendency to become hyponatremic or hypernatremic. It is incumbent upon the physician to pay special attention to fluid balance in older people.

ANATOMY OF HORMONE SYNTHESIS AND RELEASE

The posterior pituitary (unlike the anterior pituitary) is not a gland but only the distal axonal terminals of the hypothalamic magnocellular neurons that make up the neurohypophysis. The cell bodies of these neurons are located in paired supraoptic nuclei and paired paraventricular nuclei of the hypothalamus. The paraventricular nuclei are located on each side of the third ventricle and axons from these neurons trace laterally and anteriorly to the location of the magnocellular neurons of the supraoptic nucleus just lateral to and above the optic chiasm. Axons of the supraoptic nucleus join axons of the paraventricular nucleus and course to the basal hypothalamus where they join the axons from the other side and course through the infundibular stalk to the axon terminals in the posterior pituitary.

The anatomic location of the physiologic regulators of osmotic and pressure/volume (baroreceptor) are located in vastly different sites. Osmoreceptors that control both thirst and osmotic regulation of vasopressin are located in the hypothalamus just anterior to the third ventricle, so the entire regulation of osmotic-induced changes in thirst and vasopressin secretion resides in a small and discrete area in the hypothalamus. Increases in osmolality stimulate the osmoreceptor to send a positive signal to stimulate thirst and to release vasopressin. For volume and pressure regulation, the receptors are located in the chest. There are high-pressure arterial baroreceptors in the carotid sinus and aortic arch and low-pressure volume receptors in the atria and pulmonary venous system. The pressure/volume receptor afferent signals are carried through cranial nerves 9 and 10 and synapse in the medulla before carrying their input to the magnocellular neurons. Both excitatory and inhibitory baroreceptor influences act on the magnocellular neurons, although some evidence indicates that a predominant mechanism involves the tonic inhibition of vasopressin secretion. A decrease in pressure/volume decreases the inhibition and stimulates release of vasopressin.

Vasopressin and oxytocin are nonapeptides that are synthesized in the cell bodies of the magnocellular neurons as part of a larger precursor peptide. Like other polypeptide hormones, the precursor proteins traverse the endoplasmic reticulum and the Golgi apparatus to be packaged in secretory granules. The neurosecretory granules then travel down the long axons through the stalk of the infundibulum to the posterior pituitary where the granules are stored. During transport, peptide enzymes (peptidases) cleave the prohormone into the hormone (vasopressin or oxytocin), a carrier protein (neurophysin), and (for vasopressin only) a glycopeptide. The synthesis of oxytocin and vasopressin is in separate neurons organized in clusters within the paraventriculat nuclei and supraoptic nuclei. This allows stimulation of individual neurons and independent release of individual hormones. The stimulus for secretion of vasopressin or oxytocin is by neurotransmitters acting on the appropriate magnocellular cell body. An action potential propagates along the axon, causing an influx of calcium at the axon terminal and release of the hormone content of neurosecretory granules into the perivascular space.

PATHOPHYSIOLOGY

All defined pathophysiology of the posterior pituitary is related to the function of vasopressin rather than oxytocin. Both decreased function of vasopressin and increased function of vasopressin manifest as abnormalities of water balance and depend upon action of vasopressin on the V_2 receptor of the kidney rather than the V_1 vascular receptors. The clinical presentation of low vasopressin function (diabetes insipidus) or excess vasopressin function (syndrome of inappropriate secretion of antidiuretic hormone, SIADH) is determined by the physiology of thirst. In humans thirst is well regulated to turn on when needed but not well regulated to turn off when not needed. When vasopressin is decreased or absent (diabetes insipidus), there is abnormal excretion of a large volume of dilute urine. This should cause hyperosmolality and an increase in serum sodium. However, as illustrated in Figure 5-2, an elevated plasma osmolality stimulates thirst, and a patient will drink a large volume of fluid to keep their sodium in the normal range. So, the clinical presentation of decreased vasopressin is one associated with polyuria and dilute urine together with polydipsia but with a normal serum sodium. Alternatively, when vasopressin is increased, there is abnormal concentration of urine and retention of water. The volume expansion by water dilutes serum sodium. If thirst were inhibited by hypo-osmolality as efficiently as thirst is stimulated by hyperosmolality, then the decrease in osmolality would produce a profound decrease in fluid intake, and a normal serum sodium would be maintained by the natural loss of fluid with perspiration, gastrointestinal fluid loss, and the urine output necessary to excrete ingested osmoles produced by food intake. Thirst, however, is not sufficiently inhibited, and the volume expansion not only dilutes serum sodium, but induces sodium excretion to reduce extracellular volume, which worsens the hyponatremia. So, the presentation of increased vasopressin is a chemical presentation of hyponatremia. There is concurrent concentrated urine with no change in thirst, modest volume expansion, hyponatremia, and natriuresis.

The other physiologic principles which determine some of the pathophysiology of abnormal secretion of vasopressin are: osmolality is regulated by changes in water balance, and volume is regulated by changes in sodium balance. When in conflict, volume will be preserved at the expense of osmolality. Thus, as described later,
if dehydration is produced by diabetes insipidus, sodium will be retained to protect volume, even if it aggravates hypernatremia. With SIADH when sodium is diluted and extracellular volume is expanded, natriuresis is initiated to decrease extracellular volume in spite of the need to retain sodium to correct the hypo-osmolality.

**DEFICIENTVASOPRESSIN: DIABETES INSIPIDUS**

Diabetes insipidus is literally the excretion of a large volume of urine (diabetes) that is hypotonic, dilute, and tasteless (insipid). Patients present with polyuria. Other causes of polyuria such as osmotic diuresis that occur in diabetes mellitus or intrinsic renal disease must be excluded. Frequent urination, without an increase in urine volume, suggests a urologic abnormality. Most adults will tolerate polyuria without complaint until it exceeds 3 to 4 L/d. If polyuria is shown to be dilute, the pathophysiologic mechanisms include: (1) primary ingestion of excess fluid, (2) abnormally decreased synthesis and secretion of vasopressin, (3) increased metabolism of vasopressin, and (4) decreased end-organ response to vasopressin.

**A. Ingestion of excess fluid and normal urine excretion—primary polydipsia** Primary polydipsia with ingestion of large quantities of water produces modest decreases in plasma osmolality, decreased secretion of vasopressin, and excretion of profound quantities of urine. As the volume of urine dilute fluid delivered to the collecting duct is approximately 18 L/d, this quantity of dilute urine can be excreted on a daily basis while maintaining serum osmolality in the normal range. Virtually any pathologic process in the hypothalamus that causes diabetes insipidus may rarely cause primary stimulation of the thirst center and primary polydipsia on an organic basis. Alternatively, primary polydipsia may occur as a behavioral abnormality in psychiatric patients in whom the excess water ingestion and urination may represent delusions tied to bodily cleansing. The large volume of urine passing through the collecting duct in these patients washes urea out of the inner medulla and reduces the inner medulla osmolality. Additionally, the chronic suppression of vasopressin release and lack of action of vasopressin on the renal collecting duct decreases the synthesis of aquaporins in the collecting duct cells, adding to the inability to concentrate the urine maximally. Each of these abnormalities returns to normal in several days to weeks after fluid ingestion is decreased to normal.

Primary polyuria may be induced in a normal person if excess fluid is administered parenterally. This occasionally occurs in postoperative cases that do not involve the pituitary. In many surgical procedures, the stress of the surgery is a stimulus to release of vasopressin, and administered fluids may be retained during the procedure. Postoperatively, the stress is released, and patients have a normal diuresis of the retained fluids. If this normal excretion of fluid is matched by increased fluids administered parenterally, the patient will continue to excrete large volumes of urine. If the administered fluid is normal saline, the patients will excrete a large volume of isotonic urine. If the volume administered is sufficiently great, the patients will be unable to dilute or concentrate their urine above or below an iso-osmotic level regardless of therapeutic agents. The large osmotic load delivered to the kidney may make the patient unresponsive even to administered desmopressin, producing an iatrogenic therapeutic dilemma.

**B. Abnormal synthesis and secretion of vasopressin** It is important to remember that the complaint of polyuria is based upon the volume of the urine not the urinary concentration. Therefore, as evident from Figure 5–2, considerable loss of ability to secrete vasopressin may occur before there is much loss of ability to concentrate the urine and even greater loss may occur before there is a noticeable increase in urine volume.

**1. GENETIC ABNORMALITIES OF NEUROHYPOPHYSEAL NEURONS**

**Familial hypothalamic diabetes insipidus.** Familial diabetes insipidus may be caused by an autosomal dominant mutation in the vasopressin gene. Usually the mutation involves DNA sequences in the neurophysin or signal peptide region of the precursor gene rather than the region encoding vasopressin itself. These mutations cause abnormal folding of the precursor protein which produces abnormal trafficking and accumulation of a mutant prohormone in the endoplasmic reticulum. This produces alterations in packaging of the prohormone into neurosecretory granules in the Golgi apparatus. By ill-defined mechanisms, this leads to cell death of the vasopressin-producing neurons. Because the pathology in these neurons develops over time, young children may have normal urine output, and diabetes insipidus is not expressed until late childhood. An autosomal dominant form of diabetes insipidus also occurs in association with diabetes mellitus, optic atrophy, and deafness (DIDMOAD), also known as Wolfram syndrome.

**2. PATHOLOGIC LESIONS OF NEUROHYPOPHYSEAL NEURONS**

**Solid tumors and hematologic malignancies.** The most common solid tumor to produce diabetes insipidus is craniopharyngioma. Suprasellar germinoma or pinealoma, which may be associated with precocious puberty, commonly produces diabetes insipidus. Metastatic disease to the pituitary hypothalamic area, for example, from breast or lung cancer, is more likely to produce diabetes insipidus than a deficiency of anterior pituitary hormones because the metastases lodge in the portal system of the hypothalamus where the vasopressin axons from the two sides join to form the pituitary stalk. Usually, there are widespread unidentified metastatic lesions elsewhere. Lymphoma or infiltration of the hypothalamus with leukemia are rare causes of diabetes insipidus.

**Trauma or surgery.** The anatomy of the neurohypophyseal system aids our understanding of this pathology. Hormone synthesis and regulation of release is high in the hypothalamus. Surgery or trauma at the level of the pituitary traumatizes only the axon terminals. Trauma of the axon terminals may disrupt the
vasopressin. If excess fluid is administered during this time, the section of the pituitary stalk. The three phases occur. The most common occurrence after surgery in pituitary surgery, lasts for 5 to 10 days, and then resolves. Laceration of the pituitary stalk rather than total section, it is possible that the last a few days without subsequent sequelae. With partial damage to the pituitary stalk rather than total section, it is possible that the second phase will occur without preceding or subsequent diabetes insipidus (ie, isolated second phase). In the isolated second phase, there are sufficient normally functioning vasopressinergic neurons to avoid diabetes insipidus in the first and third phase; however, the damaged axon terminals leak vasopressin that will, when coupled with excess fluid intake, produce SIADH and hyponatremia. Characteristically, hyponatremia occurs 5 to 10 days after pituitary surgery, lasts for 5 to 10 days, and then resolves. Late occurrence of diabetes insipidus, that is, third phase without a first or second phase, is distinctly uncommon.

Patients with diabetes insipidus due to surgery or trauma may eventually recover. The level of section determines the number of magnocellular neurons that are actually killed. The higher in the stalk and the closer the section to the perikaria, the greater the number of neurons that die. Vasopressin-producing neurons whose axons terminate in the hypothalamus and serve as secretagogues for ACTH in the anterior pituitary may persist and hypertrophy after surgery or trauma. Additionally, branching of axons may develop in the hypothalamus after surgery or trauma, and these branches may generate new connections of vasopressinergic neurons to blood vessels. By these mechanisms, sufficient vasopressin function may return (usually within 1 year) to have normal fluid balance and no symptoms of diabetes insipidus.

**Granulomatous disease.** Langerhans cell histiocytosis is the generic term that includes severe fulminant visceral Letterer-Siwe disease, multifocal Hand-Schuller-Christian disease, and benign eosinophilic granuloma. Diabetes insipidus is part of the central nervous system involvement in these disorders and is associated with other abnormalities of the head involving the cranial bones, oral mucosa, or brain. Systemic manifestations in the lung, bone, and skin may also be present. Wegener granulomatosis and sarcoidosis may also have diabetes insipidus as a part of the central nervous system pathology.

**Lymphocytic infundibulohypophysitis.** It is now recognized that many cases of diabetes insipidus, that were previously termed idiopathic and for which there was no specific etiology, are probably due to lymphocytic infiltration of the neurohypophysis on an autoimmune basis. X-rays may reveal enlargement of the pituitary stalk as evidence of the lymphocytic invasion. There may be resolution of the autoimmune response with time and the stalk may return to normal size, but the diabetes insipidus is usually permanent.

**Essential hypernatremia—Adipsic hypothalamic diabetes insipidus.** A rare variant of diabetes insipidus involves an absent osmoreceptor function, but an intact baroreceptor function. In this form of diabetes insipidus, patients do not sense thirst and, therefore, do not drink water. This results in an elevation of serum osmolality because the osmostat does not respond to the increased osmolality by releasing vasopressin or stimulating thirst. However, vasopressin synthesis and storage are normal as demonstrated by specific tests of baroreceptor function. Characteristically, these patients do not drink water and become sufficiently dehydrated that their baroreceptors stimulate vasopressin release, they then remain in a balanced situation with an elevated serum sodium level, relatively concentrated urine, and lack of thirst.

**Cerebral anoxia/brain death.** Brain dead patients who are on life support often have diabetes insipidus as part of the central nervous system pathology. It is standard practice to maintain electrolyte and water balance for maximal preservation of organs for transplantation.

### C. Increased metabolism of vasopressin in pregnancy to produce diabetes insipidus

During pregnancy, there is a true resetting of the osmostat at an osmolality approximately

---

**FIGURE 5–3** Illustration of the phases of urine output after section of the pituitary stalk. The triphasic response consists of: (1) diabetes insipidus due to axonal shock and lack of release of vasopressin; (2) an antidiuretic interphase when vasopressin leaks from the severed neurons; and (3) return of diabetes insipidus when the store of vasopressin in the posterior pituitary is depleted.
10 mOsm/kg H₂O less than the normal pOsm–PAVP relationship. So, in Figure 5-2 (A), the pOsm–PAVP would have the same linear relationship but would be shifted downward on the graph with the increase in PAVP beginning at pOsm of 270. Both increases and decreases in plasma vasopressin occur at the lower pOsm while the uOsm and U volume response to PAVP remains the same. There is a similar change in the regulation of plasma volume. In normal pregnancy, total body water is increased by 7 to 8 L as a result of profound vasodilatation. This expanded volume is also sensed as normal with vasopressin increasing and decreasing around this new volume. Relaxin, which is produced in pregnancy, is the mediator of these effects. In pregnancy the plasma volume is also sensed as normal with vasopressin increasing and decreases in plasma vasopressin occur at the lower 10 mOsm/kg less than the normal pOsm–PAVP relationship. From 20 to 40 weeks of gestation.

Because of the reset osmostat, a “normal” serum sodium during pregnancy may represent dehydration. There are two types of diabetes insipidus that are associated with pregnancy. In the first, the patient has a preexisting limitation of vasopressin function such as partial hypothalamic diabetes insipidus or mild nephrogenic diabetes insipidus. The ability to concentrate the urine may be limited but sufficient to maintain acceptable urine volume prepartum. During pregnancy, however, the metabolism of vasopressin is accelerated. With increased metabolism of vasopressin, these patients may then not have sufficient concentrating ability to maintain an acceptable urine volume (see vasopressin–volume relationships in Figure 5–2) and manifest diabetes insipidus that reverts to the existing asymptomatic condition when the pregnancy ends. A second form of diabetes insipidus occurs when the level of cysteine aminopeptidase is extraordinarily higher than in normal pregnancy and produces diabetes insipidus in a patient with normal pituitary and renal function. There may be other associated pathology with the latter disease such as preeclampsia, fatty liver, and coagulopathies. Diabetes insipidus in this situation also abates when the pregnancy ends and may not recur with subsequent pregnancies.

**D. Decreased end organ response to vasopressin—nephrogenic diabetes insipidus**

1. **Congenital nephrogenic diabetes insipidus** There are two causes of congenital nephrogenic diabetes insipidus: (1) an X-linked recessive mutation of the V₂ receptor, which accounts for 90% of the cases; and, (2) an autosomal recessive mutation of the aquaporin-2 water channels. The X-linked disorder, of course, only occurs in males while disease due to mutations of the aquaporin-2 gene occurs in males and females. Female carriers of the X-linked V₂ receptor abnormality usually have no clinical disease nor do heterozygote carriers of the recessive aquaporin-2 mutations. Nephrogenic diabetes insipidus due to aquaporin-2 defects is produced when the child inherits a mutated gene from each parent that carries the recessive mutation.

Regardless of etiology, the presentation of nephrogenic diabetes insipidus usually occurs in the first week of life presenting with vomiting, constipation, failure to thrive, fever, and polyuria. The patients are found to be hyponatremic with low urine osmolality. When measured, vasopressin levels are elevated.

2. **Acquired nephrogenic diabetes insipidus** The ability to produce concentrated urine depends upon hyperosmolality of the inner medulla which in turn requires normal osmotic architecture with descending and ascending limbs of the loop of Henle, normal sodium transport, functional aquaporins, and intact long loop vascular structures (vasa recta) so that the hyperosmolality in the inner medulla is not washed away by normal blood flow. One form of nephrogenic diabetes insipidus is produced by renal disease that distorts the architecture of the kidney as in polycystic renal disease, infarcts, sickle cell anemia, and so forth. The polyuria associated with potassium deficiency and hypercalcemia both are associated with decreased expression of aquaporin-2. Among drugs that may produce nephrotoxicity, the most common to produce nephrogenic diabetes insipidus are lithium (commonly when used to treat bipolar disorders) and demeclocycline.

**DIAGNOSTIC TESTS OF DIABETES INSIPIDUS**

One can determine whether there is true polyuria by measuring the 24-hour urine output, but collecting this large volume is inconvenient. Alternatively, the patient can keep a diary, recording the time and volume of each voided urine without saving the urine for examination.

**A. Dehydration test** After other causes of polyuria are eliminated, the diagnosis of diabetes insipidus is accomplished by some form of dehydration test. The dehydration test should be done in a controlled environment. The description here is for adults. Dehydration of children requires special attention and should only be done by a pediatrician. Dehydration tests should not be done in infants. The patient is weighed at the beginning of the test, and a serum sodium concentration and plasma osmolality are obtained. Nothing is allowed by mouth, and the volume and osmolality of each voided urine are recorded. The patient is weighed after each liter of urine is excreted. When two consecutive measures of urine osmolality differ by less than 10% and the patient has lost 2% of his body weight, the serum sodium concentration and plasma osmolality are again determined, and a blood sample is drawn for a determination of plasma vasopressin. The patient is then given parenterally 2 μg of desmopressin, a synthetic analogue of vasopressin described later, and urine and osmolality and output are recorded for an additional 2 hours. The duration of the test varies, but in most patients a plateau in the urine osmolality will be reached by 18 hours. The test is discontinued if the patient loses 3% of the body weight. The different responses to this testing are depicted in Figure 5–4. If the patient is dehydrated and hyperosmolar and the urine is dilute when first seen, no further dehydration is necessary. Blood is drawn to measure plasma vasopressin, and the response to desmopressin is determined.

Patients with primary polydipsia are distinguished from diabetes insipidus by the concentration of the urine at a plateau which is frequently 500 to 700 mOsm/kg and by the lack of further response to administered desmopressin. Patients with
Recognizing partial defects in antidiuretic hormone secretion.

**FIGURE 5-4** Urine osmolality during a dehydration test followed by administration of desmopressin to differentiate various types of diabetes insipidus and primary polydipsia as described by Miller et al. (Miller M, Dalakos T, Moses AM, Fellerman H, Streten D. Recognition of partial defects in antidiuretic hormone secretion. Ann Int Med. 1970;73:721-729). See text for discussion of the differential diagnosis based on the plateau of urine osmolality with dehydration and subsequent response to administered desmopressin.

Hypothalamic diabetes insipidus have undetectable or low plasma vasopressin levels at the end of dehydration, minimal concentration of the urine, and an additional increase in urine osmolality to administered desmopressin of at least 50% but often 200% to 400%. Patients with nephrogenic diabetes insipidus do not concentrate their urine similar to hypothalamic diabetes insipidus, but the levels of plasma vasopressin are high, often greater than 5 pg/mL at the end of the test. Additionally, there is no further increase in urine osmolality after the administration of desmopressin. Occasionally, patients with partial hypothalamic diabetes insipidus concentrate their urine minimally with dehydration, but their maximum urinary concentration is not achieved, and there is an additional boost with administered desmopressin. This pattern can be similar to some patients with primary polydipsia who achieve a plateau level of urine osmolality before reaching their maximum attainable urine osmolality and show a boost in urine osmolality in response to desmopressin. These patients are usually distinguished by their response to desmopressin over time. Patients with partial hypothalamic diabetes insipidus do well while those with primary polydipsia may continue to drink excessive amounts of water and develop hyponatremia.

Measurements of plasma vasopressin by clinically available assays is only of help in distinguishing nephrogenic diabetes insipidus (in which the level will be unequivocally elevated) from other causes of diabetes insipidus. Recent reports have described a radioimmunoassay of copeptin, the inactive carboxy peptide that is cleaved from the provasopressin molecule and secreted with vasopressin and neurophysin, but the clinical usefulness has yet to be determined.

**B. Imaging in diabetes insipidus** Imaging of the hypothalamus is an important diagnostic tool in diabetes insipidus. The exquisite sensitivity of the kidney to vasopressin, especially with regard to urine volume, determines that even 10% of the vasopressin neurons may be sufficient to maintain homeostasis without symptoms. Because of the wide anatomic distance between the paraventricular and supraoptic nuclei, tumors that produce diabetes insipidus are either sufficiently large to destroy 90% of the vasopressin neurons or, most commonly, are located just above the diaphragma sella where the neurohypophyseal tracts of the two sides converge as they enter the pituitary stalk. Small tumors of the anterior pituitary confined to the sella are never the cause of diabetes insipidus. On T1-weighted images, the normal posterior pituitary appears as a bright spot on MRI studies. The bright spot is produced by the stored hormone in the posterior pituitary. Most normal subjects have the bright spot, although it decreases with age, and most patients with diabetes insipidus do not have a bright spot. An MRI may reveal thickening of the stalk and absence of the posterior pituitary bright spot. This is a characteristic finding of some granulomatous diseases of the neurohypophysis and of lymphocytic infundibulitis.

**TREATMENT OF DIABETES INSIPIDUS**

As noted above, adults with intact thirst mechanisms usually drink sufficient fluid to maintain serum sodium levels in the normal range. Babies and adults without access to fluid or patients who are unconscious may not drink and will develop severe dehydration and hypernatremia. If hypothalamic diabetes insipidus is caused by a specific disease such as a granulomatous disorder, that condition should be treated. Rarely, however, does successful treatment of the underlying disease produce remission of the diabetes insipidus.

Hypothalamic diabetes insipidus is best treated by the vasopressin analogue desmopressin (desamino, D-8 arginine vasopressin, DDAVP). In desmopressin, the amine at position 1 is removed, increasing the half-life of the compound, and at position 8, L-arginine is changed to D-arginine, markedly reducing the pressor activity. Thus, the agent is highly selective for the V₂ receptor and is nearly 2000 times more specific for antidiuresis than is the naturally occurring L-arginine vasopressin. Desmopressin is available as tablets (0.1 and 0.2 mg), a solution for nasal installation (100 μg/mL), and a parenteral solution (4 μg/mL). There is considerable individual variability in the duration of action of desmopressin, so the dosing should be adjusted for each individual. Usually, a satisfactory schedule can be achieved with 2 to 3 tablets per day or one to two intranasal doses. A parenteral preparation can be given intravenously, intramuscularly, or subcutaneously and is 5 to 20 times more potent than the intranasally administered dose. The drug is expensive, and in many patients, a smaller dose given more frequently is more cost-effective. Other agents that prolong the action of vasopressin or the release of vasopressin
include chlorpropamide, carbamazepine, clofibrate, and indomethacin, but these are not first-line therapies. Desmopressin is the only therapeutic agent recommended for treatment of diabetes insipidus in pregnancy because desmopressin is not destroyed by cysteine aminopeptidase and has minimal oxytocic activity on the uterus.

In patients with inadequate thirst, the best treatment is continuous administration of desmopressin to maintain a concentrated urine and then rigid adjustment of the amount of fluid that must be taken every 6 to 8 hours to maintain normal serum sodium.

In nephrogenic diabetes insipidus, any offending drug or electrolyte abnormality that might produce acquired nephrogenic diabetes insipidus should be stopped or corrected. In congenital nephrogenic diabetes insipidus, therapy is aimed at reducing urine volume through a low sodium diet and a thiazide diuretic. This causes a natriuresis which produces some contraction of the extracellular fluid volume, decreased glomerular filtration rate, decreased delivery of fluid to the collecting duct, and a decreased urine volume. Amiloride is especially recommended in this setting because it is potassium sparing. Amiloride may also have some advantage in lithium-induced nephrogenic diabetes insipidus because amiloride decreases lithium entrance into cells in the distal tubule. Indomethacin has an antidiuretic action that especially prolongs the action of vasopressin and administered desmopressin. It also decreases urine volume in nephrogenic diabetes insipidus, but there is concern about gastrointestinal bleeding.

When diabetes insipidus occurs in patients who also have anterior pituitary deficiency, adequate treatment with thyroid hormone and hydrocortisone is essential to maintain normal renal response to desmopressin. Clinical situations such as surgical procedures, treatments that require a saline diuresis, and periods when patients are not allowed fluids by mouth require careful balance of antiuretics, administered fluid, and sodium.

**EXCESS VASOPRESSIN: SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE**

Excess vasopressin becomes a clinical problem when there is concurrent retention of water producing hypo-osmolality. Hypo-osmolality is common in hospitalized patients but in most cases is due to underlying illness. Statistically, hyponatremia is associated with increased morbidity and mortality because it is a measure of the severity of the underlying illness. This chapter focuses on cases in which inappropriately elevated vasopressin and water retention are the cause of the hypo-osmolality (see also Chapter 21 Humoral Manifestations of Malignancy).

The differential diagnosis of hypo-osmolality is based upon measuring the serum sodium concentration and estimating the extracellular fluid status. Sodium is the major cation of the extracellular fluid, and potassium is the major cation of the intracellular fluid. Water moves freely between the intracellular and extracellular fluid, so osmolality is always equivalent in both compartments. The relative balance between solute depletion and water retention, as a cause of hypo-osmolality, is complex, but in virtually all cases of clinically significant hypo-osmolality, there is some element of impaired water excretion and/or excessive water intake.

Plasma osmolality can be measured directly by freezing point depression or vapor pressure of plasma, but usually, hypo-osmolality is brought to clinical attention because of decreased concentration of sodium rather than measure of osmolality. In the extracellular fluid, the major contributions to osmolality are sodium, glucose, and blood urea nitrogen (BUN). A calculated osmolality usually correlates well with measured osmolality.

**Plasma osmolality (mOsm/kg H$_2$O)**

$$\text{Plasma osmolality} = 2 \times [\text{Na}^+] (\text{mEq/L}) + \text{Glucose (mg/dL)} / 18 + \text{BUN (mg/dL)} / 2.8$$

Occasionally, when the serum sodium concentration is measured by flame photometry the measured sodium is artificially low because flame photometry calculates the sodium in a fixed volume of plasma. If a large proportion of the plasma volume is taken up by extremely elevated levels of lipid or protein, sodium determined by flame photometry is low. Plasma osmolality determined by freezing point or vapor pressure is a direct measure of particles in solution and will be normal in these situations. So the low sodium level by flame photometry is referred to as pseudohyponatremia. Hyperglycemia will produce hyponatremia because of the shift of water from the intracellular fluid to the extracellular fluid; however, the calculated osmolality will be normal. The serum sodium can be corrected for the glucose elevation by adding 1.6 to 2.4 mEq/L for each 100 mg/dL increase in serum glucose.

When true hypo-osmolality is found to exist, the differential diagnosis is of hyponatremia as illustrated in Table 5–1. The disorder is divided into four major subgroups based on the extracellular fluid volume status and the measured urinary sodium. Extracellular fluid volume status may be determined by central venous pressure, BUN/creatinine, hematocrit, or plasma protein concentrations, but usually it is estimated by physical examination.

If the patient is dehydrated and the urinary sodium is low, this indicates normal physiologic response to extra renal sodium loss (with continued intake of water) such as vomiting or diarrhea. The appropriate therapy is to replace the sodium and fluid deficiency with normal saline. If the patient is dehydrated but the urinary sodium is increased, this indicates a renal loss of sodium inappropriate to the decreased volume and hyponatremia. This may be due to intrinsic renal disease, diuretic use, aldosterone deficiency (see discussion of Addison disease in Chapter 9), or cerebral salt wasting (to be discussed later). Appropriate therapy is to replace the sodium and fluid loss with normal saline but also with appropriate treatment of the underlying defect. If the extracellular fluid volume is expanded with edema or ascites and the urinary sodium is low, this indicates hyperaldosteronism, secondary to reduced or ineffective plasma volume as in cirrhosis or congestive heart failure, and the appropriate therapy is treatment of the underlying condition. Where the extracellular fluid volume appears to be normal with increased urinary sodium, this indicates the pathophysiology of inappropriate secretion of antidiuretic hormone. Note that the urine osmolality will not be maximally dilute and that measured vasopressin will not be maximally suppressed in any of the four categories in Table 5–1. Although not appropriate to the osmolality, in the first three categories, the elevation of vasopressin is appropriate to the real or perceived decreased plasma volume. It is only in the fourth category (SIADH) that vasopressin is inappropriate both for plasma volume and osmolality. Copeptin, the inactive carboxy peptide that is cleaved from the provasopressin molecule and secreted with vasopressin and neurophysin, was mentioned earlier. Some studies have indicated that measurement of levels of this peptide might be useful in evaluating various causes of hyponatremia, but the clinical utility of such measurements is not yet established.

A. The pathophysiology of the hyponatremia in SIADH

The pathophysiology of SIADH begins with uncontrolled secretion of vasopressin. Thirst is not adequately suppressed so water intake continues. This produces volume expansion and hyponatremia in the sequence illustrated in Figure 5–5. Vasopressin

![Figure 5-5 Illustration of the changes in intracellular fluid and extracellular fluid volumes in the pathophysiology of SIADH with the chronologic pattern of: (A) Expanded ECF and ICF volume with solute dilution. (B) Natriuresis to decrease ECF volume expansion. (C) Extrusion of intracellular potassium and osmoalytes to decrease intracellular volume expansion. (D) Restoration of near normal volume in ECF and ICF. (E) Renal adaptation to allow excretion of more dilute urine in spite of excess vasopressin. (Copyright 2005, A.G. Robinson, University of California at Los Angeles.)]
limits the excretion of water in the urine. Continued ingestion of water (part A) produces an expansion of extracellular and intracellular volume. The body attempts to bring the extracellular fluid volume back to normal by natriuresis (part B) of isotonic urine. The mechanism of natriuresis is complex and involves increased glomerular filtration, pressure natriuresis, and natriuretic factors, especially atrial natriuretic peptide and brain natriuretic peptide. This natriuresis decreases total body water and total body sodium by water excretion. Next, the body attempts to return intracellular fluid volume to normal by (part C) excreting from the intracellular fluid potassium and organic osmolytes such as glutamine, glutamate, myoinositol, aspartate, and N-acetylaspartate. In spite of the attempt to normalize extracellular and intracellular fluid, there remains a tendency for these compartments to be slightly expanded. The last adaptation (part D) is caused by this tendency for volume expansion and produces changes in the kidney to make it less responsive to the chronically inappropriate excess of vasopressin and to allow an increase in water excretion. Vasopressin retains water by increasing the number of aquaporin-2 molecules in the principal cells of the collecting duct. With chronic excess of vasopressin, the density of aquaporins in the membrane increases dramatically, producing a state of super water retention. The adaptation to chronic volume expansion is to reduce the number of aquaporins in principal cells. In this new state (part E), ingestion of sodium somewhat reexpands the extracellular fluid volume and is excreted, while ingestion of water is more easily excreted because of the renal adaptation to decrease aquaporins—therefore a new steady state.

Of the differential diagnoses of hyponatremia shown in Table 5–1, the two categories that are most difficult to differentiate are those with elevated urinary sodium concentrations. On physical examination, it may be difficult to differentiate moderately low extracellular fluid volume from normal extracellular fluid volume. In this situation, the differential diagnosis may be aided by a volume challenge of normal saline infused at a modest rate over a few hours while following urinary sodium and plasma sodium determinations. If the patient is in diagnostic category 4 (SIADH) and relatively equilibrated, the administered saline will be excreted so there will be an increase in urinary sodium and no change or a slight decrease in serum sodium concentration. If the patient is in category 2 with a renal loss of sodium, sodium from the administered saline will be retained, and the water excreted will somewhat dilute urinary sodium. This will result in a decrease in urinary sodium while the serum sodium concentration will rise. This volume challenge in difficult cases is not considered therapy, but only an assist to make the appropriate diagnosis, which will then lead to the initiation of appropriate therapy.

In diagnostic category 2 (Table 5–1), there is considerable controversy regarding the diagnosis and incidence of cerebral salt wasting (CSW). CSW is severe primary natriuresis producing volume depletion and hyponatremia. The diagnosis is only confirmed when volume depletion can be confirmed by some combination of decreased central venous pressure, decreased plasma volume, increased BUN/creatinine, or increased hematocrit and plasma protein levels. Cerebral salt wasting has been intensively studied as a cause of hyponatremia in subarachnoid hemorrhage. Natriuretic peptides are increased in subarachnoid hemorrhage, but they are also increased in well-documented SIADH. Measured plasma volume in subarachnoid hemorrhage is difficult to interpret because of the lack of sensitivity of readily available clinical measures. There may be both inappropriate secretion of vasopressin and inappropriate natriuresis in these patients with the clinical presentation depending on the relative contributions of each. It is consistent that infusion of isotonic saline does not correct the hyponatremia in SIADH but may do so with CSW. The most convincing cases of cerebral salt wasting are those that occur in hospitalized patients in whom there is a sudden unexplained increase in urine volume (not seen in SIADH) and urine sodium excretion. This has been reported in several cases of children with traumatic brain injury or brain surgery. The acute massive diuresis and natriuresis is accompanied by definitive volume contraction by the measures listed above. Most of these cases respond to replacement with normal or hypertonic saline.

B. Symptoms of hyponatremia  The symptoms of hyponatremia are largely dependent on the rapidity of the development of hyponatremia. When hyponatremia develops rapidly and is severe (serum sodium level <120 mEq/L), patients are at risk for cerebral edema with herniation of the brain stem (especially children and young women). Other complications include neurogenic pulmonary edema, seizures, coma, and respiratory arrest. Hyponatremia that develops slowly over a long period of time is surprisingly well-tolerated even at very low levels of serum sodium. Neurologic symptoms usually do not occur with sodium values above 120 mEq/L, but any degree of hyponatremia might exacerbate other comorbid conditions. Hyponatremia is usually considered chronic if hyponatremia has developed slowly and persisted for greater than 48 hours.

C. Clinical syndromes of SIADH  The clinical criteria for SIADH remain those described by Bartter and Schwartz in 1967: decreased plasma osmolality; inappropriate concentration of the urine; clinical euvolemia; increased urinary sodium excretion; and absence of other causes of euvolemic hypo-osmolality such as hypothryoidism, adrenal insufficiency, or diuretic use. The three main etiologies of SIADH are ectopic production of vasopressin by cancer (see Chapter 21), drug-induced SIADH, and lesions in the pathway of the baroreceptor system, especially central nervous system disorders and pulmonary disorders. As noted earlier, the baroreceptors consist of a diffuse system of receptors in the chest and synapses in the brain. Some of the input from them is inhibitory. Lesions which disrupt the flow of signals in the lung or in the brain may decrease this inhibitory signal and produce inappropriate secretion of vasopressin. Acquired immune deficiency syndrome (AIDS) is a recognized cause of SIADH, although dehydration, adrenal insufficiency, pneumonia, and renal tubular toxicity associated with therapy may confound the ability to make the diagnosis of SIADH an exclusive cause of the hyponatremia. Prolonged strenuous exercise (eg, marathon running) may increase...
secretion of vasopressin and with excessive intake of hypotonic fluid induce SIADH. A rare cause of SIADH reported in two pediatric patients is a genetic mutation of the V2 receptor in principal cells producing unregulated activation. These patients have the manifestations of hyponatremia and SIADH but no measurable plasma vasopressin. Some elderly patients fit the criteria for SIADH without a definitive diagnosis.

Specific disorders, which have been reported to cause SIADH, are detailed in Table 5–2, but because of the diffuse regulation of the baroreceptor system and the multiple disorders that can influence vasopressin release via this system, no list should ever be considered complete.

**TREATMENT OF HYPONATREMIA IN SIADH**

The therapy of hyponatremia follows pari passu the symptoms of hyponatremia. When hyponatremia has been known to have occurred rapidly and is severe and symptomatic, the patient should be treated quickly. When the onset is slow and the syndrome chronic, the treatment should be slow. Acute hyponatremia is arbitrarily defined as having developed over less than 48 hours. Usually, the serum sodium must be less than 120 mEq/L to produce symptomatology. Discontinuing the administration of hypotonic fluid and the administration of hypertonic NaCl (eg, 3%), possibly with the addition of a diuretic, should be promptly considered. Often acute disorders occur in the hospital in a surgical or obstetrical setting and children and young women are at the greatest risk. For chronic hyponatremia, overly aggressive treatment may cause new and additional pathology. As shown in Figure 5–5, tissue adaptation to chronic hyponatremia results in the loss of intracellular osmolytes. In the brain these are the same osmolytes that would normally increase in neurons to protect brain volume from a sudden shift of intracellular fluid to the extracellular fluid when there is an acute increase in osmolality of the extracellular fluid. If during the treatment of hyponatremia in SIADH the extracellular fluid osmolality is rapidly increased, the brain has lost the ability to protect intracellular volume and water rapidly moves out of neurons. Brain shrinkage is thought to be the cause of a syndrome of myelinolysis which was first described in the pons—hence the term central pontine myelinolysis. The process can occur diffusely throughout the brain. The cause may be disruption of the blood–brain barrier and influx of plasma components that are toxic to the oligodendrocytes. The syndrome consists of neurologic deterioration over several days with fluctuating consciousness, convulsions, hypoventilation, and hypotension. Eventually, these patients may develop pseudobulbar palsy with difficulty in swallowing and inability to speak, even leading to quadriparesis. Recovery from this syndrome is variable, and many neurologic complications are permanent. MRI scans will demonstrate the demyelination, but usually not until 3 to 4 weeks after correction of the hyponatremia.

In chronic hyponatremia that is asymptomatic, the safest therapy is restriction of free water intake and slow correction of the hyponatremia over days. For chronic hyponatremia that has central nervous system symptoms, carefully controlled and limited increases in the osmolality should be undertaken. Coma or convulsions are obvious signs of neurologic symptoms that may be produced by hyponatremia, but nausea, vomiting, and confusion may be less specific signs of neurologic impairment. There is considerable debate in the literature about the exact rate of correction of the sodium concentration in these cases, and one should review the most up to date recommendations prior to initiating therapy. At present, general parameters of therapy are that the first 10% of increase of serum sodium might be accomplished at a rate of 0.5 to 1 mEq/L/h with a total correction not to exceed 12 mEq/L in the first 24 hours, and 18 in the first 48 hours. Active correction is stopped when the patient’s symptoms are abolished, the serum sodium level is greater than 120 mEq/L, or the total magnitude of correction of 18 to 20 mEq has been achieved. Further treatment is undertaken with fluid restriction as for asymptomatic hyponatremia. While fluid intake is restricted in chronic SIADH, salt intake is not, as all of these patients have some degree of sodium loss secondary to the volume expansion and natriuresis.

The tetracycline derivative demeclocycline, known to cause nephrogenic diabetes insipidus, has been used to treat chronic SIADH. Dosages in the range of 600 to 1200 mg/d in divided doses decrease urine osmolality. Three to four days are required for

the effect to reach equilibrium. Azotemia and nephrotoxicity have been reported with demeclocycline especially in patients with cirrhosis. Any of the therapies for hyponatremia and especially fluid restriction will reduce the extracellular fluid volume and, hence, remove the volume-mediated stimulus of renal adaptation illustrated in part D of Figure 5–5 in which the kidney becomes somewhat less responsive to the excess vasopressin by reduction in the amount of aquaporin-2 water channels. When the volume stimulus is removed, there is again an increase in the density of membrane water channels, and the kidney becomes more efficient in retaining water. This accounts for the common clinical observation that fluid restriction that is initially effective may have to be increasingly severe to maintain a beneficial effect.

The most specific treatment for SIADH is to block the V2 receptors in the kidney. There are recently approved vasopressin receptor antagonists, vaptans, that enhance renal free water excretion (aquaresis) without sodium excretion (natriuresis). Unlike the agonist desmopressin, these antagonist are nonpeptide drugs. Conivaptan is a combined V1a and V2 receptor antagonist that is available for intravenous administration to hospitalized patients. Tolvaptan is a selective V2 receptor antagonist that can be administered orally and is approved to treat severe hyponatremia (serum Na <125 mEq/L) in patients who are symptomatic or patients who have failed to correct with fluid restriction. Clinical trials with these agents indicate they will be useful to treat hyponatremia of SIADH and of other causes. The risk of brain myelolysis caused by too rapid correction of sodium with these agents is the same as with other therapies, so the same recommendations about rates of correction of serum sodium described earlier will apply as physicians gain further experience with these agents.

**SUMMARY**

Table 5–3 compares and contrasts pathophysiologic entities associated with decreased vasopressin, diabetes insipidus, and excess vasopressin, SIADH.

**OXYTOCIN**

The anatomy and synthesis of oxytocin is similar to that described for vasopressin. While there are a number of central nervous system actions that have been attributed to oxytocin (probably acting as a neurotransmitter), the physiologic functions are limited to lactation and parturition.

**A. Lactation** The hypothalamic/pituitary hormones critical to lactation are prolactin and oxytocin. Prolactin secretion from the anterior pituitary is described in Chapter 4, and its primary activity is to promote milk production. Oxytocin stimulates milk letdown associated with nursing. The milk-producing unit of the breast is the alveolar system in which clusters of milk-producing cells are surrounded by specialized myoepithelial cells. Milk is synthesized in glandular cells of the alveoli. Oxytocin receptors are localized on glandular cells and on myoepithelial cells along the duct. Oxytocin stimulates the cells along the duct to shorten and the ducts to widen, enhancing milk flow through the ducts to the nipple. Suckling at the breast stimulates mechanoreceptors or tactile receptors that ascend through the spinal cord to the lateral cervical nucleus and eventually to the oxytocinergic magnocellular neurons in the supraoptic and paraventricular nuclei. Neurotransmitters trigger the release of oxytocin. Oxytocin is released in a pulsatile fashion producing a pumping action on the alveoli and promoting maximal emptying of milk from the alveoli. There is no evidence for a central pacemaker to regulate the secretion of oxytocin, and the mechanism of synchrony among individual oxytocinergic neurons is unknown. The importance of oxytocin in maintaining milk secretion is demonstrated in transgenic mice with a knockout of oxytocin synthesis. These animals deliver their young normally, demonstrating the redundant systems for parturition, and produce milk normally, demonstrating the role of prolactin, but are unable to release milk when the pups suckle, demonstrating the importance of oxytocin for milk letdown. The pups die of dehydration with no milk in their stomachs. Administration of oxytocin to the knockout mothers restores milk secretion, and the pups survive.

**B. Parturition** Estrogen activates many events that initiate and stimulate parturition whereas progesterone inhibits these events. The uterine myometrial cells have intrinsic contraction activity and are responsive to oxytocin. During pregnancy, oxytocin is released, but oxytocinase decreases the plasma level of oxytocin, and progesterone and relaxin decrease the intrinsic contractility of the myometrium. In humans, there is a dramatic increase in uterine responsiveness to oxytocin as parturition approaches. Several hormones other than oxytocin including prostaglandins, endorphins, adrenergic agonists, corticotropin-releasing hormone, glucocorticoids, and cytokines also participate in the initiation and completion of labor. The most specific role of oxytocin may be the release of oxytocin brought about by vaginal and cervical dilatation, known as the Fergusson reflex. This may be important in stimulating uterine muscle to contract maximally and clamp down blood vessels to decrease blood loss. It is perhaps not surprising that parturition, which is so important to survival of the species, is controlled by many different pathways of cross-stimulation and feed-forward activity. The many redundant systems ensure survival of the species. Oxytocin remains the strongest stimulant to myometrial contraction, explaining its value as a therapeutic agent in inducing parturition.

**C. Other actions** Other actions of oxytocin have been described in a number of species including effects on behavior of animals, effects on feeding and satiety, response to stress, stimulation of sperm transport, effects on memory, and so forth. None of these have been documented to be physiologically important in humans.

Assessment of growth in stature is an essential part of the pediatric examination. Growth is an important index of physical and mental health and of the quality of the child's psychosocial environment; chronic problems in any of these areas may be reflected in a decreased growth rate which may be a critical clue as to the onset of the condition. We shall consider influences on normal growth, the normal growth pattern, the measurement of growth, and conditions that lead to disorders of growth.

**NORMAL GROWTH**

**INTRAUTERINE GROWTH**

The growth of a fetus begins with a single fertilized cell and ends with differentiation into more than 200 cell types, length increasing by 5000-fold, surface area by $6 \times 10^6$-fold, and weight by $6 \times 10^{12}$-fold. This all leads to an approximately 7 lb newborn. Overall,
the growth of the fetus is dependent on the availability of adequate oxygen and nutrition delivered by the placenta and is orchestrated by a group of growth factors, all overseen by a basic genetic plan. Genetic factors are more important early in gestation, whereas the maternal environment attains more importance late in gestation.

The classic definition of small-for-gestational age (SGA), although somewhat arbitrary, is a birth weight 2 standard deviations below the mean or below the fifth percentile for birth weight, or birth weight below 2500 g for a term infant in the United States. The term intrauterine growth retardation or intrauterine growth restriction (IUGR) is not synonymous with SGA, because IUGR refers to decreased intrauterine growth velocity noted on ultrasound. Statistics and charts showing various percentiles of weight for gestational age are available to determine which premature infants are SGA and what weights are appropriate for gestational age. About 20% of SGA infants remain short as children and adults, in contrast to appropriate-for-gestational-age premature infants, who are smaller at birth but generally experience catch-up growth in the first 2 years. Those SGA infants who do not experience catch-up growth by 2 years of age may be candidates for growth hormone therapy. Recent studies suggest that preterm, AGA babies who show poor growth in the first 3 postnatal months follow growth patterns similar to SGA infants; thus consideration of GH therapy may be warranted as this situation receives further study.

THE PLACENTA

The placenta acting as an endocrine organ influences most aspects of fetal growth, including the supply of adequate nutrition and oxygen and regulation of hormones and growth factors. Aberrant delivery or control of any of these factors affects fetal growth; placental weight is usually directly related to birth weight.

CLASSIC HORMONES OF GROWTH AND FETAL GROWTH

The hormones that mediate postnatal growth do not necessarily play the same roles in fetal growth. Growth hormone (GH) is present in very high concentrations in the fetus, in contrast to the limited presence of GH receptors. Although this discrepancy suggests limited activity of GH in the fetus, GH does play a role in fetal growth as reflected in the average birth weight 1 standard deviation (SD) below the mean in GH-deficient infants. Infants with GH resistance due to abnormal, reduced or absent GH receptors (eg, Laron syndrome) have elevated GH and low serum insulin-like growth factor (IGF)-1 levels; they also have decreased birth length and weight. Thyroid hormone deficiency does not directly affect human birth weight, but prolonged gestation can be a feature of congenital hypothyroidism, and this factor will itself increase weight. Placental lactogen exerts no effect on birth size in human beings. However, the concentration of placental-derived GH (from the GHR gene) is significantly decreased in the serum of a pregnant woman bearing a fetus with IUGR.

GROWTH FACTORS AND ONCOGENES IN FETAL GROWTH

Oncogenes may be responsible for neoplastic growth in postnatal life, but expression of these genes is important in the normal development of many fetal organs. Remarkably, the same onco-genes that cause postnatal neoplasia are prevented from causing tumors in the normally differentiating fetus. For example, a mutation in the von Hippel-Lindau gene predisposes to retinal, cerebellar, and spinal hemangio blastomas, renal cell carcinomas, and pheochromocytomas, but the normal VHL gene is expressed in all three germ cell layers of the embryo and in the central nervous system, kidneys, testis, and lung of the fetus, suggesting a role in normal fetal development for this gene.

INSULIN-LIKE GROWTH FACTORS, RECEPTORS, AND BINDING PROTEINS

IGF-I in the fetus is regulated by metabolic factors other than GH, in contrast to the dependence of IGF-I generation upon GH in postnatal life. One explanation is that there are fewer GH receptors in the fetus than after birth. In the human fetus, serum GH falls during later gestation owing to maturation of central nervous system's negative control, whereas serum IGF-I and IGFBinding protein (IGFBP)-3 rise during gestation, demonstrating their independence from GH stimulation.

Studies of knockout mice, which lack various growth factors or binding proteins, indicate a role for IGF-II in growth during early gestation and one for IGF-I during later gestation. Knockout of type 1 IGF receptors leads to a more profound growth failure than is found in IGF-I knockout mice alone, suggesting that factors other than IGF-I (eg, IGF-II) exert effects on fetal growth through the type 1 receptor.

Study of transgenic mice overexpressing IGFBPs supports the concepts that excess IGFBP-1 stunts fetal growth while excess IGFBP-3 leads to selective organomegaly. For example, overexpression of IGFBP-3 in mice led to organomegaly of the spleen, liver, and heart, although birth weight was not different from that of wild-type mice.

Although controversy remains over some of the data regarding IGFs and fetal growth, a summary of the complex IGF system in the fetus, based on the evidence from various species, appears to apply to the human being as follows.

1. IGFs are detectable in many fetal tissues from the first trimester onward.
2. Concentrations of IGFs in the fetal circulation increase during pregnancy, and at term the concentrations of IGF-I are directly related to birth weight.
3. In mice, disruption of the IGF genes leads to severe growth retardation.
4. There is a striking increase in IGFBP-1 and IGFBP-2 concentrations in amniotic fluid at the end of the first trimester.
5. The major binding proteins in the human fetus are IGFBP-1 and IGFBP-2.
6. From as early as 16 weeks, there is an inverse correlation between fetal concentrations of IGFBP-1 and birth weight.
7. In the mother, circulating concentrations of IGF-I and IGFBP-1 increase during pregnancy.
8. Maternal IGFBP-1 concentrations are elevated in severe pre-eclampsia and IUGR.
9. Fetal concentrations of IGFBP-1 are elevated in cases of IUGR, especially those associated with specific evidence of reduced uteroplacental blood flow. Production of IGFBP-1 appears to be a sensitive indicator of the short- or long-term response to reduced fetal nutrition.

**INSULIN**

Although insulin is a major regulatory factor for carbohydrate metabolism, many lines of evidence demonstrate that it is a growth factor as well and has importance in fetal growth. Macrosomia is a well-known effect of fetal hyperinsulinism as is found in the infant of the diabetic mother. Errors in the normal pattern of IGF-II gene expression from the paternal chromosome and type 2 IGF receptor (for IGF-II) from the maternally derived gene underlie the pathogenesis of Beckwith-Wiedemann syndrome. Affected infants are large and have elevated insulin concentrations. Increased weight gain in pregnant women over 40 lb leads to significantly increased risk of fetal macrosomia in gestational diabetes mellitus as well as in those with normal glucose tolerance test results. Just as increased insulin stimulates fetal growth, syndromes of fetal insulin deficiency such as congenital diabetes mellitus, pancreatic dysgenesis, or fetal insulin resistance (eg, leprechaunism) are characterized by IUGR. Infants born to diabetic mothers with vascular disease, hypertension, and or eclampsia or preeclampsia also have IUGR and are born SGA. In that situation, it is clear that limited nutrient delivery compromises the growth of the infant.

**EPIDERMAL GROWTH FACTOR**

Epidermal growth factor (EGF) is involved with fetal growth, and expression varies with disordered fetal growth. Microvilli purified from the placentas of infants with IUGR have decreased or absent placental epidermal growth factor receptor (EGF-R) phosphorylation and tyrosine kinase activity. Maternal smoking decreases birth weight by an average of 200 g, with the major effect occurring late in pregnancy; the placenta responds to smoking by significant changes in its vascularity, which leads to fetal hypoxia. There are decreased numbers of EGF-Rs and a reduced affinity of these receptors for EGF in the placentas of women who are smokers. Hypertensive patients also have decreased numbers of placental EGF-Rs, which may result in IUGR.

EGF levels in amniotic fluid are normally increased near term but decreased in pregnancies complicated by IUGR—although not, conversely, increased in infants who are large for gestational age. EGF levels in the first urines to be voided by IUGR and macrosomic infants are lower than in control infants.

EGF administered to fetal monkeys results in histologic and biochemical maturation of their lungs, leading to improved air exchange and a diminished requirement for respiratory support. Surfactant apoprotein A concentration and the lecithin-sphingomyelin ratio are both significantly higher in the amniotic fluid of EGF-treated fetuses. Whereas birth weight is not affected by EGF, adrenal and gut weights, standardized for body weight, are increased significantly. Furthermore, EGF stimulates gut muscle, gut enzyme maturation, and gut size and content, improving the ability of the infant to absorb nutrients. Lastly, EGF advances the maturation of the fetal adrenal cortex, increasing the expression of 3-beta-hydroxysteroid dehydrogenase. Because EGF can be absorbed orally, this raises a question as to whether EGF could be a useful treatment for premature infants or, postnatally, for causing more rapid maturation of the neonate and improving survival in premature infants.

**FIBROBLAST GROWTH FACTOR**

Genetically engineered fibroblast growth factor receptor 2 (FGF-R)-deficient mice are severely growth-retarded and die before gastrulation. Ablant FGF signaling during limb and skeletal development in the human being can lead to syndromes of dysmorphia. For example, achondroplasia is due to mutations in the transmembrane domain of the type 3 FGF-R.

**GENETIC, MATERNAL, AND UTERINE FACTORS**

Maternal factors, often expressed through the uterine environment, exert more influence on birth size than paternal factors. The height of the mother correlates better with fetal size than the height of the father. However, there is a genetic component to length at birth that is not sex specific. Firstborn infants are on the average 100 g heavier than subsequent infants; maternal age over 38 years leads to decreased birth weight; and male infants are heavier than female infants by an average of 150 to 200 g. Poor maternal nutrition is the most important condition leading to low birth weight and length on a worldwide basis. Chronic maternal disease and eclampsia can also lead to poor fetal growth. Maternal alcohol ingestion has severe adverse effects on fetal length and mental development and predisposes to other physical abnormalities seen in the fetal alcohol syndrome such as microcephaly, mental retardation, midfacial hypoplasia, short palpebral fissures, wide-bridged nose, long philtrum, and narrow vermilion border of the lips. Affected infants never recover from this loss of length but attain normal growth rates in the postnatal period. Abuse of other substances and chronic use of some medications (eg, phenytoin) can cause IUGR. Cigarette smoking causes not only retarded intrauterine growth but also decreased postnatal growth for as long as 5 years after parturition. Maternal infection—most commonly toxoplasmosis, rubella, cytomegalovirus infection, herpes simplex infection, and HIV infection—leads to many developmental abnormalities as well as short birth length. In multiple births, the weight of each fetus is usually less than that of the average singleton. Uterine tumors or malformations may decrease fetal growth.
CHROMOSOMAL ABNORMALITIES AND MALFORMATION SYNDROMES

Infants with abnormal karyotypes may have malformation syndromes and may also demonstrate poor fetal or postnatal growth. In most cases, endocrine abnormalities have not been noted. For further discussion of this extensive subject, the reader is referred to other sources listed in the references at the end of this chapter.

FETAL ORIGINS OF ADULT DISEASE

The metabolic syndrome, "syndrome X," or the insulin resistance syndrome consists of (1) hypertension, (2) impaired glucose tolerance, and (3) elevated triglycerides among other features (see Chapter 17). Insulin resistance is a cardinal feature and might be the basis for most or all of these complications or may be just one feature of the syndrome, according to some. The metabolic syndrome is one of the long-lasting effects of abnormalities in fetal growth. Evidence from many international studies indicates a relationship between low birth weight or low weight at 1 year of age and chronic disease in adulthood. An opposing view is that catch-up growth, rather than low birth weight, is responsible for these defects long into the child's future.

Inanition during the last two trimesters of pregnancy, which occurred during the famine in Holland during World War II, led to an 8% to 9% decrease in birth weight; however, female infants born under these conditions later gave birth to normal-sized infants. On the other hand, in the Dutch and Leningrad famines, infants born after early gestational starvation of their mothers, but with improved maternal nutrition in late gestation were of normal size at birth. However, the female infants, born of normal size after this early gestational maternal starvation themselves gave birth to small infants (SGA of 300-500 g decrease). In other populations, women with a history of SGA tend to have SGA infants themselves, and some studies show that generations of malnutrition must be followed by generations of normal nutrition before there is correction of the birth weight of subsequent infants. The sparse environment of the fetus early in gestation in a mother with various degrees of starvation programs the fetal metabolism for survival of the fetus but later in life these survival techniques become maladaptive in an environment of plenty. Insulin resistance in fetal life may spare nutrients from utilization in muscle, thus leaving them available for the brain; this mechanism would serve to minimize central nervous system damage in the fetus during periods of malnutrition. The complexity of the situation is not completely understood but is the target of extensive research in vivo, in vitro, and in long-term clinical studies.

Birth weight and rate of postnatal growth (ie, catch-up growth)—not prematurity alone—are inversely related to cardiovascular mortality and the prevalence of the metabolic syndrome. It is not yet clear what the optimal nutrition is for a premature or small-for-gestational-age infant to avoid this metabolic programming.

Studies of otherwise normal but thin children, who had a history of SGA, demonstrated insulin resistance before the teenage years, supporting the concept of early metabolic programming. Present-day adults, who were born in the Netherlands during the Dutch famine who had the lowest birth weights and the lowest maternal weights (those subjects whose mothers experienced malnutrition during the last two trimesters noted above), show a degree of insulin resistance that is directly related to their degree of SGA, further documenting the relationship between fetal undernutrition and adult insulin resistance as the etiology of poor growth.

On the other hand, large infants born to mothers with diabetes mellitus often develop childhood obesity and insulin resistance even if they have a period of normal weight between 1 and 5 years of age. Remarkably, studies of the offspring of Dutch mothers exposed to famine during World War II in the first two trimesters (the time in which birth weight is least affected by maternal starvation) demonstrated a two-fold increase in the incidence of obesity at 18 years of age, compared with a 40% decrease in the incidence of obesity if the individual was exposed to famine in the last trimester (the time in which birth weight is most negatively impacted by maternal starvation).

Individuals born SGA also have variations in pubertal development and reproductive hormones. SGA girls tend to have earlier puberty, or if puberty occurs at an average age, more rapid progression of puberty or polycystic ovarian syndrome (PCOS). Adult males born SGA have increased aromatase and increased 5-alpha reductase demonstrating effects on reproduction in the male as well as the female. In sum, prenatal and early postnatal growth affects the older child and adult in many ways.

POSTNATAL GROWTH

Postnatal growth in stature follows a characteristic pattern in normal children (Figures 6–1 and 6–2). The highest overall growth rate occurs in the fetus, the highest postnatal growth rate just after birth, and a slower growth rate follows in mid-childhood (Figures 6–3 and 6–4). There are two periods characterized by brief growth spurts in childhood: the infant-childhood growth spurt between 1½ years and 3 years and the mid-childhood growth spurt between 4 and 8 years. The mid-childhood growth spurt does not occur in all children, is more frequent in boys than girls, and its presence is hereditary. After another plateau, the striking increase in stature, the pubertal growth spurt follows, causing a second peak growth velocity. The final decrease in growth rate then ensues, until the epiphyses of the long bones fuse and growth ceases.

In addition, an adiposity rebound of accelerating weight gain and rising body mass index (BMI) occurs in early childhood after a period of relative stability of weight gain. An early adiposity rebound is a risk factor for the development of obesity later in childhood and thereafter.

Endocrine Factors

A. Growth hormone and insulin-like growth factors

As discussed in Chapter 4, somatotropin or GH is suppressed by
hypothalamic GH release-inhibiting factor (somatostatin or SRIF) and stimulated by GH-releasing hormone (GHRH or GRF). The gene for GH is located on the long arm of chromosome 17 in a cluster of five genes: \(\text{GH}V\) codes for human GH (a single 191-amino-acid polypeptide chain with a molecular weight of 22 kDa); \(\text{GH}V\) codes for a variant GH produced in the placenta; \(\text{CSH}1\) and \(\text{CSH}2\) code for prolactin; and \(\text{CSH}P1\) codes for a variant prolactin molecule. A 20-kDa variant of pituitary GH accounts for 5% to 10% of circulating GH and is derived from the same gene, \(\text{GH}N\), but results from alternative splicing. The 22-kDa variant is poorly characterized but when derived from the placental gene, \(\text{GH}V\), in vitro it has less diabetogenic effect but similar growth-promoting and lipolytic activity.

The effects of GH are mainly mediated by the IGFs, but GH also directly stimulates lipolysis, increased amino acid transport into tissues, and increased protein and glucose synthesis in liver. It also has direct effect on cartilage growth. GH in excess causes insulin resistance and is diabetogenic. GH is secreted in a pulsatile manner, so that serum concentrations are low much of the day, but peak during short intervals. Values are higher in the immediate neonatal period, decrease through childhood, and rise again as a result of increased pulse amplitude (but not frequency) during puberty. GH secretion falls again during aging.

GH circulates in plasma bound to a protein, the GH-binding protein (GHBP), with a sequence equivalent to that of the extracellular membrane domain of the GH receptor. The physiology of
the GHBP appears to reflect important interrelationships between GH and GHR in terms of effects on growth. For example, obese patients have lower plasma GH concentrations but higher GHBP levels, whereas starvation raises GH concentrations and lowers GHBP levels. Patients with abnormalities of the GH receptor (eg, Laron dwarfism) also have a defect reflected in the serum GHBP concentrations; those with decreased numbers of GH receptors have decreased serum GHBP concentrations. Patients who are unable to dimerize the GH receptors to allow activation of the complex or those who have intracellular defects in the JAK-STAT system have no alteration in GHBP concentration, but are short.

GH exerts its effects on growth mainly, but not solely, through the IGFs and their binding proteins. IGF-I and IGF-II have structures similar to that of the proinsulin molecule but differ from insulin in regulation, receptors, and biologic effects. The structure of the IGFs (originally called sulfation factor and then somatomedin), the genes responsible for their production, and information about their physiology have been elucidated. Recombinant IGF is available for clinical use and some recent studies compared the effect of a GH and IGF-I combination to see if it is more beneficial than GH treatment alone. The single copy gene for prepro-IGF-I is located on the long arm of chromosome 12. Posttranslational processing produces the 70-amino acid mature form; alternative splicing mechanisms produce structural variants of the molecule. The IGF-I cell membrane receptor (the type 1 receptor) resembles the insulin receptor in its structure consisting of two alpha and two beta chains. Binding of IGF-I to type 1 receptors stimulates tyrosine kinase activity and autophosphorylation of
Incremental growth charts for boys derived from Flemish children and generally applicable to the US population. Height velocity can be compared with the percentiles labeled on each curve. Increments in height are calculated over periods of no less than 10.2 months (0.85 years) and no more than 13.8 months (1.15 years) in order to avoid the effect of seasonal variation in growth and to reduce the effect of measurement error on the estimation of yearly increment in stature. The yearly increment in stature is calculated as the difference between measurements of height \((g_2 - g_1)\) divided by the size of the interval \((t_2 - t_1)\). This formula is also shown on the charts for yearly increments in height. It is important to plot the increments at an age which corresponds to the centre of the interval, i.e. at the age \((t_1 + t_2)/2\).

tyrosine residues in the receptor. This leads to cell differentiation or division (or both). IGF-I receptors are downregulated by increased IGF-I concentrations, whereas decreased IGF-I concentrations increase IGF-I receptors.

IGF molecules in the circulation are mostly bound to a 6 IGFBPs. IGFBP-1 and IGFBP-3 have been most extensively studied. IGFBP-1 is a 25-kD protein and mainly inhibits IGF-I action. Serum levels of IGFBP-1 are inversely proportional to insulin levels. This protein does not appear to be regulated by GH. It is present in high concentrations in fetal serum and amniotic fluid. Newborn serum concentrations of IGFBP-1 are inversely proportional to birth weight.

IGF-I circulates bound to IGFBP-3 and an acid labile subunit (ALS) in a 150-kD complex. Abnormalities of the ALS lead to decreased growth. Serum IGFBP-3 concentrations are directly proportional to GH concentrations but also to nutritional status. In malnutrition, IGFBP-3 and IGF-I levels fall while GH rises as does IGFBP-1. IGF-I directly regulates IGFBP-3 as well. IGFBP-3 rises with advancing age through childhood, with highest values achieved during puberty; however, the pattern of change of IGF-I at puberty is different from that of IGFBP-3. The molar ratio of IGF-I to IGFBP-3 rises at puberty, suggesting that more IGF-I is free to influence growth during this period.

IGF-I is produced in most tissues and is exported to neighboring cells to act on them in a paracrine manner or on the cell of origin in an autocrine manner. Thus, serum IGF-I concentrations may not reflect the most significant actions of this growth factor. The liver is a major site of IGF-I synthesis, and much of the circulating IGF-I probably originates in the liver; serum IGF-I concentrations vary in liver disease, falling with reductions in functional hepatic mass. IGF-I is a progression factor, so that a cell which has been exposed to a competence factor such as platelet-derived growth factor (PDGF) in stage G0 of the cell cycle and has progressed to G1 can, with IGF-I exposure in G1, undergo division in the S phase of the cell cycle. Aside from the stimulatory effects of IGF-I on cartilage growth, IGF-I has stimulatory effects on hematopoiesis, ovarian steroidogenesis, myoblast proliferation and differentiation, and differentiation of the lens.

IGF-I was in short supply until production by recombinant DNA technology became possible. IGF-I administration in clinical trials increased nitrogen retention and decreased blood urea nitrogen. In GH-resistant patients (Laron dwarfs), IGF-I stimulates growth in the absence of GH. IGF-I has recently been approved by the Food and Drug Administration (FDA) for use in short stature due to primary IGF-I deficiency. IGF-I may prove useful in treatment of various clinical conditions such as catabolic states, including the postoperative period and burns in addition to short stature due to primary IGF-I deficiency. IGF-I supresses GH secretion by a negative feedback mechanism, so that patients who lack GH receptors (Laron dwarfs) or who are unable to produce IGF-I, have elevated GH concentrations but negligible IGF-I concentrations. Rare patients with poor growth who lack IGF-I receptors have elevated concentrations of IGF-I which exerts no biological activity.

B. Thyroid hormone As noted above, newborns with congenital hypothyroidism are of normal length, but if untreated, they manifest exceedingly poor growth soon after birth. Infants with untreated congenital hypothyroidism suffer permanent developmental delay so early treatment is necessary. Newborn screening for congenital hypothyroidism is universal in the United States and most countries. Acquired hypothyroidism leads to a markedly decreased growth rate but no permanent intellectual defects. Bone age advancement is severely delayed in hypothyroidism, usually more so than in GH deficiency, and epiphyseal dysgenesis is seen as calcification of the epiphyses progresses. The normal decrease in the upper to lower segment ratio with age (Figure 6-5) is delayed, and therefore, the ratio is elevated, owing to poor lower limb growth in hypothyroidism.

C. Sex steroids Gonadal sex steroids exert an important influence on the pubertal growth spurt, whereas absence of these factors is not of major importance in prepubertal growth. Gonadal and adrenal sex steroids in excess can cause a sharp increase in growth rate as well as the premature appearance and progression of secondary sexual features. If unabated, increased sex steroids mediated by estrogen will cause advancement of skeletal age, premature epiphyseal fusion, and short adult stature. The pubertal rise in gonadal steroids exerts direct and indirect effects on IGF-I production. Estradiol (secreted or aromatized from testosterone) directly stimulates the production of IGF-I from cartilage and also increases GH secretion, which stimulates IGF-I production indirectly. Both actions appear important in the pubertal growth spurt.
There is correlation between midparental height and the child's cause of short stature is poverty and its effects. Thus, poor nutrition in America. Conversely, when factors are equal, the differences in the same geographic location, variations in stature are often attributable to socioeconomic factors. For example, Japanese individuals born and reared in North America after World War II were generally taller than Japanese-born immigrants to North America. Conversely, when factors are equal, the differences in average height between various ethnic groups are mainly genetic. The newest growth charts for children in the United States published by the Centers for Disease Control and Prevention (CDC) in 2001 are not ethnicity specific because it is believed that the major growth differences between ethnic groups are due to socioeconomic status and nutrition rather than genetic endowments. Indeed, the World Health Organization (WHO) has developed internationally relevant growth charts for all populations.

C. Nutritional factors The influence of malnutrition accounts for much of the socioeconomic discrepancy in height noted above, but malnutrition may occur in the midst of plenty and must always be suspected in disorders of growth. Other factors may be blamed for poor growth when nutritional deficiencies are actually responsible. For example, Sherpas were thought to have short stature mainly because of genetic factors or the effects of high altitude living on the slopes of Mount Everest; however, nutritional supplementation increased stature in this group, demonstrating the effects of adequate nutrition. The developed world places a premium on appearance, and women portrayed as beautiful in the media are characteristically thin. Significant numbers of children, chiefly teenagers, voluntarily decrease their caloric intake even if they are not obese; this accounts for some cases of poor growth. Chronic disease, which hampers adequate nutrition, often leads to short stature. For example, bronchopulmonary dysplasia decreases growth to some degree because it increases metabolic demands, shifting nutrient usage away from growth; improved nutrition increases growth in these patients. Celiac disease is another common disorder that impairs growth, pubertal development, and bone acquisition.

Feeding problems in infants, resulting from inexperience of parents or poor child-parent interactions (maternal deprivation), may account for poor growth. Fad diets, such as poorly constructed vegan diets that put children at risk for vitamin B12 or iron deficiency, as well as major dietary manipulation, such as a severely low-fat diet, may place children at risk for deficiency of fat-soluble vitamins. Deliberate starvation of children by caregivers is an extreme form of child abuse that may be first discovered because of poor growth.

Remarkably, obesity increases IGF-1 concentrations by increasing GH receptors even though GH secretion is suppressed to levels that might suggest GH deficiency. There are significant endocrine changes associated with malnutrition. Decreased GH receptors or postreceptor defects in GH action, leading to decreased production of IGF-1 and decreased concentration of serum IGF-1 are notable. The characteristic results of malnutrition are an elevation of serum GH and a decrease in IGF-1. IGFBP-1, a suppressor of IGF-1 effects, is elevated in obesity.

D. Psychologic factors Aberrant intrafamilial dynamics, psychologic stress, or psychiatric disease can inhibit growth either by altering endocrine function or by secondary effects on nutrition (psychosocial dwarfism or maternal deprivation). It is essential to diagnose those situations that might suggest organic disease states as the management approach is very different.

D. Glucocorticoids Endogenous or exogenous glucocorticoids in excess quickly stop growth; this effect occurs more quickly than weight gain. The absence of glucocorticoids has little effect on growth if the individual is clinically well in other respects (eg, in the absence of hypotension or hypoglycemia).

Other Factors

A. Genetic factors Genetic factors influence adult height. There is correlation between midparental height and the child's height; appropriate methods to utilize this phenomenon and determine the target height for a child are presented in Figure 6-6. There is a change in growth. These effects are sex specific.

B. Socioeconomic factors Worldwide, the most common cause of short stature is poverty and its effects. Thus, poor nutrition, poor hygiene, and poor health influence growth both before and after birth. Parasitic infection by endemic worms is prevalent in less developed countries and severely stunts growth and depletes energy. In people of the same ethnic group and in the same geographic location, variations in stature are often attributable to socioeconomic factors. For example, Japanese individuals born and reared in North America after World War II were generally taller than Japanese-born immigrants to North America. Conversely, when factors are equal, the differences in average height between various ethnic groups are mainly genetic. The newest growth charts for children in the United States...
FIGURE 6-6 Determination of target height in a shorter family. This 10-year-old boy is 124 cm tall, his mother is 61 in tall (adults recall their heights in inches and feet but, if they are available, their height should be actually measured in centimeters), and the father is 63 in tall. Five inches are added to the mother's height to convert her height percentile to the equivalent percentile on a boy's chart. (If we were considering a daughter whose height is plotted on a girl's chart, the mother's height would be directly plotted and 5 in would be subtracted from the father's height to correct his height percentile to the equivalent for an adult woman.) Her corrected height and that of the father are plotted at the far right of the chart where adult heights are displayed. The midparental height is calculated by adding the father's height to the corrected mother's height, and the sum is divided by two; the result is the target height. The limits of 2 standard deviations (SDs) above and below the target height are displayed by plotting 2 SDs (~4 in above and below the target height). This process is equivalent to moving the 50th percentile for the US population to a conceptual 50th percentile for the family under consideration. It is evident that the height of the child, although below the third percentile for the United States, is within the bounds of the percentiles described by ±2 SD from the target height, and the child appears to fit within the genetic pattern of the family. The growth velocity and the degree of skeletal maturation are some of the factors necessary to evaluate this child in more detail.
E. Chronic disease  Many chronic systemic diseases interfere with growth independent of poor nutrition. For example, congestive heart failure and asthma, if uncontrolled, are associated with decreased stature; in some cases, adult height is in the normal range because growth continues over a longer period of time. Children of mothers with HIV infection are often small at birth and have an increased incidence of poor postnatal growth, delayed bone age development, and reduced IGF-I concentrations. In addition, thyroid dysfunction may develop, further complicating the growth pattern. Infants born of HIV-infected mothers, who are not infected themselves, may exhibit catch-up growth.

Catch-up Growth
Correction of growth-retarding disorders may be temporarily followed by an abnormally high growth rate as the child approaches normal height for age. This catch-up growth occurs after initiation of therapy for hypothyroidism and GH deficiency, after correction of glucocorticoid excess, and after appropriate treatment of many chronic diseases such as celiac disease. Catch-up growth is usually short-lived and is followed by a more standard growth rate. Catch-up growth after small-for-gestational-age birth may not be beneficial as it is linked by some evidence to metabolic disease, particularly insulin resistance, in later life.

MEASUREMENT OF GROWTH
Accurate measurement of height is an essential part of the physical examination of children and adolescents. The onset of a chronic disease may often be determined by an inflection point in the growth chart. In other cases, a detailed growth chart indicates a normal constant growth rate in a child observed to be short for age. If careful growth records are kept, a diagnosis of constitutional delay in growth and adolescence or genetic short stature may be made in such a patient; without previous measurements, the child might be subjected to unnecessary diagnostic testing, or months of delay may occur as the child's growth is finally carefully monitored. Poor measurement technique may suggest lack of growth in a child who is growing normally, subjecting the child to unnecessary testing as well.

Height
The National Center for Health Statistics (NCHS) revised the growth charts for children in the United States in 2001 (see Figures 6–1 and 6–2). The new charts display the 3rd and 97th percentiles rather than the 5th and 95th percentiles, and SDs of height for age are also available. Charts displaying BMI by age contain data appropriate for the evaluation of obesity and underweight. All of these charts and are available online or from companies making GH or infant formulas.

But growth charts still leave 6 of 100 healthy children outside of their boundaries, with 3 of 100 below the more worrisome (to parents) lower limits of normal. It is both unnecessary and impractical to evaluate 3% of the population. Instead, the examining physician should determine which short children warrant further evaluation and which ones (and their parents) require only reasurance that they are healthy. When parents see that their child is below the third percentile and in a section of the chart colored differently from the normal area, they assume that there is a serious problem. Thus, the format of the chart can dictate parental reaction to height, because all parents want their children to be in the normal range. Figures 6–1 and 6–2 furnish data necessary to evaluate the height of children at various ages using percentiles or the SD method used by the WHO. SD determination is more useful in extremely short children below the second or first percentile.

Pathologic short stature is usually more than 3.5 SD below the mean, whereas the third percentile is only at 2 SD below the mean. However, a diagnosis of pathologic short stature should not be based on a single measurement. Serial measurements are required because they allow determination of growth velocity, which is a more sensitive index of the growth process than a single determination. A very tall child who develops a postnatal growth problem will not fall 3.5 SD below the mean in height for years but will fall below the mean in growth velocity soon after the onset of the disorder. As Figures 6–3 and 6–4 demonstrate, growth velocity varies at different ages, but as a rough guide, a growth rate of less than 5 cm/y between age 4 years and the onset of puberty is abnormal. In children under 4 years of age, normal growth velocity changes more strikingly with age. Healthy term newborns tend to be clustered in length measurements around 21 in (mostly owing to difficulties in obtaining accurate measurements).

In the ensuing 24 postnatal months, the healthy child's height will enter a channel on the growth chart and remain there throughout childhood. Thus, a child with constitutional delay in growth or genetic short stature, whose height is at the mean at birth and gradually falls to the 10th percentile at 1 year of age and to the 5th percentile by 2 years of age, may in fact be healthy in spite of crossing percentile lines in the journey to a growth channel at the 5th percentile. Although the growth rate may decrease during these years, it should not be less than the fifth percentile for age. A steeper decrease in growth rate may be a sign of disease. Alternatively, catch-up growth after SGA birth may not be beneficial because, as stated before, it is linked by some evidence to metabolic disease, particularly insulin resistance later in life. When a question of abnormal growth arises, previous measurements are essential. Every physician treating children should record supine length (<2 years of age) or standing height (>2 years of age) as well as weight at every office visit. As the child leaves infancy, height and growth velocity should be determined in relation to the standards for the child's age on a graphic chart with indication of the child's position (supine or standing) at measurement which is especially important at the time children switch from lying to standing. Failure to recognize a change in measurement technique as the child moves from lying to standing may falsely suggest a growth problem.

Patients who cannot be measured in the standing position (eg, because of cerebral palsy) require other approaches. The use of arm span is a possible surrogate for the measurement of height, and there are formulas available for the calculation of height based
on the measurement of upper arm length, tibial length, and knee length (see below).

This discussion pre-supposes accuracy of measurements. However, it is reported that screening examinations in the real world fall short of that ideal. Forty-one percent of a presumably normal population screened at a school in England met the criteria for evaluation of abnormal growth (approximately two-thirds grew faster than the normal growth category and one-third were in the slower than normal category), leading to an unreasonable size of a referral population, all due to simple measuring error.

**Relation to Midparental Height: The Target Height**

There is a positive correlation between midparental height (the average of the heights of both parents) and the stature of a child. One way to use this relationship of parents’ heights to the expected heights of children within a given family is to calculate target adult height range using parents’ heights, correcting these heights for the sex of the child and plotting the results on the child’s growth chart.

There is an average 5-in difference between adult men and women in the United States. Thus, for boys, add 5 in to the mother’s height, add the result to the father’s height, and divide by 2. This is the target height, and it is expected that sons of these parents will reach a height within 2 SD of this target—or, for simplicity, within 4 in above or below the target height. (Two inches approximates 1 SD for adult stature.) For girls, subtract 5 in from the father’s height and add the result to the mother’s height and divide by 2, leading to the target height for the girl. The range for girls will also be within 4 in above and below this target. In effect, this corrects the North American growth charts for the particular family being considered. The calculated target height corresponds to the 50th percentile for the family, and the limits of the ±2 SD approximate the 5th to 95th percentile for the family. This method is useful only in the absence of disease affecting growth, and the prediction is more valid when the parents are of similar rather than of widely different heights.

Figures 6–6 and 6–7 demonstrate the calculation of target height and the ranges. When there is a large discrepancy between the heights of the mother and the father, prediction of target height becomes difficult. A child may follow the growth pattern of the shorter parent more closely than the midparental height. A boy may, for example, follow the growth pattern of a short mother rather than a taller father.

A parent who spent the growing years in poverty, with chronic disease, or in an area of political unrest might have shorter adult height, due to nutritional factors or disease, that may not be passed on to the children. Of course, the height of an adopted child will have no relationship to the adoptive parents’ heights. All of these factors must be determined by history.

**Technique of Measurement**

Length and height must be measured accurately. Hasty measurements derived from marks made on paper at an infant’s foot and head while the infant is squirming on the paper on the examining table are useless. Infants must be measured on a firm horizontal surface with a permanently attached rule, a stationary plate perpendicular to the rule for the head, and a movable perpendicular plate for the feet. One person should hold the head stable while another makes sure the knees are straight and the feet are firm against the movable plate. Children over age 2 are measured standing up. Standing height is on the average 1.25 cm less than supine length, and it is essential to record the position of measurement each time during the change over from lying to standing height at 2 to 3 years of age; shifting from supine height at 2 years to standing height at 2½ years can falsely suggest an inadequate growth rate over that 6-month period.

These measurements cannot be accurately performed with the measuring rod that projects above the common weight scale; the rod is too flexible, and the scale foot plate will in fact drop lower when the patient stands on it. Instead, height should be measured with the child standing back to the wall with heels at the wall, ankles together, and knees and spine straight against a vertical metal rule permanently attached to the wall or to a wide upright board. The child’s head is to be horizontal with the eyes looking ahead and the chin gently elevated if necessary. Height is measured at the top of the head by a sliding perpendicular plate (or square wooden block). A Harpenden stadiometer is a mechanical measuring device capable of such accurate measurement. It is preferable to measure in the metric system, because the smaller graduations make measurements more accurate by minimizing the effect of rounding off numbers.

Growth is not constant but is characterized by short spurts and periods of slowed growth. The interval between growth measurements should be adequate to allow an accurate evaluation of growth velocity. Appropriate sampling intervals vary with age but should not be less than 3 months in childhood, with a 6-month interval being optimal.

The problem of measuring the growth rate of children with orthopedic deformities or contractures is significant, because these patients may have nutritional and/or endocrine disorders as well. The measurement of knee height, tibial length, or upper arm length correlates well with standing height \((r = 0.97)\); thus, these measurements may be translated, using special linear regression equations, into total height, which is then plotted on standard growth charts. Specialized laser-calibrated devices to measure tibial length (kneometry) are reported to be accurate for assessment of short-term growth down to weekly intervals.

In addition to height or length, other significant measurements include: (1) the frontal–occipital head circumference; (2) horizontal arm span (between the midspreader middle fingertips with the patient standing against a flat backboard); and (3) the upper segment (US) to lower segment (LS) ratio. For the latter, the LS is measured from the top of the symphysis pubis vertically to the floor with the patient standing straight, and the US is determined by subtracting the LS from the standing height measurement noted above. (Normal standard US-LS ratios are shown in Figure 6–5.) These measurements become important in skeletal or reproductive disorders. Sitting height is used in some clinical studies of growth, but the sitting stadiometer is rarely available.
FIGURE 6-7 Determination of target height in a taller family. This 10-year-old boy is 124 cm tall just as in Figure 6–6, his mother is 65 in tall, and the father is 73.5 in tall. Five inches are added to the mother’s height to convert her height percentile to the equivalent percentile on a boy’s chart. (If we were considering a daughter whose height is plotted on a girl’s chart, the mother’s height would be directly plotted and 5 in would be subtracted from the father’s height to correct his height percentile to the equivalent height percentile for an adult woman.) Her corrected height and that of the father are plotted at the far right of the chart where adult heights are displayed. The midparental height is calculated by adding the father’s height to the corrected mother’s height, and the sum is divided by 2; the result is the target height. The limits of 2 standard deviations (SDs) above and below the target heights are displayed by plotting 2 SDs (about 4 in. above and below the target height). This is equivalent to moving the 50th percentile for the United States population to a conceptual 50th percentile for the family under consideration. It is evident that the height of the child, which is below the third percentile for the United States, is even farther outside the bounds of the percentiles described by ±2 SD from the target height, and, thus, the child appears to fall far outside the genetic pattern of the family, and this is of clinical concern. The growth velocity and the degree of skeletal maturation are some of the other factors necessary to evaluate this analysis in more detail.
**Height and Growth Rate Summary**

In summary, we may consider three criteria for pathologic short stature: (1) height more than 3.5 SD below the mean for chronologic age; (2) growth rate more than 2 SD below the mean for chronologic age; and (3) height more than 2 SD below the target height when corrected for midparental height.

**Weight**

The measured weight should be plotted for age on standard graphs developed by the NCHS, which are available online or from various companies (http://www.cdc.gov/growthcharts/clinical_charts.htm). BMI charts displaying percentiles of BMI (weight in kilograms divided by height in meters squared) are widely available and provide an essential method to assess nutritional status.

**SKELETAL (BONE) AGE**

Skeletal development is a reflection of physiologic maturation. For example, menarche is better correlated with a bone age of 13 years than with a given chronologic age. However, bone age is as variable as chronologic age at the onset of puberty.

Estrogen plays the major role in advancing skeletal maturation. Patients with aromatase deficiency, who cannot convert testosterone to estradiol, and patients with estrogen receptor defects, who cannot respond to estrogen, grow taller well into their twenties without having epiphyseal fusion. Bone age indicates remaining growth available to a child and can be used to predict adult height. However, bone age is not a definitive diagnostic test of any disease; it can assist in diagnosis only when considered along with other factors.

Bone age is determined by comparing the shapes and stage of fusion of epiphyses or bones on the patient’s radiograph with an atlas demonstrating normal skeletal maturation for various ages. The Greulich and Pyle atlas of radiographs of the left hand is commonly used in the United States, but other methods of skeletal age determination, such as Tanner and Whitehouse maturity scoring, are preferred in Europe. Any bone age more than 2 SD above or below the mean for chronologic age is out of the normal range. The standard deviation of bone age readings for chronological age is a full year by the midteenage years, indicating the imprecision of prediction. Further, there appear to be ethnic differences in bone age maturation that is not reflected in the guidelines for interpretation. For newborn infants, knee and foot radiographs are compared with an appropriate bone age atlas. For late pubertal children, just before epiphyseal fusion, the knee atlas reveals whether any further growth can be expected or whether the epiphyses are fused. All the methods are imperfect, as there is great variation in bone age in relation to chronologic age even in typically developing children.

Height is predicted most often in the United States by determining bone age and height at the time the radiograph was taken and consulting the Bayley-Pinneau tables in the Greulich and Pyle skeletal atlas of the hand to determine the amount of growth left before epiphyseal fusion. Height prediction by any method becomes more accurate as the child approaches the time of epiphyseal fusion.

**DISORDERS OF GROWTH**

**SHORT STATURE DUE TO NONENDOCRINE CAUSES**

There are many causes of decreased childhood growth and short adult height (Table 6–1). The following discussion covers only the more common conditions, emphasizing those that might be included in an endocrine differential diagnosis. Shorter than average stature need not be considered a disease, because variation in stature is a normal feature of human beings, and a normal child should not be burdened with a misdiagnosis. Although the classifications described below may apply to most patients, some will still be resistant to definitive diagnosis.

1. **CONSTITUTIONAL SHORT STATURE**

Constitutional short stature (constitutional delay in growth and adolescence) is not a disease but rather a variation from normal for the population and is considered a slowing of the pace of development. There is usually an associated delay in pubertal development as well as a decrease in growth (see Constitutional Delay in Adolescence, Chapter 15). It is characterized by moderate short stature (usually not far below the third percentile), thin habitus, and retardation of bone age. The family history often includes similarly affected members (eg, mother with delayed menarche or father who first shaved later than peers and continued to grow past his teen years).

All other causes of decreased growth must be considered and ruled out before this diagnosis can be made with confidence. The patient may be considered physiologically (but not mentally) delayed in development. Characteristic growth patterns include normal birth length and height, with a gradual decrease in percentiles of height for age by 2 years; on the contrary, a rapid decrease in percentiles is an ominous sign of pathology. Onset of puberty is usually delayed for chronicologic age but normal for skeletal age. Adult height is in the normal range but varies according to parental heights. The height is often less than the predicted height, because growth is less than expected during puberty. Aromatase inhibitors have been used in clinical studies for boys with constitutional delay in growth; they inhibit the conversion of androgens to estrogen so that bone age does not advance and growth continues longer. While this is not a treatment in general clinical use, most studies suggest that it causes no ill effects, although long-term data dealing with effects on bone mineral density as a result of the use of these agents are not available. Elevated testosterone levels and testicular enlargement result from aromatase inhibition.

2. FAMILIAL SHORT STATURE

Short stature may also occur in a familial pattern without retarded bone age or delay in puberty; this is considered familial short stature. Affected children are closer to the mean on the normal population growth charts after familial correction for mid-parental height by calculation of the target height (see Figures 6-6 and 6-7). Adult height depends on the mother’s and father’s heights. Patients with the combination of constitutional short stature and genetic short stature are quite noticeably short due to both factors, and these patients are most likely to seek evaluation. Boys are brought to consultation more often than girls. Children in these families may be born AGA but exhibit slowed growth in the first 2 postnatal years; this process is gradual in comparison to the striking changes in growth rate that are characteristic of diseases that primarily affect growth, but it may still be difficult to tell the difference without extended observation.

3. PREMATURITY AND SGA

Although the majority of SGA infants show catch-up growth, about 20% may follow a lifelong pattern of short stature. In comparison, appropriate-for-gestational-age premature infants usually catch up to the normal range of height and weight by 1 to 2 years of age. Severe premature infants with birth weights less than 800 g (that are appropriate for gestational age), however, may maintain their growth retardation at least through their third year; only follow-up studies will determine whether this group of premature infants reaches reduced adult heights. Bone age and yearly growth rate are normal in SGA patients until puberty occurs, and the patients are characteristically thin. SGA is now recognized as a risk factor for premature thelarche or early menarche, so bone age may advance more rapidly after childhood (Chapter 15).

Within this grouping are many distinctive genetic or sporadically occurring syndromes. The most common example is Russell-Silver dwarfism (OMIM #180860), characterized by small size at birth, triangular facies, and a variable degree of asymmetry of the extremities; this condition is due to epigenetic changes of DNA methylation at the telomeric imprinting control region (ICR1) on chromosome 11p15, involving the H19 and IGF-II genes or to maternal, uniparental disomy of chromosome 7. Intrauterine infections with Toxoplasma gondii, rubella virus, cytomegalovirus, herpesvirus, and HIV are noted to cause SGA. Furthermore, maternal drug usage, either illicit (eg, cocaine), legal but ill-advised (eg, alcohol during pregnancy), or legally prescribed medication (eg, phenytoin) may cause SGA. Reports of other syndromes in SGA infants can be found in sources listed in the bibliography.

Although SGA is not an endocrine cause of short stature, GH treatment is approved by the FDA and leads to increased adult height. Those SGA infants with the Δ3-isosofon (genomic deletion of exon 3) of the GH receptor (GHR) are more likely catch up on GH therapy, as are girls with Turner syndrome. Remarkably, this same isofon is associated with reduced prenatal growth. The presence of this isofon does not guarantee taller adult stature even if growth velocity is greater while on GH treatment.

There are many endocrine associations with being born SGA including premature adenarche, puberty, and menarche in girls and dyslipidemia and insulin resistance in boys and girls. Girls have a predilection to develop PCOS after being SGA. GH antagonizes the action of insulin given the tendency for SGA children to have
insulin resistance, there may be concerns regarding the potential additive effect. Recent studies of insulin sensitivity in SGA subjects receiving GH treatment indicate that in most cases the effects are not long lasting and do not seem to have clinical significance.

4. SYNDROMES OF SHORT STATURE

Many syndromes include short stature as a characteristic feature, and some also include SGA. Common conditions are described briefly below. Laurence-Moon, Biedl-Bardet, or Prader-Willi syndrome may combine obesity with short stature (do the endocrine conditions, hypothyroidism, glucocorticoid excess, pseudohypoparathyroidism with Albright Hereditary Osteodystrophy (OMIM #103580), and GH deficiency). Moderately obese but otherwise normal children without these conditions tend to have slightly advanced bone age and advanced physiologic maturation with increased stature during childhood and early onset of puberty. Thus, short stature in an overweight child must be considered to have an organic cause until proven otherwise.

Turner Syndrome and Its Variants

Although classic Turner syndrome of 45,XO gonadal dysgenesis (see Chapter 14) is often correctly diagnosed, it is not always appreciated that any phenotypic female with short stature may have a variant of Turner syndrome. Thus, a karyotype determination should be performed for every short girl if no other cause for short stature is found, especially if puberty is delayed (see Chapter 15). The short stature of Turner syndrome is due to a mutation of the short stature homeobox (SHOX) gene on the short (p) arm in the pseudoautosomal region of the X chromosome (OMIM #312865). A mutation of the SHOX gene may also cause the Léri-Weill dyschondrosteosis form of short-limbed dwarfism (OMIM #127300).

Noonan Syndrome (Pseudo-Turner Syndrome) (OMIM #163950)

This syndrome shares several phenotypic characteristics of Turner syndrome, including short stature, webbed neck, low posterior hairline, and facial resemblance to Turner syndrome, but the karyotype is 46,XX in the female or 46,XY in the male with Noonan syndrome, and other features clearly differentiate it from Turner syndrome. For example, in Turner syndrome, there is characteristically left-sided heart disease and in Noonan syndrome right-sided heart disease. Noonan syndrome is an autosomal dominant disorder at gene locus 12q24 (see Chapter 14). GH therapy is approved by the FDA for Noonan syndrome to increase height. About half of patients with Noonan syndrome have a mutation of the protein tyrosine phosphatase nonreceptor type 11 (PTPN11) (OMIM #176876). These children have a decreased response to GH treatment and tend to have low IGF-1 and ALS with normal IGFBP-3 levels.

Prader-Willi Syndrome (OMIM #176270)

This condition is characterized by poor intrauterine movement, acromicria (small hands and feet), developmental delay, and almond-shaped eyes along with infantile hypotonia. Short stature is common but not invariable. Although hypotonia limits feeding in infancy, later insatiable hunger develops and leads to extreme obesity. Glucose intolerance and delayed puberty are characteristic. This syndrome is due to deletion of the small nuclear riboprotein polypeptide N (SNRPN) on paternal chromosome 15 (q11-13), uniparental disomy of maternal chromosome 15, or methylation of this region of chromosome 15 of paternal origin. If a mutation of the same locus is derived from the mother, Angelman syndrome results. GH therapy is approved by the FDA for Prader-Willi syndrome to improve body composition and muscle strength. There is the possibility of fatal complications of GH given in the presence of obstructive sleep apnea, so sleep patterns must be carefully monitored.

Laurence-Moon Syndrome and Biedl-Bardet Syndrome

Biedl-Bardet syndrome (OMIM #209900), associated with mutations on chromosome 16 (q21), is characterized by developmental delay, retinitis pigmentosa, polydactyly, and obesity. Laurence-Moon syndrome (OMIM #245800) is characterized by developmental delay, retinitis pigmentosa, delayed puberty, and spastic paraplegia. Both syndromes are associated with poor growth and obesity. They are inherited as autosomal recessive disorders. Study of large Canadian kindreds once again suggests combining the syndromes into one, as was done in the past. Biedl-Bardet syndrome is thought to be caused by a defect of the basal body of primary cilia resulting in cellular dysfunction.

Autosomal Chromosomal Disorders and Syndromes

Numerous other autosomal disorders and syndromes of dysmorphic children with or without developmental disorders are characterized by short stature. Often the key to diagnosis is the presence of several major or minor physical abnormalities that indicate the need for karyotype determination. Other abnormalities may include unusual body proportions, such as short extremities, leading to aberrant US:L S ratios, and arm spans quite discrepant from stature. Details of these syndromes can be found in the references listed at the end of the chapter.

Skeletal Dysplasias

There are more than 100 known types of genetic skeletal dysplasias (osteochondrodysplasias). Often they are noted at birth because of the presence of short limbs or trunk, but some are only diagnosed after a period of postnatal growth. The most common condition is autosomal dominant achondroplasia (OMIM #100800). This condition is characterized by short extremities in the proximal regions, a relatively large head with a prominent forehead due to frontal bossing and a depressed nasal bridge, and lumbar lordosis in later life. Adult height is decreased, with a mean of 132 cm for males and 123 cm for females. Intelligence is normal. Mutations of
the tyrosine kinase domain of the fibroblast growth factor receptor 3 (FGFR3) gene locus 4p16.3 (OMIM #134934) have been identified in this condition. Limb lengthening operations are used to increase stature in a few centers but the techniques are complex, and complications appear to be frequent.

Height, height velocity, weight, and BMI curves from birth to 16 years of age are available for achondroplasia. Children with achondroplasia who have received GH have in some instances demonstrated improved growth; however, atlanto-occipital dislocation is reported. The potential for abnormal brain growth and its relationship to aberrant skull shape mandates the caution that GH is not established therapy for this condition.

Hypochondrodysplasia (OMIM #146000) is manifested on a continuum from severe short-limbed dwarfism to apparent normal development until puberty, when there is an attenuated or absent pubertal growth spurt, leading to short adult stature. This disorder may be caused by an abnormal allele in the same gene causing achondroplasia (FGFR3 at locus 4p16.3).

5. CHRONIC DISEASE

Severe chronic disease involving any organ system can cause poor growth in childhood and adolescence. In many cases, there are adequate physical findings by the time of consultation to permit diagnosis. In some cases, however—most notably celiac disease and regional enteritis—short stature and decreased growth may precede obvious signs of malnutrition or gastrointestinal disease. In some cases, growth is only delayed and may spontaneously increase. In others, growth can be increased by improved nutrition; patients with gastrointestinal disease, kidney disease, or cancer may benefit from nocturnal parenteral nutritional infusions. Cystic fibrosis combines several causes of growth failure: lung disease impairs oxygenation and predisposes to chronic infections, gastrointestinal disease decreases nutrient availability, and late-developing abnormalities of the endocrine pancreas cause diabetes mellitus. Children with cystic fibrosis experience decreased growth rates after 1 year of age following a normal birth size. The pubertal growth spurt is often decreased in magnitude and delayed in its timing; secondary sexual development may be delayed, especially in those with impaired pulmonary function. Study of growth in these patients allowed development of a cystic fibrosis specific growth chart and indicates that a reasonable outcome is an adult height in the 25th percentile. GH treatment in several studies demonstrated increased growth and weight gain in cystic fibrosis.

Children with congestive heart failure due to a variety of congenital heart diseases or acquired myocarditis grow poorly unless successfully treated with medications or surgery. Patients with cyanotic heart disease experience less deficits in growth.

Celiac disease is very common and may present initially with growth failure. Early diagnosis can be made by determination of tissue transglutaminase antibodies and IgA values while on a normal wheat-containing diet. However, a biopsy may still be required for diagnosis. On a gluten-free diet, patients experience catch-up growth. Adult height may still be impaired, depending on the duration of the period without treatment. Untreated patients with celiac disease have decreased serum IGF-I concentrations, presumably due to malnutrition, while IGF-I concentrations rise with dietary therapy. Thus, serum IGF-I in this condition, as in many with nutritional deficiencies, is not a reliable indicator of GH secretory status.

Crohn disease is associated with poor growth and decreased serum IGF-I concentrations. On an elemental diet, growth rate increases, and with glucocorticoid therapy (moderate doses), growth rate improves even though serum IGF-I decreases.

Patients with chronic hematologic diseases, such as sickle cell anemia or thalassemia, often have poor growth, delayed puberty, and short adult stature: iron deposition may itself cause endocrine complications. Juvenile rheumatoid arthritis may compromise growth before or after therapy with glucocorticoids. GH treatment is reported to increase the growth rate of these children, but it is too early to draw conclusions about the efficacy and safety of such therapy in juvenile rheumatoid arthritis. Hypophosphatemic vitamin D-resistant rickets usually leads to short adult stature, but treatment with 1,25-hydroxyvitamin D and oral phosphate in most cases will improve bone growth as well as increase adult stature. Chronic renal disease is known to interfere with growth, but increased growth rate occurs with improved nutrition and GH therapy which is approved for affected children.

Proximal or distal renal tubular acidosis (RTA) may both cause short stature. Proximal RTA demonstrates bicarbonate wasting at normal or low plasma bicarbonate concentrations; patients have hypokalemia, alkaline urine pH, severe bicarbonaturia, and later, acidemia. The condition may be inherited, sporadic, or secondary to many metabolic or medication-induced disorders. Distal RTA is caused by inability to acidify the urine; it may occur in sporadic or familial patterns or be acquired as a result of metabolic disorders or medication. Distal RTA is characterized by hypokalemia, hypercalcuiuria, and occasional hypocalcemia. The administration of bicarbonate is the primary therapy for proximal RTA, and proper treatment can substantially improve growth rate.

Obstructive sleep apnea is associated with poor growth. The amount of energy expended during sleep in children with sleep apnea appears to limit weight and length gain, a pattern which reverses with the resolution of the obstruction. Paradoxically, obstructive sleep apnea can be found with obesity that is more likely to be found with tall stature.

Hemoglobin, white blood cell count, erythrocyte sedimentation rate, serum carotene and folate levels, tissue transglutaminase antibodies, IgA values, plasma bicarbonate levels, and liver and kidney function should be assessed in short but otherwise apparently healthy children before endocrine screening tests are performed. Urinalysis should be done, with attention to specific gravity (to rule out diabetes insipidus) and ability to acidify urine (to evaluate possible RTA). All short girls without another diagnosis should undergo karyotype analysis to rule out Turner syndrome. A list of chronic diseases causing short stature is presented in Table 6–1.

6. MALNUTRITION

Malnutrition (other than that associated with chronic disease) is the most common cause of short stature worldwide and is the cause of much short stature in the developing world. Diagnosis in
the developed world is based on historical and physical findings, particularly the dietary history. Food faddism and anorexia nervosa—as well as excessive voluntary dieting—can cause poor growth. Infection with parasites such as Ascaris lumbricoides or Giardia lamblia can decrease growth and is the cause of much short stature in the developing world.

Specific nutritional deficiencies can have particular effects on growth. For example, severe iron deficiency can cause a thin habitus as well as growth retardation. Zinc deficiency can cause anorexia, decreased growth, and delayed puberty, usually in the presence of chronic systemic disease or infection. Children with nutritional deficiencies characteristically demonstrate failure of weight gain before growth rate decreases, and weight for height decreases. This is in contrast to many endocrine causes of poor growth, where weight for height remains in the normal or high range. This simple rule often determines whether nutritional or endocrine evaluations are most appropriate. There are no simple laboratory tests for diagnosis of malnutrition. Serum IGF-I concentrations are low in malnutrition, as they are in GH deficiency. This distinction is important since misdiagnosing GH deficiency in the face of malnutrition would be tragic as well as costly.

7. MEDICATIONS

Children with hyperactivity disorders (or those incorrectly diagnosed as such) are frequently managed with chronic methylphenidate administration or similar medication. In larger doses, these agents can decrease weight gain—probably because of their effects on appetite—and they have been reported to lower growth rate, albeit inconsistently. These drugs must be used in moderation and only in children who definitely respond to them during careful evaluation and follow-up. Exogenous glucocorticoids are a potent cause of poor growth (see discussed later), as are excessive endogenous glucocorticoids.

SHORT STATURE DUE TO ENDOCRINE DISORDERS

1. GROWTH HORMONE DEFICIENCY AND ITS VARIANTS

The incidence of GH deficiency is estimated to be between 1:4000 and 1:3500, so the disorder should not be considered rare. Using the conservative criteria of height (less than third percentile) and growth velocity (<5 cm/yr for inclusion in the study), the incidence of endocrine disease in 114,881 Utah children who met these cutoff results was 5%, with a higher incidence in boys than girls by a ratio of more than 2.5:1. In this population, 48% of the children with Turner syndrome or GH deficiency were not diagnosed prior to the careful evaluation afforded by this study.

There may be abnormalities at various levels of the hypothalamic-pituitary, GH-IGF-I axis. Most patients with idiopathic GH deficiency apparently lack GHRH. One autopsied GH-deficient patient had an adequate number of pituitary somatotrophs that contained considerable GH stores. Thus, the pituitary gland produced GH, but it could not be released. Long-term treatment of such patients with GHRH can cause GH release and increase growth. Patients with pituitary tumors or those rare patients with congenital absence of the pituitary gland lack somatotrophs. Several kindreds have been described that lack various regions of the GH gene responsible for producing GH. Alternatively, gene defects responsible for the embryogenesis of the pituitary gland may cause multiple pituitary deficiencies. Absence of the PITI gene encoding a pituitary-specific transcription factor causes deficient GH, TSH, and prolactin synthesis and secretion. Mutations of the prophet of PIT 1 (PROPI) gene cause deficiencies of GH, TSH, FSH, LH, and ACTH production.

Congenital Growth Hormone Deficiency

Congenital GH deficiency presents with slightly decreased birth length (~1 SD), but the growth rate decreases in some cases strikingly soon after birth. The disorder is identified by careful measurement in the first year and becomes more obvious by 1 to 2 years of age. Patients with classic GH deficiency have short stature, increased fat mass leading to a chubby or cherubic appearance with immature facial appearance, immature high-pitched voice, and delay in skeletal maturation. Less severe forms of partial GH deficiency are described with few abnormal characteristics apart from short stature and delayed bone age. GH-deficient patients lack the lipolytic effects of GH, partially accounting for the pudgy appearance. There is a higher incidence of hyperlipidemia with elevated total cholesterol and low-density lipoprotein (LDL) cholesterol in GH deficiency, and longitudinal studies demonstrate increases in high-density lipoprotein (HDL) cholesterol levels with GH treatment. Males with GH deficiency may have microphallus (penis <2 cm in length at birth), especially if the condition is accompanied by gonadotropin-releasing hormone (GnRH) deficiency (Figure 6–8). GH deficiency in the neonate or child can also lead to symptomatic hypoglycemia and seizures; if ACTH deficiency is also present, hypoglycemia is usually more severe. The differential diagnosis of neonatal hypoglycemia in a full-term infant who has not sustained birth trauma must include neonatal hypopituitarism. If microphallus (in a male subject), optic hypoplasia, or some other midline facial or central nervous system defect is noted, the diagnosis of congenital GH deficiency is more likely (see later). Congenital GH deficiency is also correlated with breech delivery. Intelligence is normal in GH deficiency unless repeated or severe hypoglycemia is present or a significant anatomic defect has compromised brain development. When thyrotropin-releasing hormone (TRH) deficiency is also present, there may be additional signs of hypothyroidism. Secondary or tertiary congenital hypothyroidism is not usually associated with physical findings of cretinism or developmental delay as is congenital primary hypothyroidism, but a few cases of isolated TRH deficiency and severe mental retardation have been reported.

Congenital GH deficiency may present with midline anatomic defects. Optic hypoplasia with visual defects ranging from nystagmus to blindness is found with variable hypothalamic endocrinopathies in 71.7% of one series: 64.1% of subjects had GH axis abnormalities, 48.5% hyperprolactinemia, 34.9% hypothyroidism,
Thus, the patient had multiple defects in the hypothalamic-pituitary growth axis including decreased secretion of GH, ACTH, and TSH probably due to deficient secretion of hypothalamic hormones. He was given six doses of 2000 units each of human chorionic gonadotropin (hCG) intramuscularly over 2 weeks, and plasma testosterone rose to 62 ng/dL, indicating normal testicular function. He was then treated with 25 mg of testosterone enanthate every month for 3 months, and his phallus enlarged to 3.5 x 1.2 cm without significant advancement of bone age. With hGH therapy (0.05 mg/kg intramuscularly every other day), he grew at a greater than normal rate for 12 months (catch-up growth), and growth then continued at a normal rate.

17.1% adrenal insufficiency, and 4.3% diabetes insipidus (DI) in this group of 47 subjects. About half of patients with optic hypoplasia have absence of the septum pellucidum on computed tomography (CT) or magnetic resonance imaging (MRI), leading to the diagnosis of septo-optic dysplasia. Septo-optic dysplasia is most often sporadic in occurrence. Affected individuals are reported with mutations of the homeobox gene expressed in ES cells (HESXI) (OMIM #601802) and septo-optic dysplasia (OMIM #182230). Cleft palate or other forms of oral dysraphism are associated with GH deficiency in about 7% of cases. Such children may need nutritional support to improve their growth. An unusual midline defect associated with GH deficiency is described in children with a single maxillary incisor.

Congenital absence of the pituitary gland, which occurs in an autosomal recessive pattern, leads to severe hypopituitarism with hypoglycemia. Affected patients have shallow development of or absence of the sella turcica. This defect is quite rare but clinically devastating if treatment is delayed. This is the most common MRI manifestation of PROP1 gene mutation (OMIM #601538).

Hereditary GH deficiency is described in several kindreds. Various genetic defects of the GHN gene (17q22-24) occur in affected families. Isolated type 1A GH deficiency (IGHDIA OMIM #262400) is inherited in an autosomal recessive pattern. Patients have deletions, frameshifts, and nonsense mutations in the GHN gene. Unlike those with classic sporadic GH deficiency, some of these children are reported with significantly shortened birth lengths. Patients with absent or abnormal GH genes do initially respond to exogenous human GH (hGH) administration, but some soon develop high antibody titers that eliminate the effect of therapy. One reported kindred had a heterogeneous response: one sibling continued to grow and did not develop blocking antibodies, while the opposite effect occurred in two other siblings in the same family. Patients with high titers of blocking antibodies are reported to benefit from IGF-I therapy in place of GH therapy. Isolated GH deficiency (IGHD) type 1B (OMIM #612781) patients have autosomal recessive splice site mutations and incomplete GH deficiency. They are less severely affected. Type 2 (IGHD2) (OMIM #173100) patients have autosomal dominant GH deficiency due to splice site or nonsense mutations. Type 2 patients have X-linked GH deficiency often associated with hypogammaglobulinemia. A few patients are described with abnormalities of the GHRH gene, whereas others are described with mutant GH genes. Mutations in pituitary transcription factors can lead to various combinations of pituitary hormone deficiencies. Mutations in Pit1/POU1F1 (POU class 1 homeobox 1) (OMIM #173110) lead to GH, PRL, TSH deficiencies. Mutations in PROP 1 (Prophet of PIT1, paired-like homeodomain transcription factor) (OMIM #601538) leads to GH, PRL, TSH, LH, FSH, and sometimes ACTH deficiency. Mutations in HESXI lead to GH, PRL, TSH, LH, FSH, ACTH, IGHD, and CPHD deficiencies.

### Acquired Growth Hormone Deficiency

Onset of GH deficiency in late childhood or adolescence, particularly if accompanied by other pituitary hormone deficiencies, is ominous and may be due to a hypothalamic-pituitary tumor. The development of posterior pituitary deficiency in addition to anterior pituitary deficiency makes a tumor even more likely. The empty sella syndrome is more frequently associated with hypothalamic-pituitary abnormalities in childhood than in adulthood; thus, GH deficiency may be found in affected patients.

Some patients, chiefly boys with constitutional delay in growth and adolescence, may have transient GH deficiency on testing before the actual onset of puberty. When serum testosterone concentrations begin to increase in these patients, GH secretion and...
growth rate also increases. This transient state may incorrectly suggest bona fide GH deficiency but does not require therapy. A priming dose of estrogen is sometimes invoked to increase growth hormone secretion maximally so that bone fide GH deficiency is not diagnosed spuriously. Central nervous system conditions that cause acquired GH deficiency (e.g., craniopharyngiomas, germinomas, gliomas, histiocytosis X) are described in Chapter 4. It is remarkable that after craniopharyngioma removal, some patients, mainly obese subjects, continue to grow quite well in spite of the absence of GH secretion. This persistent growth appears to be caused by hyperinsulinemia.

Cranial irradiation of the hypothalamic-pituitary region to treat CNS tumors or acute lymphoblastic leukemia may result in GH deficiency starting approximately 12 to 18 months later, owing to radiation-induced hypothalamic (or perhaps pituitary) damage. Higher doses of irradiation such as the 24-Gy regimen previously used for the treatment of central nervous system leukemia have greater effect (adult height may be as much as 1.7 SD below the mean) than the lower (e.g., 18 Gy) regimens and higher doses are more likely to cause TSH, ACTH, and gonadotropin deficiency as well as hyperprolactinemia or even precocious puberty. Girls treated at an early age with this lower regimen still appear to be at risk of growth failure. All children must be carefully observed for growth failure after irradiation since growth failure may occur years later. If these patients receive spinal irradiation, upper body growth may also be impaired, causing a decreased US-LS ratio and a further tendency to short stature. Abdominal irradiation for Wilms tumor may also lead to decreased spinal growth (estimated loss of 10 cm height from megavoltage therapy at 1 year of age, and 7 cm from treatment at 5 years of age). Others receiving gonadal irradiation (or chemotherapy) have impaired gonadal function, lack onset or progression of puberty, and/or have diminished or absent pubertal growth spurt. Recent data suggests chemotherapy for acute lymphocytic leukemia without irradiation may also lead to GH deficiency, so follow-up of growth after treatment for cancer is always necessary.

CNS trauma is well established as a cause of hypopituitarism in adults. Cross sectional studies in children reveal both high and low rates of subsequent hypopituitarism after head trauma but the rare prospective studies demonstrate lower risk in children than in adults.

Other Types of GH Dysfunction

Primary IGF-I deficiency is due to GH insensitivity (Laron syndrome and its variants (OMIM #262500). These disorders reflect GH receptor or postreceptor defects that are inherited in autosomal recessive fashion. The soluble GH-binding protein (GHBP) found in the circulation derives from the extracellular portion of the GH receptor, and since they derive from the same gene, circulating GHBP reflects the abundance of GH receptors. Patients with decreased or absent GH receptors have decreased serum GHBP levels, whereas those with postreceptor defects have normal GHBP concentrations. Affected children are found throughout the world, including Israel, where the syndrome was first reported, and Ecuador, where several generations of a large kindred were studied in great detail. Defects in various kindreds include nonsense mutations, deletions, RNA processing defects, and translational stop codons. GH/JAK-STAT axis signal-transduction impairment leads to short stature when this intracellular system fails to activate in response to receptor occupancy by the GH ligand. Defects in the dimerization of the GH receptors also lead to short stature. Serum GH is elevated, due to decreased or absent IGF-I which results in lack of negative feedback inhibition. The condition does not respond to GH treatment. Patients are short at birth, confirming the importance of IGF-I in fetal growth (demonstrated previously in murine IGF-I gene knockout studies). About one-third have hypoglycemia, and half of boys have microphallus. Patients treated with recombinant IGF-I grow at an improved rate but do not respond quite as well to IGF-I as GH-deficient children do to GH treatment, indicating that GH may have a direct role in fostering growth above and beyond that conferred by IGF-I.

Other forms of GH resistance are described, but the majority of patients with disorders of the GH axis have abnormalities of GH secretion, not action. Very short, poorly growing children with delayed skeletal maturation, normal GH and IGF-I values, and no signs of organic disease have responded to GH therapy with increased growth rates equal to those of patients with bona fide GH deficiency. These patients may have a variation of constitutional delay in growth or genetic short stature, but a subtle abnormality of GH secretion or action is possible.

Pygmies (OMIM #265850) have normal serum GH, low IGF-I, and normal IGF-II concentrations. They have a congenital inability to produce IGF-I, which has greater importance in stimulating growth than IGF-II. Pygmy children are reported to lack a pubertal growth spurt, suggesting that IGF-I is essential to attain a normal peak growth velocity. Efe pygmies, the shortest of the pygmies, are significantly smaller at birth than neighboring Africans who are not pygmies, and their growth is slower throughout childhood, leading to statures displaced progressively below the mean. A few patients are reported with defects of the IGF-I gene or with deficiency of the IGF-I receptor and extreme short stature.

There are rare reports of IGF-I receptor (IGF-IR) defects (OMIM #147370) leading to short stature not responsive to IGF-I. Intrauterine growth deficiency is usually reported in these cases.

Why do certain normal children, perhaps within a short family, have stature significantly lower than the mean? There is no definite answer to this persistent question, but some patients have decreased serum GHBP concentration, which suggests a decrease in GH receptors in these children. A minority of short, poorly growing children have definable genetic abnormalities of their GH receptors. Short stature is the final common pathway of numerous biochemical abnormalities.

Adults who had GH deficiency in childhood or adolescence have decreased bone mass compared with normals even when bone mass is corrected for their smaller size. There is progressive bone loss in adults who are GH deficient even if bone density was improved with childhood therapy; GH is approved for adults with GH deficiency and can reverse this trend (see Chapter 4).
Diagnosis of GH Deficiency

Because basal values of serum GH are low in normal children and GH-deficient patients alike, the diagnosis of GH deficiency has classically rested on demonstration of an inadequate rise of serum GH after provocative stimuli or on some other measure of GH secretion. This process is complicated because different radioimmunoassay systems vary widely in their measurements of GH in the same blood sample (eg, a result on a single sample may be above 10 ng/mL in one assay but only 6 ng/mL in another). The physician must be familiar with the standards of the laboratory being used. Most insurance companies and state agencies accept inability of GH to rise above 10 ng/mL with stimulation as diagnostic of GH deficiency.

Another complicating factor is the state of pubertal development. Prepubertal children secrete less GH than pubertal subjects and, especially as they approach the onset of puberty, may have sufficiently reduced GH secretion to falsely suggest bona fide GH deficiency. This factor is sometimes addressed by administering a dose of estrogen to such subjects before testing. The very concept of GH testing provides a further complication. GH is released episodically in response to standard challenges. The very concept of GH testing provides a further complication. GH is released in episodic pulses. Although a patient who does not secrete GH in response to standard challenges is generally considered to be classically GH-deficient, a normal GH response to these tests may not rule out the efficacy of GH treatment. Testing should occur after an overnight fast; carbohydrate or fat ingestion suppresses GH response. Obesity suppresses GH secretion, and an overweight or obese child may falsely appear to have GH deficiency. Even within the normal range, variations of BMI affect peak GH after stimulation.

Because 10% or more of healthy children do not have an adequate rise in GH with one test of GH reserve, at least two methods of assessing GH reserve are necessary before the diagnosis of classic GH deficiency is assigned. Of course, if GH rises above 10 ng/mL in a single test, classic GH deficiency is eliminated. Serum GH values should rise after 10 minutes of vigorous exercise; this is used as a screening test. After an overnight fast, GH levels should rise in response to arginine infusion (0.5 g/kg body weight [up to 20 g] over 30 minutes), oral levodopa (125 mg for up to 15 kg body weight, 250 mg for up to 35 kg, or 500 mg for >35 kg), or clonidine (0.1 mg/m² orally). Side effects of levodopa include nausea; those of clonidine include some drop in blood pressure and drowsiness. Glucagon stimulation testing determines both GH and ACTH secretory ability.

GH levels also rise after acute hypoglycemia due to insulin administration; however, this test carries a risk of seizure if the blood glucose level drops excessively. An insulin tolerance test may be performed if a 10% to 25% dextrose infusion is available for emergency administration in the face of hypoglycemic coma or seizure and if the following conditions are satisfied: (1) an intravenous infusion line with heparin lock or low-rate saline infusion is available before the test begins, (2) the patient can be continuously observed by a physician, and (3) the patient has no history of hypoglycemic seizures. The patient must have normal glucose concentration at the beginning of the test in the morning after an overnight fast (water intake is acceptable).

Regular insulin, 0.075 to 0.1 U/kg in saline, may be given as an intravenous bolus. In 20 to 40 minutes, a 50% drop in blood glucose will occur, and a rise in serum GH and cortisol and ACTH should follow. Serum glucose should be monitored, and an intravenous line must be maintained for emergency dextrose infusion in case the patient becomes unconscious or has a hypoglycemic seizure. If dextrose infusion is necessary, it is imperative that blood glucose not be raised far above the normal range, because hyperosmolality has been reported from overzealous glucose replacement; undiluted 50% dextrose should not be used (see Chapter 4).

A family of pentapeptides and hexapeptides called GH-releasing peptides (GHRPs) stimulate GH secretion in normals and in GH-deficient subjects. GHRPs act via ghrelin receptors that are different from the GH-releasing factor (GHRF) receptors, and their effects are additive to that of GHRF. Ghrelin is a gastrointestinal-derived peptide that naturally binds to these receptors in the central nervous system, causing GH secretion, but it also stimulates appetite and is classified as an orexigenic agent. Recently, mutations in the GH secretagogue receptor (GHSR) were found in children with short stature; treatment with GH increases growth rate.

Patients who respond to the pharmacologic stimuli noted above, but not to physiologic stimuli such as exercise or sleep, were said to have neurosecretory dysfunction. These patients have decreased 24-hour secretion of GH (or integrated concentrations of GH) compared with healthy subjects, patterns similar to those observed in GH-deficient patients. It is not clear how frequently this condition is encountered.

This long discussion of the interpretation of GH after secretagogue testing brings into question the very standard for the diagnosis of GH deficiency. It is clear that pharmacologic testing cannot always determine which patients truly need GH therapy, and many authorities suggest that we abandon such dynamic testing in favor of measurements of IGF-I and IGFBP-3. This is the practice of the author whenever possible, although dynamic GH testing may still be required by a few insurance plans. Serum IGF-I and IGFBP-3 measurements are alternative methods for evaluating GH adequacy. Serum IGF-I values are low in most GH-deficient subjects, but, as noted above, some short patients with normal serum IGF-I concentrations may require GH treatment to improve growth rate. Moreover, starvation lowers IGF-I values in healthy children and incorrectly suggests GH deficiency. Children with psychosocial dwarfism—who need family therapy or foster home placement rather than GH therapy—have low GH and IGF-I concentrations and may falsely appear to have GH deficiency. Likewise, patients with constitutional delay in adolescence have low IGF-I values for chronologic age, but normal values for skeletal age, and may have temporarily decreased GH response to secretagogues. Thus, IGF-I determinations are not infallible in the diagnosis of GH deficiency. They must be interpreted with regard to nutrition, psychosocial status, and skeletal ages. IGFBP-3 is GH-dependent, and if its concentration is also low, it provides stronger evidence of GH deficiency than does the IGF-I determination alone.
The Growth Hormone Research Society produced criteria that attempt to deal with the diagnosis of GH deficiency in childhood in spite of the uncertainty of the methods. These criteria use clinical findings of various conditions associated with GH deficiency, the severity of short stature, and the degree and duration of decreased growth velocity to identify individuals that may have GH deficiency. The guidelines and diagnostic considerations in this chapter include most of the GH Society criteria. (See “Consensus guidelines” reference in the Short Stature section at the end of this chapter for details of the Growth Hormone Research Society statement.) A 3- to 6-month therapeutic trial of GH therapy may be necessary to determine growth response; if growth increases more than 2 cm/y, it is likely that the child will benefit from GH treatment, no matter what the tests originally showed.

**Treatment of GH Deficiency**

**A. GH replacement**  Before 1986, the only available method of treatment for GH deficiency was replacement therapy with hGH derived from cadaver donors. In 1985 and thereafter, Creutzfeldt-Jakob disease, a degenerative neurologic disease rare in patients so young, was diagnosed in some patients who had received natural hGH up to 10 to 15 years before. Because of the possibility that prions contaminating donor pituitary glands were transmitted to the GH-deficient patients, causing their deaths, natural GH from all sources was removed from distribution. Recombinant hGH now accounts for the world’s current supply.

Commercial GH has the 191-amino acid natural sequence. GH is now available in virtually unlimited amounts, allowing innovative treatment regimens not previously possible owing to scarce supplies. The potential for abuse of GH in athletes or in children of normal size whose parents wish them to be taller than average, however, must now be addressed.

Growth disturbances due to disorders of GH release or action are shown in Table 6–2. GH-deficient children require biosynthetic somatropin (natural sequence GH) at a dose of 0.3 mg/kg/wk administered in one subcutaneous dose per day 6 or 7 times per week during the period of active growth before epiphyseal fusion. The increase in growth rate (Figures 6–9, 6–10, and 6–11) is most marked during the first year of therapy. Older children do not respond as well and may require larger doses. Higher doses, up to double the standard starting dose, are approved by the FDA for use in puberty, but there are varying reports of the effect of such higher doses on adult height as by far, most of the effect of GH on adult height is exerted in the years before puberty. GH does not increase growth rate without adequate nutrition and euthyroid status. During the roughly 50 years since the first use of GH in children, long-term effects are reported in several series. If only the children most recently treated with recombinant GH are considered, the mean adult height was 1.4 SD below the mean, a significant improvement over the ~2.9 SD mean height at the start of therapy but not a true normalization of height in most patients. With earlier diagnosis and treatment, using new pubertal dosing schedules, adult height can reach genetic potential.

Monitoring of GH replacement is mainly accomplished by measuring growth rate and annually assessing bone age advancement. Serum IGF-I and IGFBP-3 will rise with successful therapy while GHB will not change appreciably. Controlled clinical studies reported the utility of titrating the dose of GH to restore serum IGF-I to the high-normal range, monitoring serum IGF-I levels during clinical treatment. Serum bone-specific alkaline phosphatase rises with successful therapy. Urinary hydroxyproline, deoxypyridinoline, and galactosyl-hydroxylysine reflect growth rate and are used in clinical studies to reflect increased growth rate with therapy.

Antibodies to GH may be present in measurable quantities in the serum of children receiving GH. However, a high titer of blocking antibodies with significant binding capacity is rare except in patients with absence or abnormality of GH genes. Only a few patients are reported to have temporarly ceased growing because of antibody formation. GH exerts anti-insulin effects.

Although clinical diabetes is not a likely result of GH therapy, the long-term effects of a small rise in glucose in an otherwise healthy child are unknown. If a tendency toward diabetes is already present, GH may cause the onset of clinical manifestations more quickly. Another potential risk is the rare tendency to develop slipped capital femoral epiphyses in children receiving GH therapy. Recent data have weakened the link between slipped capital femoral epiphyses and GH therapy, but the final import of the relationship is not yet clear. Slipped capital femoral epiphyses, if associated with endocrinopathies, are most common in treated hypothyroid patients (50% one series of 80 episodes of slipped capital femoral epiphyses), followed by treated GH-deficient patients (25% of the series). This condition may occur bilaterally, and prophylactic treatment of the nonaffected side is recommended by several authorities. Pseudotumor cerebri may rarely occur with GH therapy and is usually associated with severe headache and may be more common in obese individuals receiving GH treatment. It is reported to reverse after cessation of GH therapy, but if allowed to continue, it may impair vision and

cause severe complications. Organomegaly and skeletal changes like those found in acromegaly are other theoretical side effects of excessive GH therapy but do not occur with standard doses. Furthermore, a few cases of prepubertal gynecomastia are reported with GH therapy.

The discovery of leukemia in young adults previously treated with GH was worrisome, but no cause and effect relationship has been established, and GH treatment is not considered a cause of leukemia. GH does not increase the recurrence rate of tumors existing before therapy. Thus, patients with craniopharyngiomas, for example, may receive GH, if indicated, after the disease is clinically stable without significant worry that the GH will precipitate a recurrence. Clinicians usually wait 1 year after completion of tumor therapy before starting patients on GH therapy, but doing so is not a requirement. There are reports of a small increase in risk of colonic carcinoma decades after natural GH treatment in GH-deficient children but no such information on long-term follow-up of children treated with recombinant derived GH is available.

GH deficiency is associated with an adverse lipid profile with elevated LDL cholesterol and decreased HDL cholesterol in addition to an increased BMI; GH-deficient adolescents treated with GH develop these findings within a few years after discontinuation of GH therapy. Low-dose GH therapy is now approved for use in adults with childhood-onset GH deficiency and is said to forestall these metabolic changes. Further, adult GH therapy maintains muscle strength and bone density in GH-deficient adults. One can, therefore, inform the parents of a child with GH deficiency that the patient may still benefit from GH therapy even after he or she stops growing, if profound GH deficiency remains after repeat testing.

GH has been combined with other substances to increase its impact on height. In patients who were diagnosed late, have
FIGURE 6-10 Two examples of abnormal growth plotted on a height velocity chart. A. The plot is taken from the data recorded as squares in Figure 6-9, describing a patient with precocious puberty such as patient A in Figure 6-11, with premature epiphysial closure, and cessation of growth. B. The plot is taken from the data recorded as circles in Figure 6-9, describing a patient with GH deficiency (such as patient B in Figure 6-11) who was treated with hGH (arrow) at age 6. Initial catch-up growth is noted for 2 years, with a lower (but normal) velocity of growth following. These charts display growth rate over 6 month growth intervals rather than 12-month intervals as shown on Figures 6–3 and 6–4.
entered puberty, and appear to have limited time to respond to GH before epiphyseal fusion causes the cessation of growth, a GnRH agonist has been used to delay epiphyseal fusion in clinical trials with varying success, but this was not recommended by a consensus conference on the use of GnRH agonist therapy due to lack of strong evidence of effectiveness. While clinical trials continue, this off-label use is not yet established as safe and effective. Aromatase inhibitors have been combined with GH in some studies and while this is not yet regular clinical practice, there appears to be an effect of decreasing bone age advancement while allowing increased growth and height obtained.

There are other conditions for which the FDA has approved the use of GH. GH therapy will increase adult height in Turner syndrome to an average of 5.1 cm if started early enough; the addition of low-dose oxandrolone is reported to further increase growth rate. Estrogen is used to promote feminization and maintain bone mineral density; the optimal time to initiate treatment with estrogen should be individualized based on bone age, height, and psychological factors. Usually estrogen is administered during the adolescent years in low doses and only after the normal age of onset of puberty is reached to preserve maximal adult height, although earlier initiation of therapy is gaining credence (see Chapter 15).

In the most successful series of children with SGA treated with GH, the agent increased adult height between 2.0 SD and 2.7 SD. Girls with Turner syndrome treated with GH reach adult height of more than 150 cm, an improvement from the average untreated height which is about 144 cm. When treatment starts at or before 4 years, an adult height is achieved in the normal range.

Treatment with GH is approved for chronic renal disease in childhood. GH increases growth rate above the untreated state without excessive advancement in bone age. Prader-Willi syndrome may also be treated with GH to increase growth rate and lean tissue mass and bone density. A recent study indicated that parental education exerted the most significant effect on body composition in these children. However, there are reports that patients with Prader-Willi syndrome have died of obstructive sleep apnea following GH treatment, demonstrating a need for sleep studies to exclude sleep apnea before initiating treatment and constant surveillance. The treatment of Noonan syndrome is described earlier. In general, males are more often treated with GH than females in the United States, but this is not the case in other developed countries.

The FDA has approved the use of GH in otherwise normal children, whose stature is below 2.25 standard deviations for age and who are predicted to fall short of reaching normal adult height.
(<1 percentile of adult height). There may be pressure for treatment of children predicted to be taller than these guidelines from parents, but the FDA approval is for specific indications. While GH may increase the height of such severely affected children, it should not be used for a child whose predicted adult height is in the normal range. Treatment costs $30,000 to $40,000 per year or about $35,000 per cm gained. In the United States males are treated more often than females while the ratio is more equal in other countries, presumably due to social/cultural issues.

GH has been isolated, sequenced, and synthesized. It is available for use in diagnosis and treatment. GH-deficient patients demonstrate lower or absent GH secretion after administration of GHRH. However, episodic doses of GHRH can restore GH secretion, IGF-I production, and growth in children with idiopathic GH deficiency. The ability of GHRH administration to stimulate pituitary GH secretion further supports the concept that idiopathic GH deficiency is primarily a disease of the hypothalamus, not of the pituitary gland.

IGF-I is now produced by recombinant DNA technology. IGF-I is useful in the treatment of certain types of short stature, particularly Laron dwarfism (and perhaps for African pygmies, should treatment be desired) where neither GH nor any other treatment is effective. IGF-I has been studied clinically for more than 12 years. Side effects such as hypothymia (observed in 49% of treated subjects), injection site lipohypertrophy (32%), and tonsilar adenoidal hypertrophy (22%) are common but not said to be severe. However, there is concern among some authorities as to the safety of this therapy.

B. Psychologic management and outcome Research into the psychologic outcome of patients with short stature is flawed by lack of consistent methods of investigation and lack of controlled studies, but some results are of interest. Aromatase inhibitors have been combined with GH therapy in clinical studies to decrease the advancement of bone age and maximize adult height. This has not yet been introduced into common practice and is considered experimental.

Studies vary in their conclusions, as to whether short stature is harmful to a child's psychologic development or not, and whether, by inference, GH is helpful in improving the child's psychologic functioning. Children with GH deficiency are the most extensively studied; earlier investigations suggested that they have more passive personality traits than do healthy children, may have delayed emotional maturity, and suffer from infantilization from parents, teachers, and peers. Many of these children have been held back in school because of their size without regard to their academic abilities. Some patients retain a body image of short stature even after normal height has been achieved with treatment. More recent studies challenge these views and suggest that self-image in children with height below the fifth percentile, who do not have GH deficiency, is closely comparable to a population of children with normal height. These findings may not be representative of the patient population discussed above in that a normal ambulatory population of short children may differ from the selected group that seeks medical attention. The data suggest that short stature itself is not cause for grave psychologic concern, and such concerns should not be used to justify GH therapy. We cannot avoid the fact that our heightist society values physical stature and equates it with the potential for success, a perception that is not lost on the children with short stature and their parents. A supportive environment in which they are not allowed to act younger than their age, nor to occupy a privileged place in the family is recommended for children with short stature. Psychologic help is indicated in severe cases of depression or maladjustment.

2. PSYCHOSOCIAL DWARFISM (FIGURE 6-12)

Children with psychosocial dwarfism present with poor growth, a pot-bellied and immature appearance. They often display bizarre eating and drinking habits. Parents may report that the affected child begs for food from neighbors, forages in garbage cans, and drinks from toilet bowls. As a rule, this tragic condition occurs in only one of several children in a family. Careful questioning and observation reveal a disordered family structure in which the child is either ignored or severely disciplined. Caloric deprivation or physical battering may or may not be a feature of the history. These children have functional hypopituitarism. Testing often reveals GH deficiency at first, but after the child is removed from the home, GH function quickly returns to normal. Diagnosis rests on improvement in behavior or catch-up growth in the hospital or in a foster home. Separation from the family is therapeutic, but the prognosis is guarded. Family psychotherapy may be beneficial, but long-term follow-up is lacking.

Growth disorder due to abnormal parent–child interaction in a younger infant is maternal deprivation. Caloric deprivation due to parental neglect may be of greater significance in this younger age group. Even in the absence of nutritional restriction or full-blown psychosocial dwarfism, constant negative interactions within a family may inhibit the growth of a child.

It is essential to consider family dynamics in the evaluation of a child with poor growth. It is not appropriate to recommend GH therapy for emotional disorders.

3. HYPOTHYROIDISM

Thyroid hormone deficiency decreases postnatal growth rate and skeletal development if onset is at or before birth. It leads to severe developmental delay unless treatment is rapidly provided after birth. Screening programs for the diagnosis of congenital hypothyroidism have been instituted all over the world. Early treatment following diagnosis in the neonatal period markedly reduces growth failure and has virtually eliminated mental retardation caused by this disorder. Indeed, early treatment of congenital hypothyroidism results in normal growth. Acquired hypothyroidism in older children (eg, due to lymphocytic thyroiditis) may lead to growth failure. Characteristics of hypothyroidism are decreased growth rate and short stature, retarded bone age, and an increased US-LS ratio for chronologic age due to poor growth of the extremities. Patients are apathetic and sluggish and have constipation, bradycardia, coarsening of features and hair, hoarseness, and delayed pubertal development if the condition is untreated.
Intelligence is unaffected in late-onset hypothyroidism, but the apathy and lethargy may make it seem otherwise. Although weight gain is possible with hypothyroidism, in contrast to common wisdom, it is not extreme.

The diagnosis of congenital hypothyroidism is usually made on the basis of neonatal screening studies. In this standard procedure, currently in use throughout the world, a sample of blood is taken from the heel or from the umbilical cord at birth and analyzed for total $T_4$ or TSH. A total $T_4$ of less than 6 µg/dL or a TSH more than 25 mU/L is usually indicative of congenital hypothyroidism, but values differ by state and laboratory. A low total $T_4$ alone may be associated with low circulating thyroxine-binding globulin (TBG), but the significantly elevated TSH is diagnostic of primary hypothyroidism. The diagnosis may be accompanied by radiologic evidence of retarded bone age or epiphyseal dysgenesis in severe congenital hypothyroidism.

In older children, serum TSH is the most reliable diagnostic test. Elevated TSH with decreased free $T_4$ may eliminate the potential confusion resulting from the use of total $T_4$, which may vary with the level of TBG or other thyroxine-binding proteins. A positive test for serum thyroglobulin antibodies or thyroperoxidase antibodies would lead to the diagnosis of autoimmune thyroid disease (Hashimoto thyroiditis) as an explanation for the development of hypothyroidism (see Chapter 7). If both FT$_4$ and TSH are low, the possibility of central hypothyroidism (pituitary or hypothalamic insufficiency) must be considered (this would not be determined in the newborn screening programs that use primarily TSH screening). This should lead to a search for other hypothalamic-pituitary endocrine deficiencies such as GH deficiency and central nervous system disease (see Chapter 4).

Treatment is accomplished by thyroxine replacement. The dose varies from a range of 10 to 15 µg/kg in infancy to 2 to 3 µg/kg in older children and teenagers. Suppression of TSH to normal values for age is a useful method for assessing the adequacy of replacement in acquired primary hypothyroidism. However, there are additional considerations in treatment of neonates, and con-
sultation with a pediatric endocrinologist is essential in this age
group to ensure optimal central nervous system development.
Suppression of TSH is not necessarily appropriate in all affected
newborns.

4. CUSHING SYNDROME
Excess glucocorticoids (either exogenous or endogenous) lead to
decreased growth before obesity and other signs of Cushing syn­
drome develop. The underlying disease may be bilateral adrenal
hyperplasia due to abnormal ACTH-cortisol regulation in Cushing
disease, autonomous adrenal adenomas, or adrenal carcinoma.
The appropriate diagnosis may be missed if urinary cortisol and
17-hydroxycorticosteroid determinations are not interpreted on
the basis of the child's body size or if inappropriate doses of
dexamethasone are used for testing (appropriate doses are 20 µg/kg/d
for the low-dose and 80 µg/kg/d for the high-dose dexamethasone
suppression test) (see Chapter 9). Furthermore, daily variations in
cortisol production necessitate several urinary or plasma cortisol
determinations before Cushing disease can be appropriately diag­
nosed or ruled out. The high-dose dexamethasone test was posi­
tive in 68% of a recent series of children with Cushing disease.
The corticotropin-releasing hormone test was positive in 80% of
affected patients, whereas MRI of the pituitary was positive in
only 52%. Inferior petrosal sampling (see Chapters 4 and 9) was
100% accurate in the diagnosis of Cushing disease although tech­
nically difficult in children. The development of salivary cortisol
assays makes the sampling of early morning cortisol after late­
night dexamethasone doses an easier method to diagnose Cushing
disease in children. Transsphenoidal microadenomectomy is the
TREATMENT OF CHOICE FOR CUSHING DISEASE.

Exogenous glucocorticoids used to treat asthma or even over­
zealous use of topical corticosteroid ointments or creams may
suppress growth. These iatrogenic causes of Cushing syndrome, if
resolved early, may allow catch-up growth and so may not affect
final height. Thus, an accurate history of prior medications is
important in diagnosis. Treatment of the underlying disorder (eg,
transsphenoidal microadenomectomy for Cushing disease) will
restore growth rate to normal (catch-up growth may occur ini­
tially) if epiphyseal fusion has not occurred, but adult height will
de pend on the length of the period of growth suppression.

5. PSEUDOHYPOPARATHYROIDISM
Pseudohypoparathyroidism type 1A (OMIM #103580) is a rare
disorder consisting of a characteristic phenotype and biochemical
signs of hypoparathyroidism (low serum calcium and high serum
phosphate) in its classic form. Phosphate is elevated in states of
parathyroid hormone (PTH) deficiency, while phosphate is low in
vitamin D deficiency. Circulating PTH levels are elevated, and
target tissues fail to respond to exogenous PTH administration.
Children with classic pseudohypoparathyroidism are short and
overweight, with characteristic round facies and short fourth and
fifth metacarpals. This constellation of physical findings is called
Albright hereditary osteodystrophy, which may be expressed sepa­
rately from the biochemical disorders (see later). Developmental
delay is common. The condition is due to heterozygous loss of
function in the alpha subunit of the G_i protein transducer
(GNAS1 gene). When imprinted paternally, this results in a defect
in the G-protein that couples PTH receptors to adenylyl cyclase.
Thus, patients with pseudohypoparathyroidism type 1A have a
blunted rise of urinary cAMP in response to administration of
PTH. Remarkably, a defect occurs in the same regulatory protein
system affected in McCune-Albright syndrome, in which hyperac­
tive endocrine events result (see Chapters 1 and 8). A rarer variant
of this disorder (pseudohypoparathyroidism type 1B; OMIM
#603233) appears to be due to mutations in noncoding regions of
the GNAS1 gene. Treatment with high-dose vitamin D or
1,25-dihydroxyvitamin D (calcitriol) and exogenous calcium as
well as phosphate-binding agents (if needed) will help correct the
biochemical defects and control hypocalcemic seizures in patients
with pseudohypoparathyroidism.

Two remarkable cousins are reported with pseudohypoparathy­
roidism and premature Leydig cell maturation, both due to abnor­
malities in the same G protein. The defective protein was shown
to be inactive at normal body temperature, leading to defective
PTH activity at the level of the kidney and bone. However, it was
hyperactive at the cooler temperatures in the scrotum, leading to
ligand-independent activation of Leydig cell function.

Children with the phenotype of Albright hereditary osteo­
dystrophy but with normal circulating levels of calcium, phos­
phate, and PTH have pseudopseudohypoparathyroidism (OMIM
#612463). They require no calcium or vitamin D therapy
(see Chapter 8).

6. DISORDERS OF VITAMIN D
METABOLISM
Short stature and poor growth are features of rickets in its obvious
or more subtle forms. The cause may be vitamin D deficiency due
to inadequate oral intake, fat malabsorption, inadequate sunlight
exposure, anticonvulsant therapy, and/or renal or hepatic disease.
Classic findings of vitamin D-deficient rickets include bowing of
the legs, chest deformities (rachitic rosary), and characteristic
radiographic findings of the extremities associated with decreased
serum calcium and phosphate levels and elevated serum alkaline
phosphatase levels. There are two forms of hereditary vitamin
D-dependent rickets. Autosomal recessive type 1 hypophos­
phatemic rickets (OMIM #241520) involves a renal 25 OHD
1-hydroxylase deficiency, and type 2 (OMIM #613312) involves
an absent or defective vitamin D receptor. However, the most
common type of rickets in the United States is X-linked hypo­
phosphatemic rickets, a dominant genetic disorder affecting renal
reabsorption of phosphate. It is associated with short stature,
severe and progressive bowing of the legs (but no changes in the
wrists or chest), normal or slightly elevated serum calcium, very
low serum phosphate, and urinary phosphate wasting. Short stat­
ure is linked with rickets in other renal disorders associated with
renal phosphate wasting. Examples include Fanconi syndrome
(including cystinosis and other inborn errors of metabolism) and
renal tubular acidosis.
When treatment is effective in these disorders (e.g., vitamin D for vitamin D deficiency or alkali therapy for appropriate types of RTA), growth rates will improve. Replacement of vitamin D and phosphate is appropriate therapy for vitamin D-resistant rickets. It improves the bowing of the legs and leads to improved growth, although there is a risk of nephrocalcinosis. This necessitates annual renal ultrasound examinations when patients are receiving vitamin D therapy.

In the Williams syndrome of elfin facies, supravalvular aortic stenosis, and mental retardation with gregarious personality, patients have SGA and greatly reduced height in childhood and as adults; this disorder may include infantile hypercalcemia but is no longer considered a disorder of vitamin D metabolism because a genetic defect in the elastin gene at 7q11.23 occurs in most affected patients (see Chapters 8 and 15).

7. DIABETES MELLITUS

Growth in type 1 diabetes mellitus depends on the efficacy of therapy. Well-controlled diabetes mellitus is compatible with normal growth, whereas poorly controlled diabetes often causes slow growth. Liver and spleen enlargement in a poorly controlled short diabetic child is known as Mauriac syndrome, rarely seen now owing to improved diabetic care. Another factor that may decrease growth rate in children with type 1 diabetes mellitus is the increased incidence of Hashimoto thyroiditis in this population. Yearly thyroid function screening is advisable, especially as the peripubertal period approaches. GH concentrations are higher in children with diabetes, and this factor may play a role in the development of diabetic complications. IGF-I concentrations tend to be normal or low, depending on glucose control, but judging from the elevated GH noted above, the stimulation of IGF-I production by GH appears to be partially blocked in these children.

8. DIABETES INSIPIDUS

Polyuria and polydipsia due to inadequate vasopressin (central or neurogenic diabetes insipidus) or inability of the kidney in the classic case to respond to vasopressin (nephrogenic diabetes insipidus) leads to poor caloric intake and decreased growth. With appropriate treatment (see Chapter 5), the growth rate should return to normal. Acquired neurogenic or central diabetes insipidus may herald a hypothalamic-pituitary tumor, and growth failure may be due to associated GH deficiency.

DIAGNOSIS OF SHORT STATURE (TABLE 6–3)

Evaluation of Short Stature

An initial decision must determine whether a child is pathologically short or simply distressed because height is not as close to the 50th percentile as desired by the patient or the parents. Performing unnecessary tests is expensive and may be a source of long-term concern to the parents—a concern that could be avoided by appropriate reassurance. Alternatively, missing a diagnosis of pathologic poor growth may cause the patient to lose inches of final height or may allow progression of disease.

If a patient’s stature, growth rate, or height adjusted for mid-parental height is sufficiently decreased to warrant evaluation, an orderly approach to diagnosis will eliminate unnecessary laboratory testing. The medical history will provide invaluable informa-
tion. Birthweight and gestational age is used to determine whether the child is SGA or appropriate for gestational age (AGA), the intratropical course and toxin exposure and the possibility of birth trauma. Evaluation for dietary abnormalities and for symptoms of any chronic disease is important since almost any systemic disease or nutritional compromise can decrease growth rate (see Table 6-1). Review of past growth charts is any systemic disease or nutritional compromise can decrease growth rate. Heights of parents and age of puberty of parents are recorded although usually only a mother will recall her age of menarche while the father will not remember anything about his pubertal development (unless the father continued to grow after he left high school which might indicate constitutional delay in puberty). The height of siblings and specifically their percentile of height and whether they entered puberty at an appropriate time is important. Chronic disease in the family is also found in the history. Evaluation of psychosocial factors affecting the family and the relationship of parents and child can be carried out during the history-taking encounter. Often the diagnosis can be made at this point.

It goes without stating that accurate measurement of growth is essential. The physical examination requires determination of height as described earlier, and comparison is carried out with any previous data available. Measurement of weight and the calculation of BMI is performed so that neither obesity nor malnutrition is missed. If past heights are not available, a history of lack of change in clothing sizes or shoe sizes is useful in the absence of any other data that may allow determination of growth rate. Heights of parents and age of puberty of parents are recorded although usually only a mother will recall her age of menarche while the father will not remember anything about his pubertal development (unless the father continued to grow after he left high school which might indicate constitutional delay in puberty). The height of siblings and specifically their percentile of height and whether they entered puberty at an appropriate time is important. Chronic disease in the family is also found in the history. Evaluation of psychosocial factors affecting the family and the relationship of parents and child can be carried out during the history-taking encounter. Often the diagnosis can be made at this point.

Any clues to a diagnosis in the history or physical examination should be pursued. However, if no historical or physical features lead to the etiology, laboratory examinations are performed. Complete blood count, urinalysis, and serum chemistry screening with electrolyte measurements may reveal anemia, abnormalities of hepatic or renal disease (including concentration defects), glucose intolerance, acidosis, calcium disorder, or other electrolyte disturbances. Age-adjusted values must be used, because, eg., the normal ranges of serum alkaline phosphatase and phosphorus values are higher in children than in adults. An elevated sedimentation rate, low serum carotene, or a positive antinuclear, antigliadin, antiremnysmal, antireticulin, or antitissue transglutaminase antibody determination (with IgA determination) may indicate connective tissue disease, Crohn disease, celiac disease, or malabsorption syndrome. Serum TSH and free T4 are important measurements to exclude existing thyroid disease. Skeletal age evaluation does not alone provide a diagnosis; however, if the study shows delayed bone age, the possibility of constitutional delay in growth, hypothyroidism, or GH deficiency must be considered. The tests used for the diagnosis of GH deficiency are detailed above. If serum IGF-I is normal for age, classic GH deficiency or malnutrition is unlikely; if serum IGF-I is low, it must be considered in relation to skeletal age, nutritional status, and general health status before interpretation of the value can be made. Since IGF-I values are low under 2 or 3 years of age, the simultaneous measurement of IGFBP-3 is useful in infants. If either or both IGF-I and IGFBP-3 are low, the diagnosis may be GH deficiency if poor nutrition is ruled out. If GH deficiency or impairment is found or if there is another hypothalamic-pituitary defect, an MRI is indicated with particular attention to the hypothalamic-pituitary area to rule out a congenital defect or neoplasm in the area. Ectopic location of the posterior pituitary on MRI is relatively frequent in congenital GH deficiency, as is a decreased pituitary volume or apparent interruption of the pituitary stalk. Serum gonadotropin and sex steroid determinations are performed in pediatric assays if puberty is delayed (see Chapter 15). Serum prolactin may be elevated in the presence of a hypothalamic disorder.

Celiac disease is quite common as a cause of gastrointestinal distress and/or short stature. Serum IgA levels and antitissue transglutaminase antibody measurements are indicated in the evaluation of growth disorders. A karyotype is obtained in any short girl without another diagnosis to rule out Turner syndrome, especially if puberty is delayed or gonadotropins are elevated. If Turner syndrome is diagnosed, evaluation of thyroid function and determination of thyroid antibodies is also important.

Elevated urinary free cortisol (normal: <60 µg/m²/24 h [18.7 µmol/m²/24 h]), elevated late night salivary cortisol, or abnormal dexamethasone suppression testing suggests Cushing syndrome.

If no diagnosis is apparent after all of the above have been considered and evaluated, more detailed procedures, such as provocative testing for GH deficiency, are indicated. It must be emphasized that a long and expensive evaluation is not necessary until it is demonstrated that psychologic or nutritional factors are not at fault. Likewise, if a healthy-appearing child presents with borderline short stature, normal growth rate, and short familial stature, a period of observation may be more appropriate than laboratory tests.

**TALL STATURE DUE TO NONENDOCRINE CAUSES**

1. **CONSTITUTIONAL TALL STATURE**

A subject who has been taller than his or her peers through most of childhood, is growing at a velocity within the normal range with a moderately advanced bone age, and has no signs of the disorders listed below may be considered to be constitutionally
advanced. Predicted final height will usually be in the normal adult range for the family.

Obesity in an otherwise healthy child will often, especially in the presence of a melanocortin 4 receptor (MC4R) mutation, lead to moderate advancement of bone age, slightly increased growth rate, and tall stature in childhood. Puberty will begin in the early range of normal, and adult stature will conform to genetic influences. Thus, an obese child without endocrine disease should be tall; short stature and obesity are worrisome.

2. FAMILIAL/GENETIC TALL STATURE
Children with exceptionally tall parents have a genetic tendency to reach a height above the normal range. The child will be tall for age and will grow at a high normal rate. Bone age will be close to chronologic age, leading to a tall height prediction. Occasionally, children will be concerned about being too tall as adults. These worries are more common in girls and will often be of greater concern to the parents than to the patient. Adult height was limited in the past by promoting early epiphyseal closure with estrogen in girls or testosterone in boys, but such therapy is no longer considered appropriate. Testosterone therapy decreases HDL cholesterol levels. Acne fulminans may be caused by testosterone therapy and progression may occur, even after therapy has been withdrawn. Estrogen carries the theoretical risk of thrombosis, ovarian cysts, and galactorrhea, even if few of these complications are reported. High-dose estrogen therapy is estimated to decrease predicted final height by as much as 4.5 to 7 cm but only if started 3 to 4 years before epiphyseal fusion. Height-limiting therapy is extremely rare in the present era although, recently, long-acting somatostatin agonists have been used in an attempt to limit height. Counseling and reassurance are more appropriate.

3. SYNDROMES OF TALL STATURE
Cerebral Gigantism
The sporadic syndrome of rapid growth in infancy, prominent forehead, high-arched palate, sharp chin, and hypertelorism [Sotos syndrome (OMIM #117550)] is caused by mutation in the nuclear receptor–binding SET domain protein 1 (NSD1) gene and is not associated with GH excess. Mentation is usually impaired. The growth rate decreases to normal in later childhood, but stature remains tall.

Marfan Syndrome
Marfan syndrome (OMIM #154700) is an autosomal dominant abnormality of connective tissue exhibiting variable penetrance. The disorder is due to mutation of the fibrillin1 gene located on 15q21.1. This condition may be diagnosed by characteristic physical manifestations of tall stature, long thin fingers (arachnodactyly), hyperextension of joints, and superior lens subluxation. Pectus excavatum and scoliosis may be noted. Furthermore, aortic or mitral regurgitation or aortic root dilation may be present, and aortic dissection or rupture may ultimately occur. In patients with this syndrome, arm span exceeds height, and the US-LS ratio is quite low owing to long legs. Aortic root ultrasound and slit lamp ophthalmologic examinations are indicated.

Homocystinuria
Patients with homocystinuria (OMIM #236200) have an autosomal recessive deficiency of cystathionine beta-synthase (gene locus 21q22.3) and phenotypes similar to those of patients with Marfan syndrome. Additional features of homocystinuria include developmental delay, increased incidence of seizures, osteoporosis, inferior lens dislocation, and increased urinary excretion of homocystine with increased plasma homocystine and methionine but low plasma cystine. Thromboembolic phenomena may precipitate a fatal complication. This disease is treated by restricting dietary methionine and, in responsive patients, administering pyridoxine.

Beckwith-Wiedemann Syndrome
Patients with Beckwith-Wiedemann syndrome (OMIM #130650) demonstrate macrosomia (birth weight >90th percentile) in 88% of cases, increased postnatal growth, omphalocele in 80%, macroglossia in 97%, and hypoglycemia due to hyperinsulinism of pancreatic hyperplasia in 63%. Other reported features include fetal adrenocortical cyromegaly and large kidneys with medullary dysplasia. The majority of patients occur in a sporadic pattern due to a mutation at 11p15.5, but analysis of some pedigrees suggests the possibility of familial patterns. There is a risk of Wilms tumor, hepatoblastoma, adrenal carcinoma, and gonadoblastoma in this condition.

XXY Syndrome
Patients with one (47,XYY) or more (48,XYYY) extra Y chromosomes achieve greater than average adult heights. They have normal birth lengths but higher than normal growth rates. Excess GH secretion has not been documented (see Chapter 14).

Klinefelter Syndrome
Patients with Klinefelter syndrome (see Chapters 12 and 14) tend toward tall stature, but this is not a constant feature.

TALL STATURE DUE TO ENDOCRINE DISORDERS

1. PITUITARY GIGANTISM
Pituitary gigantism is caused by excess GH secretion before the age of epiphyseal fusion. The increased GH secretion may be due to somatotroph-secreting tumors or constitutive activation of GH secretion as is sometimes found in the McCune-Albright syndrome. Alternatively, it may result from excess secretion of GHRH. Patients—besides growing excessively rapidly—have coarse features, large hands and feet with thick fingers and toes, and often frontal bossing and large jaws.

CHAPTER 6 Growth 159
Although this condition is quite rare, the findings appear similar to those observed in the more frequent acromegaly (which occurs with GH excess after epiphysial fusion). Thus, glucose intolerance or frank diabetes mellitus, hypogonadism, and thyromegaly are predicted. Treatment is accomplished by surgery (the transphenoidal approach is used if the tumor is small enough), radiation therapy, or by therapy with a somatostatin analog.

2. SEXUAL PRECOCITY

Early onset of estrogen or androgen secretion leads to abnormally increased height velocity. Because bone age is advanced, there is the paradox of the tall child who, because of early epiphysial closure, is short as an adult. The conditions include complete and incomplete sexual precocity (including virilizing congenital adrenal hyperplasia) (see Chapter 14).

3. THYROTOSTOCOSIS

Excessive thyroid hormone, due to endogenous overproduction or overtreatment with exogenous thyroxine, leads to increased growth, advanced bone age, and, if occurring in early life, craniosynostosis. If the condition remains untreated, final height will be reduced.

4. INFANTS OF DIABETIC MOTHERS

Birth weight and size in infants of moderately diabetic mothers are quite high, although severely diabetic women who have poor control may have infants with IUGR due to placental vascular insufficiency. Severe hypoglycemia and hypocalcemia are evident in the infants soon after birth. The appearance and size of such infants is so striking (which occurs with GH excess after epiphysial fusion) . Thus, normal growth, advanced bone age, and, if occurring in early life, craniosynostosis. If the condition remains untreated, final height will be reduced.

**Tall Stature**

The Thyroid Gland

David S. Cooper, MD, and Paul W. Ladenson, MA (Oxon.), MD

The thyroid gland is the body's largest single organ specialized for endocrine hormone production. Its function is to secrete an appropriate amount of the thyroid hormones, primarily 3,5,3',5'-l-tetraiodothyronine (thyroxine, T4), and a lesser quantity of 3,5,3'-l-triiodothyronine (T3), which arises mainly from the subsequent extrathyroidal deiodination of T4. In target tissues, T3 interacts with nuclear T3 receptors that are, in turn, bound to special nucleotide sequences in the promoter regions of genes that are positively or negatively regulated by thyroid hormone. Among their life-sustaining actions, the thyroid hormones promote normal fetal and childhood growth and central nervous system development; regulate heart rate and myocardial contraction and relaxation; affect gastrointestinal motility and renal water clearance; and modulate the body's energy expenditure, heat generation, weight, and lipid metabolism. In addition, the thyroid contains parafollicular or C cells that produce calcitonin, a 32-amino-acid polypeptide that inhibits bone resorption, but has no apparent physiologic role in humans. However, calcitonin is clinically important as a tumor marker produced by medullary thyroid cancers that arise from these cells (Chapter 8).

EMBRYOLOGY, ANATOMY, AND HISTOLOGY

The thyroid gland originates in the embryo as a mesodermal invagination in the pharyngeal floor at the foramen cecum, from which it descends anterior to the trachea and bifurcates, forming two lateral lobes, each measuring approximately 4 cm in length, 2 cm in width, and 1 cm in thickness in adulthood. Ectopic thyroid tissue can be present anywhere along or beyond this thyroglossal duct, from the tongue base (lingual thyroid) to the mediastinum. The thyroglossal duct may also give rise to midline cysts lined with squamous epithelium, which can remain asymptomatic, or become infected or give rise to thyroid tumors. The caudal end of the thyroglossal duct forms the pyramidal lobe of the thyroid, which can become palpable in conditions causing diffuse thyroid inflammation or stimulation (Figure 7-1).

PHYSIOLOGY

STRUCTURE AND SYNTHESIS OF THYROID HORMONES

The thyroid hormones are iodinated thyronines, which comprise of two tyrosine moieties joined by an ether linkage (Figure 7-5). The follicular cells of the thyroid gland are specialized in their ability to synthesize the large hormonal precursor protein thyroglobulin, concentrate iodide intracellularly from the circulation, and express a receptor that binds thyroid-stimulating hormone (thyrotropin, TSH), which promotes thyrocytes' growth and biosynthetic functions.
Iodine metabolism

Iodine is a key structural component of thyroid hormones. Consequently, it is an essential micronutrient consumed in food or water as iodide or iodate, which is converted to iodide in the stomach. The World Health Organization (WHO) recommends a daily dietary iodine intake of 150 μg for adults, 200 μg for pregnant and lactating women, and 50 to 250 μg for children. Because most iodide is excreted by the kidneys, urinary iodide excretion is an excellent index of dietary intake.

Over millennia, iodine has been leached from the soil in many mountainous and inland regions of the world. Consequently, according to WHO, dietary iodine deficiency, defined as a daily iodine intake less than 100 μg/d, affects an estimated two billion people, which is about one-third of the world's population. When iodide intake is less than 50 μg/d, a normal-sized thyroid cannot sustain adequate hormone production, with resulting gland enlargement (goiter) and, ultimately, hypothyroidism. The consequences of endemic dietary iodine deficiency are especially devastating for the developing fetus and children, who require thyroid hormone for normal neurologic development and growth. In the North American diet, iodine is principally derived from iodized salt, iodate preservatives in baked goods, dairy products containing traces of iodophore antibacterial agents used in milk collection, food coloring, and seafood.

Thyroid hormone synthesis and secretion

Synthesis of T4 and T3 by the thyroid gland involves six major steps: (1) active transport of iodide across the basement membrane into the thyroid cell (trapping); (2) oxidation of iodide and iodination of tyrosyl residues in thyroglobulin (organification); (3) linking pairs of iodothyronine molecules within thyroglobulin to form the iodothyronines T3 and T4 (coupling); (4) pinocytosis and then proteolysis of thyroglobulin with release of free iodothyronines and iodothyrosines into the circulation; (5) deiodination of iodothyrosines within the thyroid cell, with conservation and reuse of the liberated iodide; and (6) intrathyroidal 5'-deiodination of T4 to T3.

Thyroid hormone synthesis requires that NIS, thyroglobulin, and the enzyme thyroid peroxidase (TPO) all be present, functional, and uninhibited. This process is summarized in Figures 7–6 and 7–7.
Thyroglobulin

Thyroglobulin is a large glycoprotein molecule (MW 660,000 kDa), composed of two subunits, each containing 5496 amino acids. Thyroglobulin includes approximately 140 tyrosyl residues, but only four tyrosyl sites are sterically oriented for effective hormonogenesis in each molecule. The iodine content of thyroglobulin can vary from 0.1% to 1% by weight. In thyroglobulin containing 0.5% iodine, for example, there are approximately three molecules of $T_4$ and one molecule of $T_3$.

The thyroglobulin gene, which resides on the long arm of chromosome 8, contains approximately 8500 nucleotides, which encode the prethyroglobulin protein monomer, including a
19-amino acid signal peptide. TSH regulates expression of the thyroglobulin gene. After thyroglobulin mRNA is translated in the rough endoplasmic reticulum (RER), the protein is glycosylated during transport through the Golgi apparatus (see Figure 7-7), where thyroglobulin dimers are incorporated into exocytic vesicles. These vesicles then fuse with the cell's apical basement membrane, from which they are released into the follicular lumen. There, at the apical-colloid border, tyrosine residues in thyroglobulin are iodinated.

**FIGURE 7-4** A. Normal rat thyroid. A single layer of cuboidal epithelial cells surrounds PAS-positive material in the follicular space (colloid). The larger, lighter-staining cells indicated by the arrows (l) are C cells that produce calcitonin. The follicular cells form an epithelial layer that surrounds the colloid (F). B. Inactive rat thyroid several weeks after hypophysectomy. The follicular lumens are larger and the follicular cells flatter. C. Rat thyroid under intensive TSH stimulation. The animal was fed an iodine-deficient diet and injected with propylthiouracil for several weeks. Little colloid is visible. The follicular cells are tall and columnar. Several mitoses (m) are visible. (Reproduced, with permission, from Halmi NS. In: Greep RO, Weiss L, eds. Histology. McGraw-Hill; 1973.)

**FIGURE 7-6** The iodide transporter in the thyroid cell. The large solid circle represents the Na+/I− symporter actively transporting I− into the cell; the large blue circle represents Na+−K+ ATPase supplying the ion gradient which drives the reaction. I− is transported across the apical membrane by pendrin. Hormone synthesis takes place in the colloid at the colloid-apical membrane, catalyzed by thyroperoxidase (TPO).
**Iodide Transport**

Iodide ($\Gamma$) is transported across thyrocytes' basal membrane by the NIS. Membrane-bound NIS, which derives its energy from a Na⁺-K⁺ ATPase, allows the human thyroid gland to maintain a concentration of free iodide 30 to 40 times higher than that in plasma. NIS action is stimulated physiologically by TSH and pathophysiologically by the TSH receptor–stimulating antibody of Graves disease. Although salivary, gastric, and breast tissues express NIS and concentrate iodide to a lesser extent than the thyroid, these other tissues do not organify or store iodide, and their NIS activities are not stimulated by TSH. Large amounts of iodide suppress both NIS activity and $\Delta NIS$ gene expression, representing mechanisms of iodine autoregulation (see later). The perchlorate ion ($\mathrm{ClO}_4^-$) competes with iodide for NIS; perchlorate has been used to treat hyperthyroidism and has the potential to be an environmental inhibitor of thyroid function. NIS can also concentrate pertechnetate ($\mathrm{TcO}_4^-$) into thyroid cells, facilitating use of the radionuclide sodium pertechnetate ($\mathrm{Tc}^{99m}\mathrm{O}_4^-$) for visualization of the thyroid gland and quantification of its trapping activity.

At the thyrocyte's apical border, a second iodide transport protein, pendrin, transports iodide to the membrane–colloid interface, where it becomes a substrate for thyroid hormonogenesis (see Figures 7–6 and 7–7). Mutations in the *pendrin* (PDS or SLC26A4) gene impairing its function cause a syndrome of goiter and hearing loss acquired in infancy or early childhood (Pendred syndrome).

**Thyroid Peroxidase**

Thyroid peroxidase (TPO), a membrane-bound glycoprotein (MW 102 kD) containing a heme moiety, catalyzes both iodide oxidation and covalent linkage of iodine to the tyrosine residues of thyroglobulin. TPO gene expression is stimulated by TSH. After TPO is synthesized in the RER, it is inserted into the RER's cis-ternal membranes, from which it is transferred to the apical cell surface through Golgi elements and exocytic vesicles. Here, at the cell–colloid interface, TPO facilitates both iodination and coupling of the tyrosine residues within thyroglobulin.

**Iodination of Thyroglobulin**

Within the thyroid cell, at the apical–colloid interface, iodide is rapidly oxidized by locally produced hydrogen peroxide in a reaction catalyzed by TPO; the resulting active iodide intermediate is bound to tyrosyl residues in thyroglobulin. The required hydrogen peroxide is probably generated by an NADPH oxidase in the presence of calcium cations, a process that is also stimulated by TSH. TPO can also catalyze iodination of tyrosyl molecules in proteins...
other than thyroglobulin, such as albumin or thyroglobulin fragments; but no active hormones arise from these proteins.

**Coupling of Iodotyrosyl Residues in Thyroglobulin**

The coupling of iodotyrosyl residues in thyroglobulin is also catalyzed by TPO. This is believed to be an intramolecular process involving oxidation of two iodotyrosyl residues brought into proximity by the tertiary and quaternary structures of thyroglobulin, their linkage as a quinol ether intermediate, and splitting of the quinol ether to form an iodothyronine (Figure 7-8). Within the thyroglobulin molecule, two molecules of diiodotyrosine (DIT) couple to form T₄, and monoiiodotyrosine (MIT) and DIT molecules couple to form T₃.

The thiocarbamide drugs, including methimazole, carbimazole, and propylthiouracil (PTU), are competitive inhibitors of TPO. Their resulting ability to block thyroid hormone synthesis (Figure 7-9) makes them useful in treatment of hyperthyroidism.

**Proteolysis of Thyroglobulin and Thyroid Hormone Secretion**

The processes of thyroglobulin proteolysis and secretion in thyroid hormonogenesis are illustrated in Figure 7-7. At the thyroid cell’s apical membrane, colloid is engulfed in vesicles by pinocytosis and absorbed into the cell. Lysosomes containing proteolytic enzymes then fuse with the colloid vesicle. This releases T₄ and T₃, as well as inactive iodotyrosines, peptides, and individual amino acids. The biologically active thyroid hormones T₄ and T₃ enter the circulation; DIT and MIT are deiodinated and their iodide conserved. Thyroid hormone secretion is stimulated by TSH and inhibited by excess iodide (see later) and lithium. A small amount of intact thyroglobulin is normally released from thyroid cell and circulates in blood. The serum thyroglobulin concentration is markedly increased in a number of thyroid conditions, including thyroiditis, nodular goiter, and Graves disease. Because thyroglobulin is also synthesized by most malignancies arising from thyroid epithelium, such as papillary and follicular thyroid cancers, it is a useful circulating tumor marker.

**Intrathyroidal Deiodination**

MIT and DIT formed during the synthesis of thyroid hormone are deiodinated by intrathyroidal deiodinase, an NADPH-dependent flavoprotein found in mitochondria and microsomes that acts on the iodotyrosines MIT and DIT, but not on T₃ and T₄. Most of the iodide released is reused for hormone synthesis, and only a small amount leaks out of the thyroid gland (Figure 7-10).

The 5'-deiodinase that converts T₄ to T₃ in peripheral tissues is also found in the thyroid gland. When there is iodide deficiency and in various hyperthyroid states, the activity of this enzyme increases the amount of T₃ secreted by the gland, increasing the metabolic efficiency of hormone synthesis.

**Abnormalities in Thyroid Hormone Synthesis and Release**

**Dietary Iodine Deficiency and Inherited Defects**

A very low iodine diet and inherited defects in genes encoding the proteins required for thyroid hormone biosynthesis (dys hormonogenesis) can both result in insufficient hormone production. In
Although iodide is an essential substrate for thyroid hormone production, the gland increases the ratios of MIT-to-DIT within thyroglobulin as well as the proportion of secreted T₃ relative to T₄. The hypothalamic-pituitary-thyroid axis also responds to thyroid hormone deficiency by increasing TSH secretion. Consequently, affected individuals typically present with thyroid gland enlargement (goiter), which may be sufficient to compensate for inefficient thyroid hormone production; but if not, they develop hypothyroidism. Severely affected neonates and infants can suffer the irreversible effects of thyroid hormone deficiency on development that result in cretinism. Specific inherited disorders are described in more detail in the section on nontoxic goiter, below.

**Effects of Iodine Excess on Hormone Biosynthesis**

Although iodide is an essential substrate for thyroid hormone production, excess iodide actually inhibits three steps in thyroid hormone production: iodide trapping, thyroglobulin iodination (the Wolff-Chaikoff effect), and thyroid hormone release from the gland. These inhibitory actions are transient, and the normal thyroid gland escapes after 10 to 14 days from these effects of excess iodide. These autoregulatory effects of iodide insulate physiologic thyroid function from short-term fluctuations in iodine intake. These actions of excess iodide also have important clinical implications, sometimes causing iodine-induced thyroid dysfunction and permitting iodide treatment of certain thyroid conditions. If the thyroid is affected by autoimmune thyroiditis or certain inherited forms of dyshormonogenesis, it may be incapable of escaping from iodide-induced inhibition of gland function, and hypothyroidism can develop. Conversely, an iodide load can induce hyperthyroidism (Jod-Basedow effect) in some patients with multinodular goiter, latent Graves disease, and rarely in individuals with thyroid glands that appear otherwise normal.

**THYROID HORMONE TRANSPORT**

Both thyroid hormones circulate in blood bound to plasma proteins; only 0.04% of T₄ and 0.4% of T₃ are unbound or free, and consequently, available for entry and action in target tissues (Figure 7-11). There are three major thyroid hormone transport proteins: thyroxine-binding globulin (TBG); transthyretin, formerly called thyroxine-binding prealbumin (TBPA), and albumin (Figure 7-12). The plasma protein binding permits blood delivery of the iodothyronines, which are otherwise poorly soluble in water. It also creates a large circulating thyroid hormone pool with a stable 7-day plasma half-life and ensures the homogeneous distribution of thyroid hormones in target tissues.

**Thyroxine-Binding Globulin**

Thyroxine-binding globulin (TBG) is a liver-derived glycoprotein member of the SERPIN family of serine antiproteases composed of a single 54-kDa polypeptide chain, to which are attached 4 carbohydrate chains normally containing approximately 10 sialic acid residues. Each TBG molecule has a single binding site for T₄ or T₃. The serum concentration of TBG is 15 to 30 μg/mL (280-560 nmol/L), and its high binding affinity for T₄ and T₃ allows it to carry about 70% of circulating thyroid hormones. TBG and its binding of the thyroid hormones can be altered by congenital TBG derangements, certain physiologic and pathophysiologic circumstances, and several drugs. TBG deficiency occurs with a frequency of 1:5000 live births, with a number of variants described in several ethnic and racial groups. It is an X-linked recessive trait that, consequently, is much more commonly expressed in males. Despite low circulating total T₄ and T₃ levels in affected individuals, free hormone levels are normal, and these patients remain euthyroid. Congenital TBG deficiency is often associated with congenital corticosteroid-binding globulin deficiency (Chapter 9). Conversely, congenital TBG excess, which is rare, is characterized by elevated total T₄ and T₃ concentrations in blood, but normal free hormone levels and a euthyroid clinical state. Pregnancy, estrogen-secreting tumors, and estrogen therapy all increase the sialic acid content of the TBG molecule, resulting in decreased metabolic clearance and elevated serum TBG levels. TBG levels can decrease in major systemic illness, and due to cleavage by leukocyte proteases, its binding affinity for the thyroid hormones can also be reduced. Both effects lower the serum total thyroid hormone concentrations in sick patients (Table 7-1). Certain drugs can also decrease (androgenic steroids, glucocorticoids, danazol, L-asparaginase) or increase (estrogens, 5-fluourouracil) the plasma TBG concentration. Other drugs (eg, salicylates, high-dose phenytoin, and intravenous furosemide) can bind to TBG, displacing T₄ and T₃. In this circumstance, the hypothalamic-pituitary-thyroid axis (discussed later) preserves normal, free hormone concentrations.

---

2Jod is German for iodine; Carl Adolph von Basedow was one of the first physicians to describe hyperthyroidism.
FIGURE 7-10 Iodine metabolism. The values indicated are representative of those that might be found in a healthy subject ingesting 500 µg of iodine a day. The actual iodine intake varies considerably among different individuals.

FIGURE 7-11 Representation of free T₄ (and free T₃) as the biologically active hormones at the level of the pituitary and the peripheral tissues. Most of the thyroid hormones circulating in plasma are protein-bound and have no biologic activity. This pool of bound hormone is in equilibrium with the free hormone pool. (Reproduced, with permission, from DeGroot LJ, Stanbury JB. The Thyroid and Its Diseases. 4th ed. Wiley; 1975.)

by lowering serum total thyroid hormone levels. Similarly, heparin stimulation of lipoprotein lipase releases free fatty acids that displace thyroid hormones from TBG. In vivo, this can result in lower total thyroid hormone concentrations, whereas in vitro (eg, in blood drawn through a heparin lock), heparin increases measured levels of free T₄ and T₃.

**Transthyretin (Thyroxine-Binding Prealbumin)**

Transthyretin, a 55-kDa globular polypeptide composed of four identical 127-amino acid subunits, binds 10% of circulating T₄. Its affinity for T₄ is 10-fold greater than for T₃. The dissociation of T₄ and T₃ from transthyretin is rapid, so that transthyretin is a source of readily available T₄. Increased affinity of transthyretin binding for T₄ can occur as a heritable condition. Affected individuals have an elevated total T₄ but a normal free T₄. Ectopic production of transthyretin, which has been reported to occur in patients with pancreatic and hepatic tumors, also causes euthyroid hyperthyroxinemia.

**Albumin**

Albumin binds to T₄ and T₃ with lesser affinity than TBG or transthyretin, but its high plasma concentration results in its
transport of 15% of circulating T₄ and T₃. Rapid thyroid hormone dissociation rates from albumin make it a major source of free hormone to tissues. Hypoalbuminemia, as occurs in nephrosis or cirrhosis, is associated with a low total T4 and T3, but the free hormone levels are normal.

Familial dysalbuminemic hyperthyroxinemia is an autosomal dominant inherited disorder in which 25% of the albumin exhibits a higher than normal T₄-binding affinity. This results in an elevated total T₄ level but a normal free T₄ concentration and euthyroidism. In most affected kindreds, the T₃-binding affinity is normal. Because these albumin variants do not bind the thyroxine analogs used in many free T₄ immunoassays, they may falsely report elevation of the free T₄ in affected individuals.

**METABOLISM OF THYROID HORMONES**

The normal thyroid gland secretes about 100 nmol of T₄ and only 5 nmol of T₃ daily; less than 5 nmol of metabolically inactive reverse T₃ (rT₃) is produced (Figure 7–13). Most of the plasma pool of T₃ (80%) is derived from peripheral outer ring- or 5'-monodeiodination of T₄ in tissues outside of the thyroid gland, particularly the liver, kidney, and skeletal muscle (Table 7–2). Because T₃ has a higher binding affinity for the nuclear T₃ receptors that affect thyroid hormone action, this 5'-monodeiodination generates a more biologically active iodothyronine. On the other hand, deiodination of the inner ring of T₄ (5-deiodination) produces 3,3',5'-triiodothyronine or reverse T₃ (rT₃), which is metabolically inert.

The three deiodinase enzymes that catalyze these reactions differ in tissue localization, substrate specificity, and physiologic and pathophysiologic modulation, as summarized in Table 7–2. Type 1 5'-deiodinase, the most abundant form, is found predominantly
in liver and kidney, and in lesser quantities in the thyroid gland, skeletal and heart muscle, and other tissues. The type 1 5'-deiodinase contains a selenocysteine moiety that is probably at the active deiodinating site. The major function of type 1 5'-deiodinase is to provide T3 to the circulation. Its activity is increased in hyperthyroidism and decreased in hypothyroidism. This partially accounts for the relatively higher circulating T3 levels compared to T4 levels seen in hyperthyroid patients. The enzyme is inhibited by the thionamide antithyroid drug PTU, but not methimazole, and by the antiarrhythmic drug amiodarone and iodinated radiocontrast dyes, such as sodium ipodate. Dietary selenium deficiency can also impair T4 to T3 conversion.

Type 2 5'-deiodinase is predominantly expressed in the brain and pituitary gland, where it maintains a constant level of intracellular T3 in the central nervous system. This deiodinase is very sensitive to circulating T4, so a lower circulating T4 rapidly increases enzyme concentration in brain and pituitary, by altering the rate of T4 degradation and inactivation. In doing so, it maintains the level of intracellular T3 and its neuronal cellular functions. Conversely, elevated plasma T4 reduces the type 2 5'-deiodinase level, protecting brain cells from excessive T3. Consequently, this deiodinase represents a mechanism by which the hypothalamus and pituitary can respond to the level of circulating T4. T3 can also modify the activity of type 2 5'-deiodinase in the brain and the pituitary gland, and α-adrenergic compounds stimulate type 2 5'-deiodinase in brown fat, but the physiologic significance of these effects is not clear. Type 3 5-deiodinase is found in chorionic membranes of the placenta and glial cells in the central nervous system, where it inactivates T4 by converting it to rT3, and it inactivates T3 by converting it to 3,3'-diiodothyronine (3,3'-T2) (Figure 7–14). Type 3 deiodinase levels are elevated in hyperthyroidism and decreased in hypothyroidism and, therefore, may help insulate the fetus and the brain from T4 excess or deficiency. Placental type 3 deiodinase accelerates thyroxine disposal in pregnant women, which partly explains the increased thyroxine dose requirements in treated hypothyroid women.

Overall, the functions of the deiodinas are physiologically important in three ways. First, they permit local tissue and cellular modulation of thyroid hormone actions. Second, they help the organism adapt to changing states, including iodine deficiency or chronic illness. Third, they regulate thyroid hormone actions in the early development of many vertebrates, including amphibians and mammals.

About 80% of T4 is metabolized by deiodination, 35% to T3, and 45% to rT3 (see Figure 7–13). The remainder is inactivated mainly by glucuronidation in the liver and biliary secretion, and to a lesser extent, by sulfation in the liver or kidney. Other metabolic reactions include deamination of the alanine side chain, forming thyroacetate or derivatives of low biologic activity; or decarboxylation or cleavage of the ether link, forming inactive compounds.

As a result of these metabolic pathways, approximately 10% of the total 1000 nmol extrathyroidal T4 pool is cleared each day, and the plasma half-life of T4 is 7 days. Due to T4's lower binding affinity for plasma proteins, the turnover of its much smaller extrathyroidal pool is more rapid, with a plasma half-life of 1 day. The total body pool of rT3 is about the same size as that of T3, but rT3 has an even more rapid turnover, with a plasma half-life of only 0.2 day.

CONTROL OF THYROID FUNCTION AND HORMONE ACTION

Growth and function of the thyroid gland are controlled by the hypothalamic-pituitary-thyroid axis (Figure 7-15) and, as previously discussed, by iodide through the elements of autoregulation. Hypothalamic thyrotropin-releasing hormone (TRH) stimulates thyrotropic cells in the anterior pituitary to produce TSH, which in turn promotes thyroid gland growth and hormone secretion. In addition, deiodinases in the pituitary and peripheral tissues modulate thyroid hormone effects by their tissue-specific conversion of T4 to the more active iodothyronine T3. Finally, the molecular effects of T3 in individual tissues are modulated by the subtype of T3 receptor with which it interacts; the specific gene activation or repression response that it induces; and in a realm just now being revealed, the T3 receptor’s interaction with other ligands, closely related receptors (eg, retinoid X receptor; RXR), and coactivators and corepressors that interact with it in modulating gene expression.

Thyrotropin-Releasing Hormone

Thyrotropin-releasing hormone (TRH) is a tripeptide, pyroglutamyl-histidyl-proline amide (pyro-Glu-His-Pro-NH2), synthesized by neurons in the supraoptic and supraventricular nuclei of the hypothalamus (Figure 7-16). TRH is stored in the median eminence of the hypothalamus and then transported via the pituitary portal venous system down the pituitary stalk to the anterior pituitary, where it controls synthesis and release of TSH. TRH is produced in the hypothalamus reaches the thyrotrophs in the anterior pituitary by the hypothalamo-hypophysial portal system and stimulates the synthesis and release of TSH. In both the hypothalamus and the pituitary, it is primarily T3 that inhibits TRH and TSH secretion, respectively. T4 undergoes monodeiodination to T3 in neural and pituitary as well as in peripheral tissues.
also found in other portions of the hypothalamus, brain, and spinal cord, where it may have distinct functions as a neurotransmitter. The pre-pro-TRH gene, which encodes a large molecule with five copies of the TRH progenitor sequence Glu-His-Pro-Gly, is located on chromosome 3. TRH gene expression is negatively regulated by thyroid hormone—both the T₃ delivered by the circulation and that arising from T₄ deiodination in peptideergic neurons themselves (see Table 7–2).

In the anterior pituitary, TRH binds to a specific membrane receptor located on TSH- and prolactin-secreting cells, stimulating synthesis and release of their respective hormones. The TRH receptor is a member of the 7-transmembrane-spanning, G protein–coupled receptor family (Table 1–1; Figure 1–4). TRH binds to the receptor’s third transmembrane helix, activating both its cyclic guanosine monophosphate-producing complex and the inositol 1,4,5-triphosphate (IP₃) signaling cascade that releases intracellular Ca²⁺ and generates 1,2-diacylglycerol, thereby activating protein kinase C. These pathways are responsible for stimulating TSH release. They coordinate transcription of the genes encoding the TSH subunits and posttranslational glycosylation of TSH, which is necessary for full biologic activity.

TRH-stimulated TSH secretion is pulsatile (Figure 7–17), with a mean TSH pulse amplitude of 0.6 mU/L every 2 hours. Normal individuals have a circadian rhythm in TSH release, with a peak circulating level between midnight and 4 AM, which is presumably controlled by a hypothalamic neuronal pulse generator driving TRH synthesis.

Thyroid hormones exert additional negative feedback on TSH production at the level of the pituitary by downregulating the number of TRH receptors on pituitary thyrotropes. Consequently, in patients with hyperthyroidism, both TSH pulses and its nocturnal surge are markedly suppressed; whereas in hypothyroid patients, the TSH pulse amplitude and nocturnal surge are much suppressed.

greater. In experimental animals and newborn humans, exposure to cold temperature increases TRH and TSH secretion. Certain other hormones and drugs (eg, vasopressin and α-adrenergic agonists), stimulate TRH synthesis and release.

When synthetic TRH is administered intravenously to humans as a 200 to 500 μg bolus, it generates a prompt threeto fivefold rise in the serum TSH concentration, peaking at about 30 minutes and lasting for 2 to 3 hours (see Figure 4–14). In patients with primary hypothyroidism, in whom basal TSH is elevated, there is an exaggerated TSH response to exogenous TRH; and this response is suppressed in patients with hyperthyroidism, high-dose thyroxine therapy, and central hypothyroidism.

TRH is also found in the islet cells of the pancreas, gastrointestinal tract, placenta, heart, prostate, testes, and ovaries. TRH production in these peripheral tissues is not inhibited by T3; the role of TRH in these tissues remains unknown.

**Thyrotropin (Thyroid-Stimulating Hormone)**

Thyroid-stimulating hormone (TSH) is a 28-kD glycoprotein composed of α and β subunits that are noncovalently linked. The α subunit is common to the two other pituitary glycoproteins, follicle-stimulating hormone (FSH) and luteinizing hormone (LH), and the placental hormone human chorionic gonadotropin (hCG), whereas the β subunit is unique for each glycoprotein hormone, conferring specific binding properties and biologic activity. The genes for the TSH α and β subunits are located on chromosomes 6 and 1, respectively. The human α subunit has an apoprotein core of 92 amino acids and contains two oligosaccharide chains; the TSH β subunit has an apoprotein core of 112 amino acids and contains one oligosaccharide chain. The α and β subunit amino acid chains of TSH each form three loops that are intertwined into a cystine knot (Figure 7–18). Glycosylation takes place in the RER.

---

**FIGURE 7–18** Schematic configuration of the TSH-TSHR complex. The central portion of the figure represents the ribbon-like structure of TSH within the TSH receptor. The dark blue line represents the β subunit and the light blue line the α subunit. See also Figure 7–19. (Reproduced, with permission, from Szukulinski MW, et al. Thyroid-stimulating hormone and thyroid-stimulating hormone receptor structure-function relationships. Physiol Rev. 2002;82:473.)
and the Golgi, where glucose, mannose, and fucose residues and terminal sulfate or sialic acid residues are linked to the apoprotein core. These carbohydrate residues prolong its plasma half-life and enhance its ability to induce TSH receptor activation.

TSH controls thyroid cell growth and hormone production by binding to a specific TSH receptor, one of approximately 1000 located on the basolateral cell membrane of each thyroid cell. TSH binding activates both the cyclic adenosine monophosphate (cAMP) and the phosphoinositol pathways for signal transduction. The TSH receptor gene is located on chromosome 14; the product is a single-chain glycoprotein composed of 764 amino acids. The TSH receptor is a member of the 7-membrane spanning, G protein-coupled receptor family, with an ectodomain involved in ligand binding and an intracelluar and intramembrane and intracellular portion responsible for activation of the signaling pathways that promote thyroid cell growth and hormone synthesis and release (see Figure 7-19).

The TSH receptor is involved in the pathogenesis of numerous congenital and acquired forms of hypothyroidism and hyperthyroidism. Heritable defects resulting in impaired TSH synthesis or action have been described, including mutant genes for transcription factors required for pituitary thyrotrope differentiation (POU1F1, PROP1, LHX3, HESX1), TRH receptor, TSH β-chain, TSH receptor, and Gαs, which transduces TSH receptor binding to adenylate cyclase activation. Acquired TSH receptor blocking antibodies can also cause hypothyroidism.

The most common TSH receptor–related disorder causing hyperthyroidism is Graves disease, in which autoantibodies bind and stimulate the TSH receptor. However, the TSH receptor is involved in the etiology of several other forms of hyperthyroidism. Germline mutations activating the TSH receptor can cause familial hyperthyroidism, and somatic activating mutations result in toxic adenomas. Other mutations can lead to aberrant TSH receptor activation by hCG, the placental glycoprotein hormone that is structurally similar to TSH, in familial gestational hyperthyroidism.

**Effects of TSH on the Thyroid Cell**

TSH has many actions on the thyroid cell. Most of its actions are mediated through the G protein-adenylyl cyclase-cAMP system, but activation of the phosphatidylinositol (PIP3) system with a resulting increase in intracellular calcium is also involved. The major actions of TSH include the following:

**A. Changes in thyroid cell morphology**

TSH rapidly induces pseudopods at the follicular cell-colloid border, accelerating thyroglobulin resorption. Colloid content is diminished as intracellular colloid droplets are formed and lysosome formation is stimulated, increasing thyroglobulin hydrolysis and thyroid hormone release.

**B. Cell growth**

Individual thyroid cells increase in size; vascularity is increased; and, over a period of time, thyroid enlargement, or goiter, develops.

**C. Iodine metabolism**

TSH stimulates all phases of iodide metabolism, from increased iodide uptake and transport to increased iodination of thyroglobulin and increased secretion of thyroid hormones and thyroglobulin itself. Increased NIS expression and the stimulation of cAMP production mediate increased iodide transport, and PIP3 hydrolysis and increased intracellular...
Ca\textsuperscript{2+} stimulate the iodination of thyroglobulin. The TSH effect on iodide transport across the cell is biphasic: initially, it is depressed (iodide efflux), and then, after a lag of several hours, iodide uptake is increased. The efflux of iodide may be due to the rapid increase in hydrolysis of thyroglobulin with release of hormone and leakage of iodide out of the gland. The TSH-mediated stimulation of thyrocyte iodine uptake and thyroglobulin secretion also occur after administration of recombinant TSH for radiiodine treatment and monitoring of patients with well-differentiated thyroid cancers.

**D. Other effects of TSH** Other effects include increased transcription of the mRNAs for thyroglobulin and TPO; increased incorporation of iodide into MIT, DIT, T\textsubscript{3}, and T\textsubscript{4}; and increased lysosomal activity, with increased secretion of T\textsubscript{4} and T\textsubscript{3} from the gland. There is also increased activity of type 1 5'-deiodinase, which helps conserve intrathyroidal iodine.

TSH has additional effects on the thyroid gland, including stimulation of glucose uptake, oxygen consumption, and glucose oxidation. There is accelerated turnover of phospholipids and stimulation of synthesis of purine and pyrimidine precursors, with increased synthesis of DNA and RNA.

**Serum TSH**

Intact TSH and isolated α subunit are both present in circulating blood and detectable by immunoassay in concentrations that are normally 0.5 to 4.0 mU/L and 0.5 to 2 μg/L, respectively. The serum TSH level is increased in primary hypothyroidism and decreased in thyrotoxicosis, whether endogenous or from excessive oral intake of thyroid hormones. The plasma half-life of TSH is about 30 minutes, and the daily production rate is about 40 to 150 mU/d.

The glycoprotein α subunit is often disproportionately elevated in patients with TSH-secreting pituitary tumors (see later); it is also increased in normal postmenopausal women due to increased synthesis and secretion related to increased gonadotropin production.

**Control of Pituitary TSH Secretion**

Two major factors control synthesis and release of TSH: (1) T\textsubscript{3} level within thyrotrophic cells, which regulates mRNA expression, TSH translation, and the hormone’s release; and (2) TRH, which controls posttranslational glycosylation and also release.

TSH synthesis and release are inhibited by high serum levels of T\textsubscript{4} and T\textsubscript{3} (hyperthyroidism) and stimulated by low levels of thyroid hormone (hypothyroidism). In addition, certain hormones and drugs inhibit TSH secretion. These include somatostatin, dopamine, dopamine agonists such as bromocriptine, and high doses of glucocorticoids. Severe disease may cause inhibition of TSH secretion, and there may be a rebound increase in TSH as the patient recovers. The magnitude of these effects varies; the drugs mentioned above usually only partially suppress serum TSH, but it remains detectable. In contrast, overt hyperthyroidism can suppress the TSH concentration to beneath the detection limits of even the most sensitive TSH immunoassays.

Tumors and other disorders of the hypothalamus or anterior pituitary gland can impair TRH and TSH secretion, respectively. Pituitary disorders causing hypothyroidism are termed secondary, whereas hypothalamic disease resulting in hypothyroidism is called tertiary. Differential diagnosis of these lesions is discussed later (see Thyroid Tests).

**Other Thyroid Stimulators and Inhibitors**

The thyroid follicle has a rich supply of capillaries that carry noradrenergic nerve fibers from the superior cervical ganglion and acetylcholine esterase-positive nerve fibers derived from the vague nerve and thyroid ganglia. The parafollicular C cells secrete both calcitonin and calcitonin gene-related peptide (CGRP). In experimental animals, these and other neuropeptides modify thyroid blood flow and hormone secretion. In addition, growth factors such as insulin, insulin-like growth factor-1, insulin-like growth factor binding proteins, epidermal growth factor, transforming growth factor β1, and fibroblast growth factors and their receptors, as well as autocrine factors such as prostaglandins and cytokines, modify thyroid cell growth and hormone production. However, it is not yet clear how clinically important these effects are.

**Role of Pituitary and Peripheral Deiodinases**

Pituitary type 2 5'-deiodinase converts T\textsubscript{4} to T\textsubscript{3} in the brain and pituitary, providing the main source of T\textsubscript{3} within thyrotropes. Its activity increases in hypothyroidism, initially maintaining a normal intracellular T\textsubscript{4} level in the cerebrum despite a falling plasma T\textsubscript{4} concentration. In hyperthyroidism, a decrease in its activity moderates exposure of pituitary and neural cells to thyroid hormone excess. In contrast, type 1 5'-deiodinase is decreased in hypothyroidism, conserving T\textsubscript{4}, and increased in hyperthyroidism, accelerating T\textsubscript{4} metabolism but also leading to increased serum levels of T\textsubscript{3} (see Table 7-2).

**Thyroidal Autoregulation**

Autoregulation may be defined as the capacity of the thyroid gland to modify its function to adapt to changes in the availability of iodine, independent of pituitary TSH. Thus, humans can maintain normal thyroid hormone secretion with iodide intakes varying from 50 μg to several milligrams per day. Some of the effects of iodide deficiency or excess are discussed earlier. The major adaptation to low iodide intake is the preferential synthesis of T\textsubscript{3} rather than T\textsubscript{4}, increasing the metabolic effectiveness of the secreted hormone. Iodide excess, on the other hand, inhibits many thyroidal functions, including iodide transport, cAMP formation, hydrogen peroxide generation, and hormone synthesis and secretion. Some of these effects may be mediated by the formation of intrathyroidal iodinated fatty acids. The ability of the normal thyroid to escape from these inhibitory effects (Wolff-Chaikoff effect) allows the gland to continue to secrete hormone despite a high dietary iodide intake. It is important to note that this is different from the therapeutic effect of iodide in the treatment of
Graves disease. Here, the high levels of iodide persistently inhibit thyroglobulin endocytosis and lysosomal activity, decreasing thyroid hormone release and lowering circulating hormone levels. In addition, pharmacologic amounts of iodide reduce the vascularity of the gland, which may be beneficial during thyroid surgery for Graves disease. However, this effect is also transient, lasting 10 to 14 days.

The Actions of Thyroid Hormones

1. THE THYROID HORMONE RECEPTORS AND MECHANISMS OF ACTION

The thyroid hormones exert their actions through two general mechanisms: (1) genomic actions effected through T₃ interactions with its nuclear receptors, regulating gene activity; and (2) nongenomic actions mediated by T₃ and T₄ interactions with certain enzymes (eg, calcium ATPase, adenylate cyclase, monomeric pyruvate kinase), glucose transporters, and mitochondrial proteins.

Thyroid hormones, that are unbound in plasma, are transported intracellularly, by either specific carriers including monocarboxylate transporter 8 (MCT8), MCT10, and organic anion transporting polypeptide (OATP1C1). OATP1C1 is expressed predominantly in brain capillaries and the choroid plexus, and transports T₄ preferentially, while MCT8 and MCT10 are expressed in many tissues and transport both T₄ and T₃. Thyroid hormones are transported through the cell membrane into the cytoplasm, and subsequently into the nucleus, where T₃ binds to its specific receptor. Clinical syndromes associated with mutations in these transporters have recently been recognized, such as the Allan-Herndon-Dudley syndrome in which affected male children develop mental retardation, myopathy, a movement disorder in association with elevated serum T₃ and low serum T₄ levels.

The T₃ nuclear receptor is member of a nuclear receptor superfamily that includes nuclear receptors for glucocorticoids, mineralocorticoids, estrogens, progestins, vitamin D₃, and retinoids (see Figure 1–16). There are two thyroid hormone receptor (TR) genes in humans: TRα located on chromosome 17 and TRβ on chromosome 3. Each gene yields at least two differentially spliced products, TRα 1 and 2 and TRβ 1 and 2, although TRα 2 is believed to be biologically inactive (see Figure 7–20). Each of these receptors has a carboxyl terminal ligand-binding domain and a centrally located DNA-binding domain with two cysteine zinc fingers that facilitate their specific attachment to thyroid hormone response elements (TREs) in the promoters of target genes and regulate their transcription (see Figures 1–16 and 1–17). The concentration of these receptors in tissue varies among tissues and with their stage of development. For example, the brain contains predominantly TRα, the liver mostly TRβ, and cardiac muscle contains both. Point mutations in the ligand-binding domain of the TRβ gene have been shown to be responsible for the syndrome of generalized resistance to thyroid hormone (GRTH). The TRs bind to TREs, which are typically paired, specific oligonucleotide sequences (eg, AGGTCA) (Figure 7–21). The TRs can also function as heterodimers with receptors for other transcription factors, such as the retinoid X and retinoic acid receptors. TREs are generally located upstream of the transcription start site for the coding regions of thyroid hormone–responsive genes. In positively regulated genes, unbound TRs interact with corepressors (eg, nuclear receptor corepressor [NCoR]) and silencing mediator for retinoic and thyroid hormone receptors [SMRT]) to repress basal transcription by recruiting histone deacetylases that alter the nearby chromatin structure. When TRs are bound by T₃, these corepressor complexes are released, and the T₃-bound TRs associate with coactivator complexes that promote local histone acetylation; they also associate with another protein complex (vitamin D receptor-interacting protein/TR-associated proteins) that recruits RNA polymerase II and starts gene transcription. Some genes are negatively regulated by T₃-bound TRs, such as pre-pro-TRH and TSH-α and -β subunit genes, but the

![Deduced protein structure of the thyroid hormone receptor α and β gene products. The receptor protein has three domains: a DNA-binding domain with a high degree of similarity among the different types of receptors, a carboxyl terminal triiodothyronine (T₃)-binding domain, and an amino terminal domain that is not required for full function. The numbers above the structures represent amino acid numbers.](image-url)
Thyroid hormone's actions to alter expression levels of specific mRNAs and their translated proteins generate a constellation of specific tissue responses (see Figure 7–21).

The nongenomic actions of thyroid hormones have long been suspected based on certain rapid tissue responses that take place before RNA transcription could occur and by recognition of $T_T$- and $T_T$-binding sites outside of the nucleus. For example, it has recently been shown that thyroid hormones bind the membrane protein integrin $\alpha_\text{V}\beta_3$, which is involved in thyroid hormone–mediated activation of the MAP kinase cascade and stimulation of angiogenesis.

2. PHYSIOLOGIC EFFECTS OF THYROID HORMONES

The transcriptional effects of $T_T$ characteristically demonstrate a lag time of hours or days to achieve full effect. These genomic actions have a number of vital effects, including tissue growth, brain maturation, increased calorigenesis and oxygen consumption, as well as other specific effects on the heart, liver, kidneys, skeletal muscle, and skin. However, some actions of $T_T$ are believed not to be genomic, including its reduction of pituitary type 2 5'-deiodinase activity and the increased glucose and amino acid transport that it can induce in some tissues. Some specific effects of thyroid hormones are summarized below.

Effects on Fetal Development

Iodide concentration by thyroid tissue and pituitary TSH both appear in the human fetus at about 11 weeks’ gestation. Because of the high placental content of type 3 5'-deiodinase, most maternal $T_T$ and $T_T$ are inactivated, and very little free hormone reaches the fetal circulation. However, this small amount of free hormone from the mother may be important for early fetal brain development. After 15 to 18 weeks of gestation, the fetus is largely dependent on its own thyroidal secretion. Although some fetal growth occurs in the absence of fetal thyroid hormone secretion, brain development and skeletal maturation are markedly impaired if congenital hypothyroidism is undiagnosed and thyroid hormone therapy is not begun promptly after birth. Congenital hypothyroidism results in cretinism, the features of which include mental retardation and dwarfism.

Effects on Oxygen Consumption, Heat Production, and Free Radical Formation

$T_T$ increases $O_2$ consumption and heat production in part by stimulation of Na"-K" ATPase in all tissues except the brain, spleen, and testis. This contributes to the increased basal metabolic rate (total somatic $O_2$ consumption at rest) and the increased sensitivity to heat in hyperthyroidism—and the opposite in hypothyroidism. Thyroid hormones stimulate mitochondrial calorigenesis, augmenting the cell's oxidative capacity. They also induce changes in the mitochondrial inner membrane protein and lipid composition that increase oxidative metabolism by both genomic and nongenomic effects. The reduced efficiency of oxidative metabolism caused by thyroid hormone is also reflected in the increased futile cycling of intermediary carbohydrate metabolites.

Cardiovascular Effects (Figure 7–22)

$T_T$ stimulates transcription of sarcoplasmic reticulum Ca$^{2+}$ ATPase, increasing the rate of myocardial diastolic relaxation. It also increases expression of the more rapidly contractile isoforms of myosin heavy chain, the $\alpha$ isoforms, which contributes to
enhanced systolic function. In myocardium, T₃ also alters expression of different isoforms of the Na⁺-K⁺ ATPase genes, increases expression of α-adrenergic receptors, and decreases the concentration of the inhibitory G protein Gi α T₃ also increases the rates of both depolarization and repolarization of the sinoatrial node, increasing heart rate. Consequently, thyroid hormones have positive inotropic and chronotropic effects on the heart, which, along with the heightened adrenergic sensitivity (see later), accounts for the increased heart rate and contractility in hyperthyroidism and the reverse in hypothyroidism. Thyroid hormones also affect diastolic ventricular function, lower peripheral vascular resistance, and increase intravascular volume, which contributes further to the increase in cardiac output associated with thyroid hormone action.

**Sympathetic Effects**

Thyroid hormones increase the number of β-adrenergic receptors in heart and skeletal muscle, adipose tissue, and lymphocytes. They may also amplify catecholamine action at a postreceptor site. Many of the clinical manifestations of thyrotoxicosis appear to reflect increased sensitivity to catecholamines. Furthermore, therapy with β-adrenergic blocking agents is often helpful in controlling these sympathomimetic manifestations of thyroid hormone excess.

**Pulmonary Effects**

Thyroid hormones maintain ventilatory responses to hypoxia and hypercapnia in the brain stem respiratory center. Consequently, in patients with severe hypothyroidism, hypoventilation can occur.
Respiratory muscle functions are also regulated by thyroid hormone, and can be weakened in hyperthyroidism, leading to a sense of breathlessness.

**Hematopoietic Effects**

The increased cellular demand for O\textsubscript{2} in hyperthyroidism leads to increased production of erythropoietin and increased erythropoiesis. However, blood volume is usually not increased because of hemodilution and increased red cell turnover. Thyroid hormones increase the 2,3-diphosphoglycerate content of erythrocytes, allowing increased O\textsubscript{2} dissociation from hemoglobin and increasing O\textsubscript{2} availability to tissues. The reverse occurs in hypothyroidism.

**Gastrointestinal Effects**

Thyroid hormones promote gut motility, which can result in increased motility and hyperdefecation (ie, increased frequency of formed bowel movements) in hyperthyroidism. Conversely, slowed bowel transit and constipation occurs in hypothyroidism.

**Skeletal Effects**

Thyroid hormones stimulate bone turnover, increasing bone resorption and, to a lesser degree, bone formation. Consequently, hyperthyroidism can be associated with hypercalcioria, and less often, hypocalcemia. Furthermore, chronic thyroid hormone excess can cause clinically significant bone mineral loss.

**Neuromuscular Effects**

In hyperthyroidism, there is increased protein turnover and loss in skeletal muscle, which can lead to a characteristic proximal myopathy. There is also an increase in the speed of muscle contraction and relaxation, noted clinically as the hyperreflexia of hyperthyroidism and the delayed deep tendon reflex relaxation phase in hypothyroidism. A fine distal hand tremor is also typical in hyperthyroidism. As noted above, thyroid hormones are essential for normal development and function of the central nervous system, and failure of fetal thyroid function results in severe mental retardation. In the adult, hyperactivity in hyperthyroidism and sluggishness in hypothyroidism can be striking. Similarly, hyperthyroid patients can be anxious or agitated, while hypothyroidism is typically associated with a depressed mood.

**Effects on Lipid and Carbohydrate Metabolism**

Hyperthyroidism increases hepatic gluconeogenesis and glycolysis, as well as intestinal glucose absorption, and there may also be thyroid hormone–mediated decreases in insulin sensitivity. Thus, hyperthyroidism can worsen glycemic control in patients who also have diabetes mellitus. Cholesterol synthesis and degradation are both increased by thyroid hormones. The latter effect is due largely to an increase in hepatic low-density lipoprotein (LDL) receptor number, accelerating LDL clearance. Consequently, total and LDL cholesterol levels are typically elevated in patients with hypothyroidism. Lipolysis is also increased, releasing fatty acids and glycerol into circulating plasma.

**Endocrine Effects**

Thyroid hormones alter the production, responsiveness, and metabolic clearance of a number of hormones. In hypothyroid children, impaired growth hormone release slows longitudinal growth. Hypothyroidism can cause delayed puberty by impairing gonadotropin-releasing hormone (GnRH) and gonadotropin secretion. Conversely, primary hypothyroidism can also cause precocious puberty, perhaps as an effect of very high TSH levels on gonadotropin receptors. In adults, hypothyroidism causes hyperprolactinemia in a minority of affected women. Menorrhagia (prolonged and heavier menses) and anovulation are common in hypothyroid women, the latter resulting in infertility. The responsiveness of the hypothalamic-pituitary-adrenal axis to stress is blunted in hypothyroid patients. A slowing of the cortisol metabolic clearance rate compensates for this in the hypothyroid state. Conversely, however, restoration of euthyroidism can rarely provoke adrenal insufficiency as cortisol metabolism is accelerated in patients with diminished cortisol reserve due to concomitant disease affecting the adrenal axis.

In hyperthyroidism, accelerated aromatization of androgens to estrogens and increased sex hormone–binding globulin levels contribute to the gynecomastia and elevated total testosterone levels seen in affected men. Hyperthyroidism can also impair normal GnRH and gonadotropin regulation of ovulation and menses, causing infertility and amenorrhea, respectively. All of the endocrine derangements occurring with thyroid dysfunction are reversed by appropriate treatment to restore euthyroidism.

**PHYSIOLOGIC CHANGES IN THYROID FUNCTION**

**Thyroid Function in the Fetus**

Before the fetus develops its own independent thyroid function, it depends on maternal thyroid hormones for early neural development. By the 11th week of gestation, however, the hypophysial portal system has developed, and measurable TSH and TRH are present. At about the same time, the fetal thyroid begins to trap iodide. The secretion of thyroid hormone probably begins in mid gestation (18-20 weeks). TSH increases rapidly to peak levels at 24 to 28 weeks, and T\textsubscript{4} levels peak at 35 to 40 weeks. T\textsubscript{3} levels remain low during gestation; T\textsubscript{4} is converted to rT\textsubscript{3} by type 3 5’-deiodinase during fetal development. At birth, there is a sudden marked rise in TSH stimulated by exposure to the colder extrauterine environment, with a rise in T\textsubscript{4}, a rise in T\textsubscript{3}, and a fall in rT\textsubscript{3}. These parameters gradually stabilize over the first month of life.

**Thyroid Function in Pregnancy**

A number of thyroid parameters change during pregnancy. There is an increase in urinary iodide clearance; in areas of low dietary iodine
intake, this can cause maternal goiter, or when severe, hypothyroidism. During pregnancy, there is a rise in TBG due to an estrogen-induced increase in hepatic glycosylation of TBG, prolonging its metabolic clearance rate. Consequently, serum total T4 and to a lesser extent, total T3 concentrations rise. Rising levels of hCG, which has weak TSH receptor agonist activity, contributes to minimal thyroid enlargement. Maternal hCG levels peak at approximately 12 weeks resulting in a transient high-normal or even modestly elevated serum-free T4 level and a physiologic suppression of serum TSH to the low-normal or even subnormal range. Pathologically elevated hCG levels, found in women with a molar pregnancy or choriocarcinoma, can cause overt hyperthyroidism. Women with severe vomiting in pregnancy, called hyperemesis gravidarum, may also have higher levels of hCG, and can develop a transient gestational thyrotoxicosis. As noted earlier, placental type 3 deiodinase accelerates thyroxine clearance during pregnancy, which partly accounts for the increased thyroxine dose requirement in treated hypothyroid women, and occasionally causes mild hyperthyroidism in women with autoimmune thyroiditis and decreased thyroid gland reserve.

Transplacental delivery of thyroid-related substances can have consequences for the fetus. Maternal iodide crossing the placenta is essential for fetal thyroid hormone production; however, large amounts of iodide can actually inhibit fetal thyroid function and cause a goiter substantial enough to obstruct delivery. In women with autoimmune thyroid disease, maternal immunoglobulins that stimulate or block the TSH receptor can cross the placenta and cause thyroid dysfunction in the fetus. The antithyroid drugs methimazole and PTU cross the placenta, and in large doses will impair fetal thyroid function (see Chapter 16).

Changes in Thyroid Function with Aging

T4 turnover is highest in infants and children, and gradually falls to adult levels after puberty. The T4 turnover rate is then stable until after age 60, when it again begins to decline. In the elderly, the metabolic clearance of T3 can decrease by as much as 50%, necessitating a reduction in T4 dose for treated patients.

### Effects of Acute and Chronic Illness on Thyroid Function (Euthyroid Sick Syndrome)

Acute or chronic illness has several striking effects on thyroid function and hormone economy. The most common and earliest effect is inhibition of T₄-to-T₃ conversion, with a resulting decrease in the circulating T₃ level. This change is accompanied by a rise in the serum reverse T₃ level, due to both its decreased conversion to 3,3'-'T₂ and some acceleration of its production from T₄. These changes occur physiologically in the fetus and pathologically in circumstances of caloric restriction, as in malnutrition, starvation, and anorexia nervosa, and in patients with a variety of acute or chronic systemic illnesses (Table 7–3). The pathogenesis of this low T₃ syndrome is thought to involve cytokines, such as tumor necrosis factor, secreted by inflammatory cells, which inhibit type 1 5'-deiodinase. Drugs can also inhibit type 1 5'-deiodinase and lower the serum T₃ levels in treated patients; these agents include corticosteroids, amiodarone, iodinated cholecystographic dyes, PTU, and high-dose propranolol. Initially, low serum T₃ levels are typically accompanied by total and free T₄ levels that are normal or, less commonly, slightly elevated (Figure 7–23). As illness becomes more severe, however, there is a...
T4 binding to TBG, liberating more free T4. This, in turn, feeds back on the hypothalamus and pituitary to reduce TSH and establish a new equilibrium with a lower total T4. TSH can also be suppressed by cytokines circulating in severely ill patients and by the dopamine or corticosteroids often used to treat critically ill patients. Finally, T4 clearance is accelerated in illness. All of these factors can contribute to the lower serum levels of T4 and free T4 as measured by free hormone immunoassays and estimated T3 resin-uptake procedures. However, the free T4 level measured by equilibrium dialysis has been reported to be normal in most, but not all patients. This suggests that the low serum free T4 levels reported by most commercially available free T4 assays may be a measurement artifact that is unique to critically ill patients.

Two clinical questions arise in sick patients with this constellation of thyroid function test abnormalities. First, it can be challenging to distinguish the euthyroid sick syndrome from central hypothyroidism; in both conditions, the T4 and TSH levels can be low. Clinical information can be helpful, including a history of known pituitary or thyroid disease, head trauma or surgery, or manifestations of other elements of hypopituitarism (eg, small testes in a man). Additional laboratory testing can sometimes be informative. The serum free T4 level determined by equilibrium dialysis is typically normal in the euthyroid sick syndrome. In postmenopausal women, an elevated serum FSH attests to at least one intact pituitary function, although gonadotropin levels can be normal in these patients. This suggests that the low serum free T4 levels may be a measurement artifact that is unique to critically ill patients.

The second clinical question is whether the euthyroid sick syndrome itself should be treated with thyroid hormone. Certainly, many critically ill patients have clinical problems that are reminiscent of hypothyroidism, such as hypothermia, altered sensorium, ventilatory and myocardial dysfunction, and hyponatremia. It has been postulated that intracellular hypothyroidism may exist in these patients and that thyroid hormone therapy might be beneficial. Conversely, it has been proposed that these changes in thyroid status are, in fact, compensatory mechanisms for reducing rates of oxygen consumption and protein catabolism and that thyroid hormone therapy might actually be harmful. Furthermore, two randomized trials, small clinical series, and animal models of systemic illness all have failed to demonstrate any benefit of thyroid hormone therapy in this setting. Although the issue remains unresolved, current practice is generally to withhold thyroid hormone therapy unless there is convincing clinical and biochemical evidence of true hypothyroidism.

## THYROID AUTOIMMUNITY

Autoimmunity is involved in the pathogenesis of many thyroid diseases, including hyperthyroid Graves disease, hypothyroidism with autoimmune or Hashimoto thyroiditis, silent and postpartum thyroiditis, and certain forms of neonatal thyroid dysfunction. Immunologic defense against foreign substances and neoplastic cells involves macrophages that ingest and digest the foreign material and present peptide fragments on the cell surface in association with a class II protein encoded by the HLA-DR region of the MHC gene complex. This complex is recognized by a T-cell receptor on a CD4 helper T cell, which stimulates the release of cytokines such as interleukin-2 (IL-2). These cytokines amplify the response by inducing T-cell activation and proliferation, induction of killer cell activity in CD8 suppressor cells, and stimulation of antibody formation against the foreign antigen by B lymphocytes. Eventually, the activation process is muted by the action of the CD8 suppressor cells (see Chapter 2).

Early observations suggested the possibility that immunologic reactions could affect the thyroid gland. Thyroiditis was induced by immunization of mice with thyroid tissue and Freund adjuvant. Thyroglobulin antibodies were identified in the sera from patients with thyroiditis, and a long-acting thyroid stimulator, later shown to be an antibody to the TSH receptor, was found in the sera of patients with Graves disease.

There are three major thyroidal autoantigens: thyroglobulin, TPO, and the TSH receptor. Circulating autoantibodies to these antigens are useful markers for thyroid autoimmunity, but T-cell-mediated immune mechanisms are central to the pathogenesis of thyroid diseases. Thyroid cells have the capacity to ingest antigen (eg, thyroglobulin) and, when stimulated by cytokines such as gamma interferon, express cell surface class II molecules (eg, HLA-DR4) that present these antigens to T lymphocytes. In addition to the antigen and the class II molecule, other factors such as costimulatory signals from antigen-presenting cells are doubtless required to initiate autoimmune thyroid disease. One hypothesis is that the process is initiated or promoted by external antigens (eg, infectious agents) that lead to antibody and cellular immune responses through cross-reactivity. In addition, genetic factors clearly predispose individuals to thyroid autoimmunity. HLA typing in patients with Graves disease reveals a high frequency of HLA-B8 and HLA-DR3 in Caucasians, HLA-Bw46 and HLA-B5 in Chinese, and HLA-B17 in blacks. In Caucasians, atrophic thyroiditis has been associated with HLA-B8 and goitrous Hashimoto thyroiditis with HLA-DR5. It has been suggested that a genetically induced antigen-specific defect in suppressor T lymphocytes may be the basis for autoimmune thyroid disease.

The increased incidence of autoimmune thyroid disease in postpubertal and premenopausal women, as well as the occurrence of postpartum thyroiditis, implies a role for female sex hormones in the pathogenesis of autoimmune thyroid disease. A high iodine intake may result in more highly iodinated thyroglobulin that is...
more immunogenic and would favor the development of autoim­
mune thyroid disease. Therapeutic doses of lithium, used for the
treatment of bipolar disorder, can interfere with suppressor cell
function and may precipitate autoimmune thyroid disease.

TESTS OF THYROID FUNCTION

The high prevalence of thyroid dysfunction and neoplasia make
testing for thyroid disease a daily necessity in virtually every field
of medical practice—whether a pediatrician screening a neonate
for congenital hypothyroidism, an internist considering possible
thyroid dysfunction in a patient with nonspecific complaints, an
obstetrician-gynecologist evaluating a woman with infertility, a
surgeon assessing a thyroid nodule, or virtually any type of special­
considering thyroid disease as the potential cause for a com­
plaint or test abnormality in the field of interest (eg, cardiologist,
gastroenterologist, neurologist, psychiatrist, ophthalmologist).

Several levels of laboratory and radiologic investigation for
thyroid diseases should be considered. First, it is common for cli­
nicians with a relatively low index of suspicion for thyroid dys­
function in a particular patient to want to exclude its presence
with greater certainty. For this purpose, a test with high sensitivity
(ie, few false-negative results), wide availability, and low cost is
most appropriate. The serum TSH concentration often plays this
role in clinical consideration of hypothyroidism and hyperthy­
roidism. Second, when suspicion of thyroid disease is moderate to
high, based on clinical or other routine laboratory results, testing
with even greater sensitivity to detect rare thyroid disorders is
required, as is a test that can begin to define the severity and
underlying cause of thyroid dysfunction. For example, in a patient
with hypothermia, confusion, periorbital edema, and hypercholes­
terolemia, measurement of both the serum TSH and free T4 con­
centrations would permit exclusion of both primary and central
forms of hypothyroidism; furthermore, if hypothyroidism is con­
firmed, the site of responsible disease would be implicated. Third,
when thyroid dysfunction is clinically obvious or already bio­
chemically confirmed by first-line testing, then more sophisticated
studies are sometimes indicated to identify the underlying cause
and plan appropriate therapy. For example, in a postpartum
woman with thyrotoxicosis, an additional serum TSH, thyroid­
stimulating immunoglobulin titer, and radionuclide thyroid
uptake may be needed to differentiate Graves disease and postpar­
tum thyroiditis—for which there are distinct therapeutic
approaches.

TESTS OF THYROID HORMONES
IN BLOOD

Serum TSH Measurement

Because thyroid dysfunction usually arises from primary disorders
of the thyroid gland, serum TSH measurement is the most widely
employed test to determine whether thyroid dysfunction exists.
The sensitivity of the hypothalamic-pituitary-thyroid axis ensures
that both primary hypothyroidism and thyrotoxicosis, due to
either primary thyroid disorders or exogenous thyroid hormones,
are detected. Furthermore, even mild degrees of thyroid dysfunc­
tion, in which the serum thyroid hormone concentrations have
fallen or risen significantly but remain within the broad reference
range (ie, subclinical or mild thyroid dysfunction) are identified.
The inverse logarithmic relationship between serum TSH and free
T4 concentration in various situations is shown in Figures 7–24A
and 7–24B. TSH assays must be sensitive (ie, able to distinguish
low from very low and undetectable TSH levels) to be used for
diagnosis of thyrotoxicosis. A National Academy of Clinical
Biochemistry guideline specifies that sensitivity, or lower limit of
detection, for TSH assays should be less than 0.02 mU/L. It is
better to assess and compare TSH assays by this quantitative crite­
orian rather than marketing terms such as third generation or ultra­
sensitive.

There are, in general, two sorts of immunoassays used to mea­
sure TSH (and T4 and T3) in serum samples: immunometric assays
(IMA) and radioimmunoassay (RIA). In an IMA or sandwich
assay, an antibody—usually a mouse monoclonal antibody—
directed against one epitope on the TSH molecule is fixed to a
solid matrix, and a second monoclonal TSH antibody that binds
another TSH epitope is labeled with a detectable marker, which
may be a radioisotope, a colorimetrically quantifiable enzyme, or a
fluorescent or chemiluminescent tag. In such IMAs, the concen­
tration of TSH, which links the solid state and labeled antibodies,
is proportionate to the intensity of signal emitted by the marker
once unbound second antibody has been separated off. In con­
trast, in conventional RIAs, a small amount of a TSH tracer, to
which a radioactive molecule has been linked, competes for bind­
ing to first antibody (eg, a rabbit antihuman TSH polyclonal
antibody). Then antibody-bound TSH, both in the sample and
the tracer, is separated from the free tracer in the supernatant
using one of several techniques: a second antibody directed against
the first (eg, goat antirabbit immunoglobulin antibody), polyeth­
ylene glycol, or staphylococcal protein A. In RIAs, the concen­
tration of TSH in the sample is inversely proportional to tracer
activity. In general, TSH RIAs are less sensitive and less widely
employed than IMAs.

There are infrequent but important limitations of the serum
TSH assay alone for diagnosis of thyroid dysfunction when clinical
suspicion of hypothyroidism is high and in certain other special
circumstances (Table 7–4). First, central hypothyroidism can
be overlooked. In patients with hypothyroidism due to a pituitary
tumor, for example, the serum TSH is typically not elevated, but
rather low or inappropriately normal. Consequently, simultane­
ous measurements of both the serum free T4 and TSH would be
required to further substantiate or exclude this diagnosis. Central
hypothyroidism can also be confirmed by assessing the serum
TSH response to an injection of TRH. To perform this test, serum
samples for TSH are obtained before and 30 to 60 minutes after
200 μg of TRH is administered intravenously. The absence of a
significant rise in serum TSH concentration (eg, to a peak value
>7 mU/L) indicates pituitary or hypothalamic disease or suppres­
sion by exogenous thyroid hormone. A modest and delayed
rise may be seen in patients with hypothalamic disease and
tertiary hypothyroidism. Currently, TRH is not available in the
United States. Another cause of a misleadingly low serum TSH concentration is drug treatment with either high-dose corticosteroids or dopamine, both of which inhibit TSH secretion (see Table 7-4).

A second limitation of TSH testing alone is that there are other nonthyroidal causes of an elevated serum TSH concentration, as described in Table 7-4.

**Serum T₄ and T₃ Measurements**

The concentrations of total and free (unbound) T₄ and T₃ are measurable by a variety of automated assay techniques. Serum total thyroid hormone concentrations are widely available and accurate for assessment of most patients with overt thyroid dysfunction. However, a limitation of these assays is they can provide false-positive and false-negative results when changes in the concentration or binding affinity of the thyroid hormone–binding plasma proteins are altered. For example, a pregnant woman with an estrogen-induced increase in the concentration of TBG could be misdiagnosed as being hyperthyroid if only a total T₄ assay was employed. Conversely, a pregnant patient with primary hypothyroidism might be overlooked if the elevated TBG concentration produced total T₄ within the reference range. Despite these reservations, diagnostic accuracy is high when total T₄ assay results are interpreted along with TSH assay findings.

These problems are circumvented by measuring the free thyroxine (FT₄) concentration by free T₄ IMAs or equilibrium dialysis or estimating it using the free thyroxine index (FT₄I), also called the thyroid hormone–binding ratio (THBR). Free T₄ assays employ strategies to measure only the unbound fraction of T₄ in serum samples. One approach is to employ a competing thyroxine analog tracer that binds to the assay antibody but not to plasma proteins. Such free T₄ assays are quite accurate in distinguishing straightforward TBG derangements from true FT₄ abnormalities. However, they may be influenced to some extent by variations in total T₄, and they can yield misleadingly high readings in dysalbuminemic hyperthyroxinemia. Because they are

*"Inappropriate" refers to disruption of the usual reciprocal relationship between serum TSH and free thyroid hormone concentrations.

Equilibrium dialysis entails equilibrating a serum sample with buffer across a membrane with pores that permit passage only of unbound $T_4$; then the dialysate is assayed for its $T_4$ concentration, from which the serum concentration can be derived. Although equilibrium dialysis is considered the gold standard for free $T_4$ determination, it is cumbersome, relatively expensive, and not widely available. Consequently, it is not the optimal first-line method for free $T_4$ measurement, and it is best reserved for special circumstances.

Free $T_4$ estimation by free $T_4$ index entails measuring the total $T_4$ in a conventional IMA and then estimating the partition of a tracer iodothyronine between plasma proteins and a matrix with a virtually limitless binding capacity for small molecules (resin, charcoal, or talc). Radiolabeled $T_3$ is often the tracer employed, although $T_4$ tracer can be used as well. The free $T_4$ index is then calculated as the product of the total $T_4$ multiplied by the percentage of iodothyronine tracer taken up by the matrix, the so-called $T_3$ uptake. It is important to note that this refers to the $T_3$ tracer used in the assay, not the $T_3$ level in the serum sample.
When the free $T_4$ concentration alone is used to diagnose thyroid dysfunction, there are a number of conditions from which true hyperthyroidism or hypothyroidism must be distinguished. First, there are several conditions in which euthyroid individuals can develop hyperthyroxinemia (see Table 7–1). These include rare patients with nonthyroidal illnesses; unusual plasma-binding proteins abnormalities, such as familial dysalbuminemic hyperthyroxinemia (see later); and drugs that block $T_4$-to-$T_3$ conversion (eg, iodinated contrast media, amiodarone, glucocorticoids, and propranolol). In these conditions, true hyperthyroidism is excluded by the normal serum TSH level. Conversely, there are also conditions in which the serum-free thyroxine can be subnormal in euthyroid individuals. Antiepileptic drugs, such as phenytoin and carbamazepine, have multiple actions that lower total and free $T_4$ levels, including inhibition of TSH secretion and accelerating $T_4$ catabolism. However, the normal accompanying serum TSH and equilibrium dialysis $T_4$ levels implies that these patients are, in fact, euthyroid.

Total and free $T_3$ concentrations can also be quantitated in specific IMAs. Measurement of serum $T_3$ is used (1) to recognize patients who have $T_3$ toxicosis, a milder degree of hyperthyroidism in which the serum $T_3$ level is elevated with a normal serum $T_4$ (2) to fully define the severity of hyperthyroidism and monitor the response to therapy; and (3) to help in the differential diagnosis of patients with hyperthyroidism. Because $T_3$ is preferentially secreted in most patients with Graves disease, and some with toxic nodular goiter, the ratios of serum $T_3:T_4$ (expressed in ng/dL: J.lg/dL) are typically greater than 20 in patients with these conditions.

The serum $T_3$ concentration is not accurate for diagnosis of hypothyroidism because a normal $T_3$ level is often maintained in patients with mild to moderate primary hypothyroidism; TSH stimulation increases the relative secretion of $T_3$. Because $T_3$ is bound to TBG, the total serum $T_3$ concentration varies with the TBG level, although less than the serum total $T_4$ (Table 7–5). Serum-free $T_3$ can be measured by IMA or more precisely by equilibrium dialysis.

Reverse $T_3$ ($rT_3$) can be measured by RIA; its serum concentration in adults is about one-third of the total $T_3$ concentration. However, there is little or no clinical indication for $rT_3$ measurement. Previous claims that it is useful to differentiate hypothyroidism from the thyroid function test changes of nonthyroidal illness have not shown that $rT_3$ levels are sufficiently accurate for that purpose.

Thyroglobulin can be measured in serum by either IMA or RIA, which now have sensitivities as low as 0.1 ng/mL. There are two indications for thyroglobulin measurement: (1) detection of residual or recurrent epithelial thyroid cancers (papillary, follicular, and Hurthle cell carcinomas) after thyroidectomy (see section on Management of Thyroid Cancer); and (2) differentiation of thyrotoxicosis due to exogenous thyroid hormone, in which the thyroglobulin level is suppressed, from all forms of endogenous hyperthyroidism, including various forms of thyroiditis, in which it is elevated or normal.

There are several potential limitations of current thyroglobulin IMAs. The most important is interference caused by the presence of circulating antithyroglobulin antibodies. This typically leads to spuriously low values in thyroglobulin IMAs and elevated values in RIAs. Serum thyroglobulin determinations are not useful to differentiate malignant from benign thyroid nodules.

### ASSESSMENT OF THYROID IODINE METABOLISM AND BIOSYNTHETIC ACTIVITY

Radionuclide uptake measurements can be useful to differentiate among the causes of thyrotoxicosis, particularly when used in conjunction with imaging. Radioiodine uptake determinations permit in vivo assessment of fractional iodine uptake and turnover by the thyroid gland. Iodine-123 is the ideal isotope for this purpose, with 13-hour half-life and emitting quantifiable 28-keV x-rays and 159-keV gamma photons but no tissue damage by beta particles. Iodine-131—or when it is unavailable, a low dose of Iodine-131—is given orally, and radioactivity over the thyroid is quantified with a scintillation counter at 4 or 6 hours and again at 24 hours (Figure 7–25). The fractional radioactive iodine uptake (RAIU) by

![FIGURE 7-25 Typical curves of 24-hour radioiodine uptake in normal subjects and in patients with thyroid disease. A high-turnover curve may be seen in patients taking an iodine-deficient diet or with a defect in hormone synthesis.](image-url)
the thyroid varies with recent dietary iodide intake. In countries with a relatively high iodide intake (eg, Chile, Brazil), the normal RAIU is 5% to 15% at 6 hours and 8% to 30% at 24 hours, whereas in areas of low iodide intake and endemic goiter (eg, some parts of Europe and sub-Saharan Africa), the 24-hour RAIU can be as high as 60% to 90%.

In hyperthyroid Graves disease, the 24-hour RAIU is markedly elevated (eg, 40%-95%), although if iodide turnover is very rapid, the 1-3-hour uptake may be even higher than the 24-hour uptake (Figure 7-25). Similarly, the 24-hour RAIU is increased to a lesser extent in toxic nodular goiter (eg, 30%-70%). Thyrotoxicosis with a low thyroidal RAIU occurs in patients with several conditions: (1) subacute and lymphocytic (postpartum, silent) thyroiditis with inflammatory release of preformed hormone causing spontaneously resolving thyrotoxicosis; (2) in iatrogenic or factitious thyrotoxicosis resulting from excessive thyroid hormone medication; and (3) following excess oral or intravenous iodide intake, as occurs, for example, with amiodarone therapy or after radioidine uptake. There can also be low RAIU over the anterior neck when there is excessive thyroid hormone production elsewhere in the body, as occurs with ectopic thyroid tissue at the tongue base (lingual thyroid); in the mediastinum; with struma ovarii, an ovarian teratoma with functioning thyroid tissue; and with functioning metastases from thyroid carcinoma after total thyroidectomy.

The T₃ suppression test is a permutation of the RAIU that is rarely used to ascertain whether thyroid function is autonomous. When one gives T₃ to normal individuals (75-100 μg in divided doses daily for 5 days) it reduces the 24-hour RAIU by more than 50% from baseline. Failure of the radioiodine uptake to suppress indicates autonomous thyroid function, such as occurs in Graves disease or with an autonomously functioning thyroid nodule.

A rare use of RAIU is in determining whether a goitrous thyroid gland has an iodide organification defect. The perchlorate discharge test assesses efficiency of iodide organification by the gland. Perchlorate (KClO₄) acutely blocks the NIS, halting further influx of iodide into the gland and permitting leakage of trapped but nonorganified iodide out of the cell. Specifically, after administering a radioiodine tracer dose and measuring an initial RAIU at 4 hours, 0.5 g KClO₄ is administered to block further radioiodine uptake. If a second RAIU 1 hour later shows that the measured RAIU has been diminished by 5% or more, this indicates an organification defect.

Positive perchlorate discharge tests are seen in some patients with congenital iodide organification defects, as well as in autoimmune thyroiditis, in Graves disease, especially after ¹³¹I therapy, and in patients receiving antithyroid drug inhibitors of iodide organification. The perchlorate discharge test is rarely used clinically, and perchlorate is not available in the United States.

### THYROID IMAGING

#### 1. RADIONUCLIDE IMAGING

¹²³I and technetium ⁹⁹ᵐTc pertechnetate (⁹⁹ᵐTcO₄⁻) are useful for determining the functional activity and morphology of the thyroid gland. ¹²³I (200-300 μCi) is administered orally, and an image of the thyroid is obtained 8 to 24 hours later. ⁹⁹ᵐTcO₄⁻ (1-10 mCi), which is trapped by the NIS, but not organified and retained in the gland, is administered intravenously, and the scan image is obtained earlier than usual—at 30-60 minutes. Images can be obtained with either a rectilinear scanner or a gamma camera. The rectilinear scanner moves back and forth over the area of interest and produces a life-size picture, on which regions of interest, such as nodules, can be marked (Figure 7-26A). The gamma camera has a pinhole collimator, and the scan is obtained on a fluorescent screen and recorded on film or a computer monitor. The camera has greater resolution, but regions of interest must be identified with a radioactive marker for clinical correlation (Figure 7-26B).

Radionuclide scans provide information about the size and shape of the thyroid gland and the distribution of tracer activity within the gland. This is useful in differentiating among the causes of thyrotoxicosis; an enlarged gland with intense and homogenous concentration of tracer is typical of Graves disease. In contrast,
one or more discrete regions of tracer activity, especially corresponding to a palpable nodule or nodules, with suppression of extranodular tissue are characteristic of toxic nodular goiter.

Radionuclide imaging has a limited role in differentiation of benign from malignant thyroid nodules. When a patient with a thyroid nodule has a suppressed serum TSH concentration, a radionuclide scan is often appropriate to determine if the nodule is hot (i.e., functioning with suppression of extranodular thyroid tissue). If this is the case, the nodule can generally be considered benign. Because both most benign and malignant thyroid nodules are cold, or hypofunctioning, documenting this is not particularly helpful, and cytologic evaluation must be performed in any case.

Radionuclide whole body scanning is useful in follow-up of patients with treated thyroid cancer and for confirmation that a mass on the tongue (lingual thyroid), in the midline of the neck (thyroglossal duct), or in the mediastinum (substernal goiter) represents ectopic thyroid tissue.

THYROID ULTRASONOGRAPHY AND OTHER IMAGING TECHNIQUES

The size of the thyroid gland and characteristics of nodular lesions within it are best ascertained by high-resolution ultrasonography (Figure 7–27). Sonography can differentiate solid nodules from cystic lesions and characterize complex cysts that have both solid and cystic components. Certain features of nodules are more common in malignant lesions (e.g., irregular nodule capsule and microcalcifications), and other features are typical of benign lesions (e.g., a spiciform appearance and cystic change), but none of these features can be considered definitive. Sonography can be used to serially monitor the size of thyroid nodules over time, to guide fine-needle aspiration of thyroid nodules, and to assess regional lymph nodes in thyroid cancer patients both preoperatively and in long-term follow-up.

Computed tomography (CT) and magnetic resonance imaging (MRI) are useful in patients with thyroid disease in special settings. They may be required to define the posterior cervical and substernal extent of large goiters, and whether there is tracheal deviation or compression. In thyroid cancer patients, they can be helpful in identifying metastatic disease outside of the neck (e.g., in the lungs, liver). It should be remembered that administration of iodine-containing radiocontrast dye for CT imaging interferes with subsequent radioiodine imaging and therapy for up to several months. Positron emission tomography (PET) scanning has a role in localization of metastatic disease in treated thyroid cancer patients who have a serum thyroglobulin concentration greater than 10 ng/mL.

When any of the above-described techniques are used for other indications to image structures in the cervical region, thyroid nodules are commonly detected incidentally. Studies indicate that the prevalence of thyroid cancer in such thyroid incidentalomas is the same as in palpable nodules, so they should usually be biopsied if greater than 1.0 to 1.5 cm in diameter, and monitored by serial ultrasound if smaller. PET incidentalomas, in particular, should be thoroughly evaluated; as some studies have shown that as many as two-thirds of these hypermetabolic lesions have been found to be cancers.

THYROID BIOPSY

Fine-needle aspiration biopsy (FNAB) of a thyroid nodule is the best method for differentiating benign from malignant thyroid nodules and diffuse goiters. FNAB is a minor outpatient procedure performed in awake, nonfasting patients with appropriate aseptic technique; local anesthesia may or may not be required. The procedure is typically performed with a 27- or 25-gauge needle, which is inserted into the nodule or goiter, and moved in

**FIGURE 7–27** Ultrasound of the normal thyroid gland. (Tr, trachea; LL, left lobe of thyroid; RL, right lobe of thyroid; Is, isthmus; CA, carotid artery; JV, jugular vein; STM, sternothyroid muscle.) (Courtesy of Dr. R.A. Filly)
and out until a small amount of bloody material is seen in the hub of the needle. The aspirated material is then expressed onto a glass slide and prepared as a thin smear, which is either air-dried for definitive staining and preliminarily assessed, or placed in fixative for definitive staining and cytopathologic assessment. FNAB can also be useful to evacuate cystic lesions, although the fluid will recollect in one-half of these cysts.

Cytologic diagnosis of malignancy in thyroid nodules is highly accurate. The sensitivity (true-positive diagnoses divided by total number of nodules proven to be cancer by surgery) is 95% to 98%, and the specificity (true-negative results divided by total number of cases without disease) is also 95%.

**TEST OF PERIPHERAL THYROID HORMONE ACTIONS**

Theoretically, the most definitive test of thyroid function would be a method of quantifying thyroid hormone responses in peripheral tissues. In practice, however, these tests have limited accuracy because the response parameters may be imprecisely quantified (eg, ankle reflex relaxation time) or because they are also modulated by nonthyroidal factors (eg, serum cholesterol and echocardiographic systolic time intervals). Nonetheless, these techniques are useful in clinical research and in assessment of rare patients suspected of having resistance to thyroid hormone action.

Basal oxygen consumption reflects thyroid hormones' effects on oxygen consumption and calorigenesis in most body tissues, especially the liver. There is considerable overlap between the measured levels in hypothyroidism, euthyroidism, and hyperthyroidism. Echocardiography can be used to assess systolic and diastolic functions, both of which are altered with thyroid dysfunction; but this is exclusively a research technique.

Thyroid hormones influence the concentrations of a number of analytes in blood. For example, serum total and LDL cholesterol is usually elevated in hypothyroidism and lowered in hyperthyroidism. In hyperthyroidism, sex hormone–binding globulin, ferritin, and angiotensin-converting enzyme concentrations are often higher, as are markers of bone formation and degradation. However, none of these test results is sensitive or specific enough for routine diagnostic use.

**MEASUREMENT OF THYROID AUTOANTIBODIES**

Detection of thyroid autoantibodies can be helpful in establishing the diagnosis of autoimmune thyroid disease. To establish the diagnosis of autoimmune (Hashimoto) thyroiditis in a patient with diffuse goiter or hypothyroidism, serum anti-TPO or the less sensitive antithyroglobulin antibodies can be employed. An older test, antimicrosomal antibodies has intermediate sensitivity. Anti-TPO and antithyroglobulin antibodies can be measured by hemagglutination, enzyme-linked immunosorbent assay (ELISA), or RIA; RIA is more sensitive, precisely quantifiable, and generally preferred. Although these antibodies are most typical of autoimmune thyroiditis, they are also detected in significant proportions of patients with Graves disease. Due to their high prevalence in the population, especially in women, a positive result does not rule out presence of a second thyroid disorder (eg, cancer in an asymmetrical goiter).

TSH receptor stimulating, binding, and blocking antibodies can all be detected. Thyroid-stimulating immunoglobulin (TSI) is present in approximately 90% of patients with Graves disease and is almost never detected in unaffected patients or those with other autoimmune thyroid diseases. The test is performed by isolating the patient's immunoglobulins from a serum sample, exposing cultured thyroid cells to these antibodies, and then measuring their cAMP response in comparison with reference TSI and TSH standards. TSI testing is used in a few special settings: (1) pregnant women to define risk of subsequent neonatal hyperthyroidism in their fetus and neonate; (2) to differentiate Graves disease from postpartum thyroiditis in women who are breast feeding and cannot have a radionuclide thyroid uptake; and (3) to make the diagnosis of Graves disease in euthyroid patients with apparent thyroid-related ophthalmopathy. Some have advocated use of TSI to predict whether antithyroid drug-treated Graves patients will relapse when drug is later discontinued; however, its prognostic accuracy for this purpose is limited. TSH receptor–binding immunoglobulins can also be detected by in vitro demonstration that circulating immunoglobulins compete with radiolabeled TSH in binding to recombinant TSH receptors. It is a simpler and more sensitive alternative for the TSI indications described earlier, but does not distinguish between stimulating and blocking anti-TSH receptor antibodies. TSH receptor blocking antibodies have been implicated as the cause of hypothyroidism in a minority of hypothyroid patients in certain populations; they can also be transmitted transplacentally to the fetus and inhibit thyroid function during pregnancy and in the neonatal period.

**DISORDERS OF THE THYROID**

Patients with thyroid disease usually complain of one or more of the following: (1) thyroid enlargement, which may be diffuse or nodular; (2) symptoms of thyroid hormone deficiency, or hypothyroidism; (3) symptoms of thyroid hormone excess, or hyperthyroidism; or (4) complications of a specific form of hyperthyroidism—Graves disease—that may present with striking prominence of the eyes (exophthalmos) and, rarely, thickening of the skin over the lower legs (thyroid dermopathy or pretibial myxedema). Patients with thyroid nodules, whether benign or malignant, often have no symptoms, as do persons with mild perturbations of thyroid function.

**History**

The history should include evaluation of symptoms related to the above complaints, discussed in more detail later. Exposure to ionizing radiation in childhood has been associated with an increased incidence of thyroid disease, including cancer. Iodide ingestion in the form of amiodarone, an iodine-containing antiarrhythmic
Although dietary iodide is generally adequate in developed countries, there are still over 2 billion people with iodine-deficient diets in developing countries in Africa, Asia, South America, and inland mountainous areas in Europe. Finally, the family history should be explored with particular reference to goiter, hyperthyroidism, hypothyroidism, or thyroid cancer as well as immunologic disorders such as Type 1 diabetes, rheumatoid disease, pernicious anemia, alopecia, vitiligo, or myasthenia gravis, which may be associated with an increased incidence of autoimmune thyroid disease. Multiple endocrine neoplasia types 2A (Sipple syndrome) and 2B with medullary carcinoma of the thyroid gland are autosomal dominant conditions.

Physical Examination

Physical examination of the thyroid gland is illustrated in Figure 7–28. The thyroid is firmly attached to the anterior trachea midway between the sternal notch and the thyroid cartilage; it is often easy to see and to palpate. The patient should have a glass of water for comfortable swallowing. There are three maneuvers:

1. With a good light coming from behind the examiner, the patient is instructed to swallow a sip of water. Observe the gland as it moves up and down. Enlargement and nodularity can often be noted.

2. Palpate the gland anteriorly with swallowing. The thumb placed anteriorly along the trachea allows localization of the isthmus and connected lobes, as well as the pyramidal lobe, which extends superiorly from the isthmus and is often palpable in patients with autoimmune thyroid disease.

3. Then, the examiner’s right hand is placed on the patient’s left shoulder, and the examiner’s right thumb is used to palpate the left lobe, as the patient swallows. This permits a full appreciation of the size, texture, and contour of the lobe. Then, using the left hand, the right lobe can be palpated. The examiner’s thumbs should be medial to the sternocleidomastoid muscles to avoid mistaking them for the thyroid lobes. Some experts recommend palpation from behind using three fingers to palpate each lobe while the patient swallows, but this technique has the disadvantage of not being able to see the gland during palpation.

Normally, the thyroid is just barely palpable, has a smooth surface, and has a soft to rubbery consistency. The palpable bulboas portion of each lobe of the normal thyroid gland measures about 2 cm in vertical dimension and about 1 cm in horizontal dimension above the isthmus. An enlarged thyroid gland is called a goiter. Generalized enlargement is termed diffuse goiter; irregular or lumpy enlargement is called nodular goiter. In Hashimoto thyroiditis, the gland is often symmetrically enlarged, firm, and has a bosselated (cobblestone) or finely nodular surface. In the atrophic form of Hashimoto thyroiditis, the gland may not be palpable at all. In patients with Graves disease, the gland is usually, but not always, symmetrically enlarged and smooth and rubbery in consistency. Multinodular goiters have one or more distinct nodules palpable, although both small and large and nodules are often not palpable because of their location or consistency. Tenderness of the gland should be noted. In patients with Graves disease, the presence of a bruit by auscultation should be sought, and a thrill may be palpable over the gland. Tracheal deviation by a goiter, cervical lymphadenopathy possibly related to thyroid cancer, and jugular venous distention and facial erythema from thoracic inlet obstruction by a large goiter should be noted as well. An outline of the gland can be traced on the skin of the neck and measured (Figure 7–28D). Nodules can be measured in a similar way. Thus, changes in the size of the gland or in nodules can easily be followed.

**Hypothyroidism**

Hypothyroidism is a clinical syndrome resulting from a deficiency of thyroid hormones, which in turn results in a generalized slowing down of metabolic processes. Hypothyroidism in infants and children results in marked slowing of growth and development, with serious permanent consequences, including mental retardation, when it occurs in infancy. Hypothyroidism with onset in adulthood causes a generalized decrease in metabolism, with slowed heart rate, diminished oxygen consumption, and deposition of glycosaminoglycans in intracellular spaces, particularly in skin and muscle, producing in extreme cases the clinical picture of myxedema. The symptoms and signs of hypothyroidism in adults are reversible with therapy.

**Etiology and Incidence (Table 7–6)**

Hypothyroidism may be classified as (1) primary (thyroid failure) (by far the most common), (2) secondary (due to pituitary TSH deficiency), or (3) tertiary (due to hypothalamic deficiency of TRH)—or may be due to (4) peripheral resistance to the action of thyroid hormones. Hypothyroidism can also be classified as goitrous or nongoitrous, but this classification is probably unsatisfactory, because Hashimoto thyroiditis (autoimmune thyroiditis) may produce hypothyroidism with or without goiter.

The incidence of various causes of hypothyroidism varies depending on geographic and environmental factors, such as dietary iodide and goitrogen intake, the genetic characteristics of the population, and the age distribution of the population (pediatric or adult). The causes of hypothyroidism, listed in approximate order of frequency in the United States, are presented in Table 7–6. Hashimoto thyroiditis is by far the most common cause of hypothyroidism in the developed world. In younger patients, it is more likely to be associated with goiter; in older patients, the gland may be totally destroyed by the immunologic process, and the only trace of the disease is a persistently positive test for TPO antibodies. Similarly, the end-stage of Graves disease may be hypothyroidism, occurring spontaneously or following destructive therapy with radioactive iodine or thyroidectomy.

**Peripheral resistance to the action of thyroid hormone**

Thyroid glands involved in autoimmune disease are particularly susceptible to excessive iodide intake (e.g., ingestion of kelp tablets, iodide-containing cough preparations, or the antiarrhythmic drug amiodarone) or intravenous administration of iodide-containing radiographic contrast media. Large amounts of iodide block thyroid hormone synthesis via the Wolff-Chaikoff effect (see earlier), producing iodine-induced hypothyroidism with goiter in the patient with an abnormal thyroid gland; the normal gland escapes from the Wolff-Chaikoff effect or iodide block, but for unclear reasons autoimmunity renders the gland more sensitive to the inhibitory effects of iodine. Hypothyroidism may occur during the late phase of subacute thyroiditis or silent thyroiditis; this is usually transient, but it may be permanent especially in silent thyroiditis, where permanent hypothyroidism occurs in about 25% of patients. Iodine deficiency is not a cause of hypothyroidism in the United States, but it is still frequently seen in developing countries, and is the most common cause of hypothyroidism worldwide. Certain drugs can block hormone synthesis and produce hypothyroidism with goiter; at present, the most common pharmacologic causes of hypothyroidism (other than iodide) are lithium carbonate, used for the treatment of bipolar disease, and
amiodarone. Chronic therapy of hyperthyroidism with the anti-
thyroid drugs PTU and methimazole have the same effects.
Interferon alfa, used to treat hepatitis C and other conditions, can
cause altered immunity that can result in hypothyroidism due to
Hashimoto thyroiditis. Inborn errors of thyroid hormone synthe-
sis, called thyroid dysmorphogenesis, result from genetic defi-
ciciencies in enzymes necessary for hormone biosynthesis. These
effects may be complete, resulting in a syndrome of severe con-
genital hypothyroidism (cretinism) with goiter; or partial, result-
ing in goiter with milder hypothyroidism. At least five separate
bioisomeric abnormalities have been reported: (1) impaired trans-
port of iodide; (2) deficient thyroid peroxidase with impaired
oxidation of iodide to iodine and failure to incorporate iodine into
thyroglobulin; (3) impaired coupling of iodinated tyrosines to
triiodothyronine or tetraiodothyronine; (4) absence of deficiency
of iodotyrosine deiodinase, so that iodine is not conserved within
the gland; and (5) excessive production of metabolically inactive
iodoprotein by the thyroid gland (see Figure 7–6). The latter may
involve impaired or abnormal thyroglobulin synthesis.

Pituitary and hypothalamic deficiencies as causes of hypoathy-
roidism are quite rare and are usually associated with other symp-
toms and signs of pituitary insufficiency (Chapter 4). Peripheral
resistance to thyroid hormones is discussed later.

Pathogenesis
Thyroid hormone deficiency affects virtually every tissue in the
body, so that the symptoms are multiple. Pathologically, the most
characteristic finding is the accumulation of glycosaminoglycans—
mostly hyaluronic acid—in interstitial tissues. Accumulation of
this hydrophilic substance and increased capillary permeability to
albumin account for the interstitial nonpitting edema that is par-
ticularly evident in the skin, heart muscle, and striated muscle.
The accumulation is due not to excessive synthesis but to decreased
metabolism of glycosaminoglycans.

Clinical Presentations and Findings

A. Newborn infants (cretinism) The term cretinism was
originally applied to infants born in areas of severe iodine defi-
ciency with mental retardation, short stature, a characteristic puff}r
appearance of the face and hands, and (frequently) deaf mutism
and neurologic signs of pyramidal and extrapyramidal tract abnor-
malities. In the United States, neonatal screening programs have
revealed that in the Caucasian population the prevalence of spo-
radic neonatal hypothyroidism is 1:5000, whereas in the African
American population the prevalence is only 1:32,000. In areas of
iodine sufficiency, neonatal hypothyroidism typically results from
failure of the thyroid to descend during embryonic development
from its origin at the base of the tongue to its usual site in the
lower anterior neck, resulting in an absent or ectopic thyroid gland
that functions poorly. Placental transfer to the embryo of blocking
anti-TSH receptor antibodies from a mother with Hashimoto
thyroiditis may result in agenesis of the thyroid gland and athy-
reotic cretinism, but usually it only causes transient hypothyroid-
ism. Inherited defects in thyroid hormone biosynthesis may also
cause neonatal hypothyroidism and goiter. Other possible causes
of neonatal hypothyroidism include exposure during pregnancy to
iodides, antithyroid drugs given to the mother, or inadvertent
administration of radioactive iodine for thyrotoxicosis or thyroid
cancer.

The signs of hypothyroidism in newborns include respiratory
difficulty, cyanosis, jaundice, poor feeding, hoarse cry, umbilical
hernia, and marked retardation of bone maturation. The proximal
tibial epiphysis and distal femoral epiphysis are present in almost
all full-term infants with a body weight over 2500 g. Absence of
these epiphyses strongly suggests hypothyroidism. The introduc-
tion of routine screening of newborns for TSH or T₄ in the devel-
oped world has been a major public health achievement, because
early diagnosis can prevent permanent mental retardation. A drop
of blood obtained by heel stick 24 to 48 hours after birth is placed
on filter paper and sent to a central laboratory. A serum T₄ under
6 μg/dL or a serum TSH over 25 mU/L is suggestive of neonatal
hypothyroidism. The diagnosis can then be confirmed by repeat
testing and radiologic evidence of retarded bone age. Note that
euthyroid infants born to hypothyroid mothers who have been
inadequately treated with levothyroxine during pregnancy are not
hypothyroid, but may have diminished intellectual potential later
in childhood—emphasizing the importance of maintaining the
mother in a euthyroid state throughout pregnancy.

B. Children and adolescents Hypothyroidism in children and
adolescents is characterized by retarded growth and short
stature, the typical signs and symptoms of hypothyroidism seen in
adults (see later), and variable but usually declining school perfor-
ance. Precocious puberty may occur, and there may be enlarge-
ment of the sella turcica due to pituitary thyrotropin hyperplasia
associated with augmented TSH production.

C. Adults In adults, the common features of moderate to
severe hypothyroidism include easy fatigability; cold sensitivity;
weight gain (generally <10-20 lb); constipation; menstrual abnor-
malities, especially menorrhagia; and muscle cramps. Physical
findings may include a cool, rough, dry skin; puffy face and
hands; a hoarse, husky voice; and slow reflexes. Reduced conver-
sion of carotene to vitamin A and increased blood levels of caro-
tene may give the skin a yellowish color. However, many or all of
the symptoms and signs are diminished or absent in patients with
milder degrees of thyroid failure.

1. Cardiovascular signs—Hypothyroidism is manifested by
impaired ventricular contraction, bradycardia, and increased
peripheral resistance, resulting in diminished cardiac output.
The electrocardiogram (ECG) may reveal low voltage of QRS
complexes and P and T waves, with improvement in response
to therapy. Cardiac enlargement may occur, due in part to inter-
stitial edema, nonspecific myofibrillary swelling, and left ven-
tricular dilation, as well as nonhemodynamically significant
pericardial effusion (Figure 7–29). The degree of pericardial
effusion can easily be determined by echocardiography. Although
cardiac output is reduced, congestive heart failure and pulmo-
nary edema are rarely noted. There is controversy about whether
hypothyroidism induces coronary artery disease, but coronary artery disease is more common in patients with hypothyroidism, likely related to increased levels of total cholesterol, LDL cholesterol, and possibly other nontraditional atherogenic factors such as lipoprotein A and homocysteine. In patients with angina pectoris, hypothyroidism may protect the heart from ischemic stress, and replacement therapy may aggravate the angina by increasing myocardial oxygen consumption.

2. Pulmonary function—In the adult, hypothyroidism is characterized by shallow, slow respirations and impaired ventilatory responses to hypercapnia or hypoxia. Respiratory failure is a major problem in patients with myxedema coma (see later).

3. Intestinal peristalsis—Peristalsis is markedly slowed, resulting in chronic constipation and occasionally severe fecal impaction or ileus.

4. Renal function—Renal function is impaired, with decreased glomerular filtration rate and impaired ability to excrete a water load. This predisposes the hypothyroid patient to hyponatremia from water intoxication if excessive free water is administered.

5. Anemia—There are at least four mechanisms that may contribute to anemia in patients with hypothyroidism: (1) impaired hemoglobin synthesis as a result of thyroxine deficiency; (2) iron deficiency from increased iron loss with menorrhagia, as well as impaired intestinal absorption of iron; (3) folic acid deficiency from impaired intestinal absorption of folic acid; and (4) pernicious anemia, with vitamin B₁₂-deficient megaloblastic anemia. Pernicious anemia is often part of a cluster of autoimmune diseases, including hypothyroidism due to Hashimoto or autoimmune thyroiditis associated
with thyroid autoantibodies, pernicious anemia associated with parietal cell autoantibodies, diabetes mellitus associated with islet cell autoantibodies, and adrenal insufficiency associated with adrenal autoantibodies (Schmidt syndrome; see Chapter 2). These conditions are part of what has been termed the polyglandular failure syndrome.

6. Neuromuscular system—Many patients complain of symptoms referable to the neuromuscular system, including severe muscle cramps, paresthesias, and muscle weakness.

7. Central nervous system—Symptoms may include chronic fatigue, lethargy, and inability to concentrate. Patients with hypothyroidism are usually quite placid but can be severely depressed or even extremely agitated (myxedema madness).

8. Reproductive system—Hypothyroidism impairs the conversion of estrogen precursors to estrogens, resulting in altered FSH and LH secretion and in anovulatory cycles and infertility. This may be associated with menorrhagia, which may also be due, in part, to altered platelet function. Men may have decreased libido and erectile dysfunction.

**Diagnosis**

The combination of a low serum FT$_4$ and an elevated serum TSH rather than elevated.

This represents the mildest form of hypothyroidism and is a consequence of the very sensitive feedback relationship between the thyroid and the pituitary gland. In this situation, a small decrement in thyroid hormone output by the thyroid gland, in which serum T$_4$ levels are still within the normal range, results in a serum TSH level that is elevated, albeit usually less than 10 mU/L. Subclinical hypothyroidism is usually due to underlying Hashimoto thyroiditis, which can be confirmed by assessing anti-TPO antibody titers. In patients with secondary or central hypothyroidism, the serum FT$_4$ will be low and serum TSH will be low or normal, rather than elevated.

The patient may be taking thyroid hormone (T$_4$ tablets) when first seen. A palpable or enlarged thyroid gland and a positive test for thyroid autoantibodies would suggest underlying Hashimoto thyroiditis, in which case the medication should be continued. If antithyroid antibodies are absent and the indication for therapy uncertain, the medication could be withdrawn for 6 weeks and determination made for FT$_4$ and TSH. The 6-week period of withdrawal is necessary because of the long half-life of T$_4$ (7 days) and to allow the pituitary gland to recover after a long period of suppression. The pattern of recovery of thyroid function after withdrawal of T$_4$ is noted in Figure 7–31. In hypothyroid individuals, serum TSH becomes elevated at 5 to 6 weeks and FT$_4$ remains subnormal, whereas both are normal after 6 weeks in euthyroid individuals.

The clinical picture of fully developed myxedema is usually quite clear, but the symptoms and signs of mild or subclinical hypothyroidism may be very subtle or absent. This has led to the recommendation by some professional organizations that screening for hypothyroidism be undertaken, especially in high-risk groups, such as older women where the prevalence is high (up to 20% in women > age 65), and in pregnant women, where untreated hypothyroidism may cause adverse outcomes in the child.

At times, patients with hypothyroidism present with unusual features: neurasthenia with symptoms of muscle cramps, paresthesias, and weakness; refractory anemia; disturbances in reproductive function, including infertility, delayed or precocious puberty, or menorrhagia; idiopathic edema or pleuropericardial effusions; retardation growth; obstipation; chronic rhinitis or hoarseness due to edema of nasal mucosa or vocal cords; and severe depression progressing to emotional instability or even frank paranoid psychosis. In the elderly, hypothyroidism may present with apathy and withdrawal, often attributed to senility (Chapter 23). In such cases, assessing thyroid function with serum FT$_4$ and TSH measurements confirms or rules out hypothyroidism as a contributing factor.

**Complications**

A. **Myxedema coma** Myxedema coma, an extremely rare condition, is the end stage of untreated hypothyroidism (see also Chapter 24). It is characterized by progressive weakness, stupor, hypothermia, hyperventilation, hypoglycemia, and hyponatremia, and it may ultimately result in shock and death. It occurs most frequently in the winter in older female patients with underlying pulmonary and vascular disease, and the mortality rate may be greater than 50%.

![FIGURE 7–30 Diagnosis of hypothyroidism.](image-url)
The patient (or a family member if the patient is comatose) may recall previous thyroid disease, radioactive iodine or radiation therapy to the neck area, or thyroidectomy. The medical history is essential. Clinical clues to the presence of pituitary disease include the following: a history of amenorrhea or impotence, scanty pubic or axillary hair, and normal serum cholesterol and normal or low serum TSH levels. CT or MRI may reveal an enlarged sella turcica. The treatment of myxedema coma is discussed later.

B. Hypothyroidism and heart disease In the past, treatment of patients with severe hypothyroidism and heart disease, particularly coronary artery disease, was very difficult, because levothyroxine replacement was sometimes associated with exacerbation of angina, heart failure, or myocardial infarction. Now that

FIGURE 7–31 Changes in T₄, T₃, TSH, and TRH response following abrupt withdrawal of suppressive thyroxine therapy. Note that in euthyroid individuals, the T₄ may not return to normal until 6 weeks after withdrawal of therapy and that serum TSH is never elevated. In hypothyroid patients, TSH may be elevated as early as 2 weeks after withdrawal of therapy, and TRH response is exaggerated. (LLN, lower limit of normal; ULN, upper limit of normal). Reproduced, with permission, from Wood LC. Controversial questions in thyroid disease. Workshop in the Thyroid, American Thyroid Association, Nov 1979, as adapted from Vagenakis AG, et al. Recovery of pituitary thyrotropic function after withdrawal of prolonged thyroid suppression therapy. N Engl J Med. 1975;293:681.)
β-adrenergic blocking agents, coronary angioplasty, and coronary artery bypass surgery are available, hypothyroid patients with coronary artery disease can be treated medically or surgically first, and thyroxine replacement therapy is then better tolerated.

C. Hypothyroidism and neuropsychiatric disease
Hypothyroidism is often associated with depression, which may be quite severe. More rarely, severely hypothyroid patients may become confused, paranoid, or even manic (myxedema madness). Screening of psychiatric admissions with serum FT4 and TSH is an efficient way to identify these patients, who frequently respond to T4 therapy alone or in combination with psychopharmacologic agents. The effectiveness of T4 therapy in depressed hypothyroid patients has given rise to the hypothesis that the addition of T3 or T4 to psychotherapeutic regimens for depression may be helpful in patients without demonstrable thyroid disease, but this concept has been difficult to prove.

Treatment

A. Treatment of hypothyroidism
Hypothyroidism is treated with T4, which is available in pure form and is stable and inexpensive. Because T4 is converted to T3 in peripheral tissues, both hormones become available, even though only one is administered. Desiccated thyroid is now considered obsolete because it contains both T4 and T3, and triiodothyronine (as liothyronine) is unsatisfactory because of its rapid absorption, short half-life, and transient effects. The half-life of T4 is about 7 days, so it needs to be given only once daily. It is well absorbed, and blood levels are easily monitored by following FT4 and serum TSH levels. T4 and T3 levels are stable throughout the day, although there is a slight increase in free T4 levels several hours after the medication is taken; this is not clinically significant.

B. Dosage of levothyroxine
Replacement doses of T4 in adults range from 0.05 to 0.2 mg/d, with a mean of about 0.125 mg/d. The dose of T4 varies according to the patient's age and body weight (Table 7-7). Because of more rapid T4 metabolism, infants and young children require a surprisingly high dose of T4 compared with adults. In adults, the mean replacement dose of T4 is about 1.7 μg/kg/d, or about 0.8 μg/lb/d. In older adults, the replacement dose is usually lower, about 1.6 μg/kg/d, or about 0.7 μg/lb/d. For TSH suppression in patients post-thyroidectomy for thyroid cancer, the average dose of T4 is about 2.2 μg/kg/d (1 μg/lb/d). In most patients with hypothyroidism, one can begin treatment with the full estimated dose requirement. After 4 to 6 weeks, the final dose is adjusted based on the serum TSH level. The goal is to normalize the serum TSH, which is typically between 0.5 and 4 mU/L. In older patients or patients with underlying heart disease, it is best to start with a low dose of T4 (eg, 0.025 mg daily) and increase the dose at 4- to 6-week intervals based on serum TSH measurements. Malabsorptive states or concurrent administration of soy products, aluminum hydroxide antacids, bile acid-binding resins such as cholestyramine and colestipol, calcium supplements, sucralfate, or iron compounds decrease T4 absorption. In these patients, T4 should be given before breakfast, when the stomach is empty, and the other compounds taken 4 hours later. Other drugs, such as the antisiezure medication carbamazepine, may increase thyroid hormone requirements by increasing T4 metabolism. Proton pump inhibitors such as omeprazole may also impair T4 absorption, possibly by decreasing gastric acid, but data on this point are conflicting. Estrogen replacement may increase T4 requirements by increasing binding of free T4 to TBG, whereas androgen therapy has the opposite effect. T3 has a sufficiently long half-life (7 days), so that if the patient is unable to take medications by mouth for a few days, omitting T4 therapy will not be detrimental. If a hospitalized patient is being managed by sustained parenteral therapy, the parenteral dose of T4 is about 75% to 80% of the usual oral dose.

C. Treatment of myxedema coma
Myxedema coma is an acute medical emergency and should be treated in the intensive care unit. Blood gases must be monitored regularly, and the patient usually requires intubation and mechanical ventilation. Associated illnesses such as infections or heart failure must be sought for and appropriately treated. Intravenous fluids should be administered with caution, and excessive free water intake must be avoided. Because patients with myxedema coma may absorb drugs poorly, it is imperative to give T4 intravenously. These patients have marked total body depletion, and they should receive an initial loading dose of 300 to 400 μg of T4 intravenously followed by 80% of the calculated full replacement dose intravenously daily. Management of patients with known or suspected heart disease is described later. If, after a few days, the clinical response has been suboptimal, some experts recommend adding intravenous T3 to the regimen at a dose of 5 μg every 6 hours. The clinical guides to improvement are a rise in body temperature and the return of normal cerebral and respiratory function. The possibility of concomitant adrenal insufficiency (due to autoimmune adrenal disease or pituitary insufficiency) needs to be considered and ruled out with a cosyntropin stimulation test (see Chapter 9). Full adrenal support should then be administered (eg, hydrocortisone hemisuccinate) 100 mg intravenously, followed by 50 mg intravenously every 6 hours, tapering the dose over 7 days. Adrenal support can be withdrawn if the pretreatment plasma cortisol is 20 μg/dL or greater or if results of a cosyntropin stimulation test are within normal limits. When giving T4 intravenously

in large doses, there is an inherent risk of precipitating angina, heart failure, or arrhythmias in older patients with underlying coronary artery disease.

At one time, the mortality rate of myxedema coma was about 80%. The prognosis has been vastly improved as a result of recognition of the importance of mechanically assisted respiration and the use of intravenous T4. At present, the outcome probably depends on how well the underlying comorbidities and consequences of severe hypothyroidism can be managed.

D. Myxedema with heart disease In older patients—particularly those with known cardiovascular disease—it is wise to start treatment slowly. T4 is given in a dosage of 0.025 mg/d for 2 to 4 weeks, increasing by 0.025 mg every 2 to 4 weeks until a daily dose of 0.075 mg is reached. This dose is continued for about 6 weeks. Serum TSH is then measured and the dosage adjusted accordingly. It typically takes 2 to 4 months for a patient to come into equilibrium on full dosage. In some patients, the heart is very sensitive to the level of circulating T4, and if angina pectoris or cardiac arrhythmia develops, it is essential to reduce the dose of T4 immediately.

Adverse Effects of T4 Therapy

There are no reported instances of allergy to pure T4; although it is possible that a patient may develop an allergy to the coloring dye or some component of the tablet. The major toxic effects of T4 overdosage are symptoms and signs of hyperthyroidism. Palpitations are the most common thyrotoxic cardiac symptom, and arrhythmias, particularly paroxysmal atrial tachycardia or fibrillation, may occur. Insomnia, tremor, restlessness, and excessive warmth may also be troublesome. Simply omitting the daily dose of T4 for 3 days and then reducing the dosage will correct the problem.

Increased bone resorption and osteoporosis have been associated with long-standing hyperthyroidism and will also develop in postmenopausal women chronically overtreated with T4. This can be prevented by regular monitoring and by maintaining normal serum TSH levels in patients receiving long-term replacement therapy. In patients receiving TSH-suppressive therapy for thyroid cancer, if serum FT4 levels are kept in the upper range of normal—even if TSH is suppressed—the adverse effects of T4 therapy on bone will be minimal (Chapter 23). In addition, concomitant administration of estrogen or bisphosphonates to postmenopausal women receiving high-dose T4 therapy minimizes bone resorption.

Course and Prognosis

The course of untreated hypothyroidism is one of slow deterioration, potentially leading eventually to myxedema coma and death. With appropriate treatment, however, the long-term prognosis is excellent. Because of the long half-life (7 days) of T4, it takes time to establish equilibrium on a fixed dose. Therefore, it is important to monitor the serum FT4 and TSH every 4 to 6 weeks until equilibrium is reached. Thereafter, FT4 and TSH can be monitored once in every 6 to 12 months. The dose of T4 is increased by about 50% in most women during pregnancy with the greatest dosage increases in those women with the least thyroid reserve (i.e., in women who have had a thyroidectomy or who have received radioactive iodine therapy). Older patients metabolize T4 more slowly, and the dose likely gradually decreases with age (see Chapter 23).

HYPERTHYROIDISM AND THYROTOXICOSIS

Thyrotoxicosis is the clinical syndrome that results when tissues are exposed to high levels of circulating thyroid hormones. It results in a generalized acceleration of metabolic processes. In most instances, thyrotoxicosis is due to hyperactivity of the thyroid gland, or hyperthyroidism. Occasionally, thyrotoxicosis may be due to other causes such as excessive ingestion of thyroid hormone or, very rarely, excessive secretion of thyroid hormones from an ovarian tumor (struma ovari). The various forms of thyrotoxicosis are listed in Table 7–8. These syndromes will be discussed individually below.

1. DIFFUSE TOXIC GOITER (GRAVES DISEASE)

Graves disease is the most common form of thyrotoxicosis. Females are involved about five times more commonly than males. The disease may occur at any age, with a peak incidence in the 20- to 40-year age group (see section on Thyroid Autoimmunity, above). The syndrome consists of one or more of the following features: (1) thyrotoxicosis, (2) goiter, (3) ophthalmopathy (exophthalmos), and (4) dermopathy (pretibial myxedema).

Etiology

Graves disease is currently viewed as an autoimmune disease of unknown cause. There is a strong familial predisposition, in that about 15% of patients with Graves disease have a close relative with the same disorder, and about 50% of relatives of patients with Graves disease have circulating thyroid autoantibodies. There is a much higher concordance rate of Graves disease in monozygotic twins compared to dizygotic twins, but because the concordance rate in monozygotic twins is far less than 100%, there must be environmental factors that come into play as well.
FIGURE 7-32. One theory of the pathogenesis of Graves disease. There is a defect in suppressor T lymphocytes (T_s) that allows helper T lymphocytes (T_h) to stimulate B lymphocytes (B) to synthesize thyroid auto-antibodies. The thyroid-stimulating immunoglobulin (TSI) is the driving force for thyrotoxicosis. The inflammatory process in the orbital muscles may be due to sensitization of cytotoxic T lymphocytes (T_c), or killer cells, to orbital antigens in association with cytotoxic antibodies. The thyroid and the eye are linked by a common antigen, the TSH-R, found in thyroid follicular cells and orbital fibroblasts. It is not yet clear what triggers this immunologic cascade. (Tg Ab, thyroglobulin antibody; TPO Ab, thyroperoxidase or microsomal antibody; Ag, antigen; Ab, antibody).

environmental triggers include stress, tobacco use, infection, and iodine exposure. The postpartum state, which may be associated with heightened immune function, also may trigger the development of Graves disease in genetically susceptible women.

Pathogenesis

In Graves disease, T lymphocytes become sensitized to antigens within the thyroid gland and stimulate B lymphocytes to synthesize antibodies to these antigens (see Chapter 2; see also the section on Thyroid Autoimmunity above and Figure 7–32). One such antibody is directed against the TSH receptor in the thyroid cell membrane, stimulating thyroid gland growth and function. The antibody is called a thyroid-stimulating antibody (TSAb), or thyroid-stimulating immunoglobulin (TSI). The presence of this circulating antibody is positively correlated with active disease and with relapse of the disease following therapy with antithyroid drugs. There is an underlying genetic predisposition, but it is not clear what triggers the initial onset of hyperthyroidism. Some factors that may incite the immune response of Graves disease are (1) pregnancy, particularly the postpartum period; (2) iodide excess, particularly in geographic areas of iodide deficiency, where the lack of iodide may hold latent Graves disease in check; (3) interferon α, perhaps by modifying immune responsiveness; (4) viral or bacterial infections; and (5) psychological stress. The pathogenesis of ophthalmopathy may involve cytotoxic lymphocytes (killer cells) and cytotoxic antibodies sensitized to a common antigen such as the TSH receptor that is found in orbital fibroblasts, orbital muscle, and thyroid tissue (see Figure 7–32). Cytokines from these sensitized lymphocytes may cause activation and proliferation of orbital fibroblasts and preadipocytes, resulting in increased amounts of retro-orbital fat and glycosaminoglycans, as well as swollen extraocular muscles; this results in proptosis (protrusion) of the globes and diplopia, as well as redness, congestion, and conjunctival and periorbital edema (thyroid-associated ophthalmopathy or orbitopathy). For unclear reasons, smoking cigarettes is a potent risk factor for the development of thyroid-associated ophthalmopathy.

The pathogenesis of thyroid dermopathy (pretibial myxedema) (Figure 7–33) and the rare subperiosteal inflammation on the phalanges of the hands and feet (thyroid osteopathy or acropathy) (Figure 7–34) may also involve lymphocyte cytokine stimulation of fibroblasts in these locations. Many symptoms of thyrotoxicosis suggest a state of catecholamine excess, including tachycardia, tremor, sweating, lid lag, and stare. However, circulating levels of epinephrine and norepinephrine are normal or low; thus, in Graves disease, the body appears to have an increased sensitivity to

FIGURE 7-33. Dermopathy of Graves disease. Marked thickening of the skin is noted, usually over the pretibial area. Thickening occasionally extends downward over the ankle and the dorsal aspect of the foot but almost never above the knee.
catecholamines. This may be due in part to a thyroid hormone-mediated increase in membrane-bound β-adrenergic receptors in various tissues.

**Clinical Features**

**A. Symptoms and signs** In younger individuals, common manifestations include palpitations, nervousness, easy fatigability, hyperkinesia, diarrhea, excessive sweating, intolerance to heat, and preference for cold. There is often marked weight loss without loss of appetite. Thyroid enlargement, thyrotoxic eye signs (see later), and mild tachycardia commonly occur. Muscle weakness and loss of muscle mass may be so severe that the patient cannot rise from a chair without assistance. In children, rapid growth with accelerated bone maturation occurs. In patients over age 60, cardiovascular and myopathic manifestations predominate; the most common presenting complaints are palpitations, dyspnea on exertion, tremor, nervousness, and weight loss (see Chapter 23).

The eye signs of Graves disease have been classified by Werner as set forth in Table 7–9. This classification is useful in describing the extent of the eye involvement. However, it is not helpful in following the progress of the illness, because one class does not necessarily progress into the next. The first letters of each class form the mnemonic NO SPECS. Class 1 involves retraction of the upper lids associated with active thyrotoxicosis and usually resolves spontaneously when the thyrotoxicosis is adequately controlled. Lid retraction can be seen in any form of thyrotoxicosis, because it is due to adrenergic stimulation of the upper eyelid. Classes 2 to 6 represent true infiltrative disease involving orbital muscles and orbital tissues and are specific to Graves disease. Class 2 is characterized by soft tissue involvement with periorbital edema, congestion or redness of the conjunctiva, and edema of the conjunctiva (chemosis). Class 3 consists of proptosis as measured by the Hertel exophthalmometer. This instrument consists of two prisms with a scale mounted on a bar. The prisms are placed on the lateral orbital ridges, and the distance from the orbital ridge to the anterior cornea is measured on the scale (Figure 7–35). The upper limits of normal according to race are listed in the footnote to Table 7–9. Class 4 consists of extraocular muscle involvement, which typically is due to fibrosis and failure of muscle relaxation, limiting the function of the antagonist muscle. The inferior rectus is the muscle most commonly involved in the infiltrative process. By failing to relax normally, upward gaze limitation is the most common physical finding in patients with eye muscle involvement. The muscle next most commonly involved is the medial rectus, impairing lateral gaze. Class 5 is characterized by corneal involvement (keratitis) due to inability to close the eyes completely. Class 6 is a loss of vision from optic nerve involvement, likely due to ischemia of the nerve from compression of the surrounding enlarged extraocular muscles. As noted earlier, thyroid ophthalmopathy is due to infiltration of orbital fibroblasts and the extraocular muscles with lymphocytes and edema fluid due to an inflammatory reaction. The orbit is a cone enclosed by bone, and swelling of the extraocular muscles within this closed space causes proptosis of the globe and impaired muscle movement, resulting in diplopia. Ocular muscle enlargement can be demonstrated by orbital ultrasound, orbital CT scanning, or MRI (Figure 7–36).

*Upper limits of normal according to race: white, Asian, 20 mm; black, 22 mm. Increase in proptosis of 3-4 mm is mild involvement; 5-7 mm, moderate involvement; and over 8 mm, severe involvement. Other classes can be similarly graded as mild, moderate, or severe.

Although only about one-third of patients have eye involvement clinically, enlarged muscles can be detected by imaging in over 90% of patients.

Thyroid dermopathy consists of thickening of the skin, particularly over the lower tibia, due to accumulation of glycosaminoglycans (see Figure 7–33). It is relatively rare, occurring in about 2% to 3% of patients with Graves disease. It is usually associated with significant ophthalmo­p­athy and with a very high serum titer of TSAb. The skin is markedly thickened with a peau d’orange surface, and cannot be picked up between the fingers. Sometimes the dermopathy involves the entire lower leg and may extend onto the feet. Finally, bony involvement (osteopathy or thyroid acropachy), with subperiosteal bone formation and swelling, is particularly evident in the metacarpal bones (see Figure 7–34) and as clubbing of the digits. This too is a relatively rare finding. A more common finding in Graves disease is separation of the fingernails from their beds (onycholysis or Plummer nails), likely caused by rapid growth of the nails (Figure 7–37).

B. Laboratory findings The laboratory findings in hyperthyroidism are summarized in Figure 7–38. The combination of an elevated FT₄ and a suppressed TSH makes the diagnosis of hyperthyroidism. Approximately 5% of patients have normal FT₄ levels but elevated serum T₃ levels, a situation termed T₃ thyro­toxicosis. Also, very mild Graves disease may result in FT₄ and T₃ serum levels that are within the range of normal but are high enough to lead to suppressed serum TSH levels, a situation termed subclinical hyperthyroidism. If both FT₄ and TSH are elevated, and the RAIU is also elevated, consider a TSH-secreting pituitary tumor or generalized or pituitary-resistance syndromes. Patients who are severely ill may have low serum TSH levels but also have low serum FT₄ and T₃ levels (the so-called sick euthyroid syndrome).

In the condition called familial dysalbuminemic hyperthyro­x­inemia, an abnormal albumin is present in serum that preferentially binds T₄ but not T₃. This results in elevation of serum T₄ and FT₄, and often the free T₄ when measured by usual clinical analogue free T₄ assays, but free T₃ is usually normal by equilibrium dialysis methods, as are serum T₃ and TSH. It is important to dif­ferentiate this euthyroid state from true hyperthyroidism. In addi­tion to the absence of clinical features of hyperthyroidism, a normal serum T₃ and a normal TSH level rule out hyperthyroidism.

If eye signs are present, the diagnosis of Graves disease can be made without further tests. If eye signs are absent and the patient is hyperthyroid with or without a goiter, a RAUI test should be done. An elevated uptake is typical of Graves disease. In contrast, a low uptake is seen in patients with several forms of spontaneously resolving hyperthyroidism, as in subacute thyroiditis or silent thyroiditis also termed postpartum thyroiditis, (see discussed later). A low radioiodine uptake is also found in patients who are iodine-loaded or who are taking T₄ therapy—or, rarely, in association with a struma ovarii, where ectopic thyroid tissue is located within an ovarian teratoma. Thyroid autoantibodies—to thyroglobulin and TPO—are usually present in the serum in both Graves disease and silent thyroiditis, a variant of Hashimoto thy­roiditis, but TSAb is relatively specific for Graves disease. This may be a useful diagnostic test in the patient who presents with unilateral or bilateral exopthalmos without obvious signs or laboratory manifestations of Graves disease (so called “euthyroid Graves disease”). The ¹²³I or technetium scan is useful to evaluate the size of the gland as well as the presence of hot or cold nodules. CT and MRI scans of the orbits reveal extraocular muscle enlargement in most patients with Graves disease even when there is no clinical evidence of ophthalmo­p­athy. In patients with clinical ophthalmo­p­athy, orbital muscle enlargement may be striking (see Figure 7–36).

Other Presentations
Graves disease occasionally presents in an unusual or atypical fashion, in which case the diagnosis may not be obvious. Marked muscle atrophy may suggest severe myopathy that must be differenti­ated from a primary neuromuscular disorder. Thyrotoxic periodic paralysis usually occurs in Asian males and presents with a sudden attack of flaccid paralysis and hypokalemia due to a shift...
CHAPTER 7 The Thyroid Gland

202

of K⁺ intracellularly. The paralysis usually subsides spontaneously and can be prevented by K⁺ supplementation and β-adrenergic blockade. The illness is cured by appropriate treatment of the thyrotoxicosis (see Chapter 24). Patients with thyrocardiac disease, especially those over age 60, present primarily with symptoms of heart involvement—especially refractory atrial fibrillation insensitive to digoxin—or with high-output heart failure. About 50% of these patients have no evidence of underlying heart disease, and cardiac problems are cured by treatment of the thyrotoxicosis. Some older patients present with weight loss, small goiter, slow atrial fibrillation, and severe depression, with none of the clinical features of increased catecholamine reactivity. These placid patients have apathetic thyrotoxicosis. Finally, some young women may present with amenorrhea or infertility as the primary symptom. In all of these instances, the diagnosis of hyperthyroidism can usually be made on the basis of the clinical and laboratory studies described earlier.

Complications

Thyrotoxic crisis (thyroid storm) is the acute exacerbation of all of the symptoms and signs of thyrotoxicosis, often presenting as a syndrome that may be of life-threatening severity (see Chapter 24). Occasionally, thyroid storm may be mild and present simply as an unexplained febrile reaction after thyroid surgery in a patient who has been inadequately prepared. More commonly, it occurs in a more severe form after surgery, radioactive iodine therapy, or par¬turbation in a patient with inadequately controlled thyrotoxicosis—or during a severe, stressful illness or disorder such as uncontrolled diabetes, trauma, acute infection, severe drug reaction, or myocardial infarction. The clinical manifestations of thy¬roid storm are marked hypermetabolism and excessive adrenergic response. Fever ranges from 38°C to 41°C and is associated with flushing and sweating. There is marked tachycardia, often with atrial fibrillation and high pulse pressure; occasionally heart failure occurs. Central nervous system symptoms include marked agita¬tion, restlessness, delirium, and coma. Gastrointestinal symptoms include nausea, vomiting, diarrhea, and jaundice. A fatal outcome is associated with heart failure and shock.

At one time it was thought that thyroid storm was due to sud¬den release or dumping of stored T₄ and T₃ from the thyrotoxic gland. Careful studies have revealed, however, that the serum lev¬els of T₄ and T₃ in patients with thyroid storm are not necessarily higher than in thyrotoxic patients without this condition. There is no evidence that thyroid storm is due to excessive production of T₃. Also, in thyrotoxicosis, the number of adrenergic-binding sites

FIGURE 7–38 Laboratory tests useful in the differential diagnosis of hyperthyroidism (see text for details).
for catecholamines increases, so that heart and nerve tissues have increased sensitivity to circulating catecholamines. In addition, there is decreased binding to TBG, with further elevation of free T₃ and T₄. One theory is that in this setting, with increased binding sites available for catecholamines, an acute illness, infection, or surgical stress triggers an outpouring of catecholamines which, in association with high levels of free T₄ and T₃, precipitates the acute problem.

The most striking clinical diagnostic feature of thyrotoxicosis is hyperpyrexia out of proportion to other findings. Laboratory findings include elevated serum T₄, FT₄, and T₃ as well as a suppressed TSH (see Chapter 24).

**Treatment of Graves Disease**

Although autoimmune mechanisms are responsible for the syndrome of Graves disease, management has been largely directed toward controlling the hyperthyroidism. Three good methods are available: (1) antithyroid drug therapy, (2) surgery, and (3) radioactive iodine therapy.

**A. Antithyroid drug therapy (Figure 7-9)** The antithyroid drugs methimazole, carbimazole, and PTU act by inhibiting TPO-mediated iodination of thyroglobulin to form T₄ and T₃ within the thyroid gland. PTU but not methimazole blocks peripheral T₄ to T₃ conversion; however, this effect is not generally considered to be clinically important except possibly in patients with severe thyrotoxicosis or thyroid storm. Carbimazole, used in the United Kingdom and parts of the British Commonwealth, is a derivative of methimazole that is rapidly metabolized to methimazole. Additionally, each of these drugs may have immunosuppressive effects that may be responsible for the remission from the disease that some patients have after 1 to 2 years of treatment. In general, antithyroid drug therapy as a first-line therapy is most useful in young patients with small glands and mild disease. The drug is given for 1 to 2 years and then it is tapered or discontinued to see whether the patient has achieved a remission. Remissions, defined as normal thyroid function for 1 year following discontinuation of the antithyroid drug, occur in 20% to 50% of patients but may not be lifelong. Antithyroid drug therapy is generally started with larger doses. When the patient becomes biochemically euthyroid after 4 to 12 weeks, maintenance therapy may be achieved with a lower dose. Because of the potential for severe and potentially fatal hepatotoxicity with PTU, methimazole is the antithyroid drug of choice in most patients. Methimazole has a longer duration of action and single daily dosing leads to improved compliance. A typical regimen starts with a 10 to 20-mg dose of methimazole each morning for 1 to 2 months; this dose would then be reduced to 5 to 10 mg each morning for maintenance therapy. PTU could be considered in patients with mild allergic reactions to methimazole, and is preferred in pregnant women in the first trimester because of rare teratogenic effects of methimazole in the fetus. A common regimen consists of giving PTU, 100 mg every 8 hours initially, and then in 4 to 8 weeks, reducing the dose to 50 to 200 mg once or twice daily. The laboratory tests of most value in early monitoring the course of therapy are serum FT₄ and T₃. TSH levels often remain suppressed for many weeks or even months, and hence are not a reliable index of thyroid function early in the course of treatment.

An alternative method of therapy utilizes the concept of a total block of thyroid activity. The patient is treated with methimazole until euthyroid (about 3–6 months), but instead of continuing to taper the dose of antithyroid drug, at this point T₄ is added in a dose of about 0.1 mg/d. The patient then continues to receive the combination of antithyroid drug and T₄ (0.1 mg/d) for another 12 to 24 months. At the end of this time or when the size of the gland has returned to normal, the drugs are discontinued. This combined therapy prevents the development of hypothyroidism due to excessive doses of antithyroid drugs, but the frequency of relapse is about the same as after treatment with antithyroid drugs alone. It is more expensive, because two drugs are needed, and there may be a greater frequency of side effects. Consequently, this strategy is not recommended for most patients.

1. **Duration of therapy and other factors related to remissions**—The duration of therapy with antithyroid drugs in Graves disease is usually 12 to 24 months; some patients prefer to be treated, if necessary, for prolonged periods of time (eg, decades) but this is not typical. A sustained remission is most likely in the following circumstances: (1) if the thyroid gland returns to normal size, (2) if the disease can be controlled with a relatively small dose of antithyroid drugs, and (3) if TSAbs are no longer detectable in the serum at the end of the course of therapy.

2. **Reactions to antithyroid drugs**—Allergic reactions to antithyroid drugs can be minor, especially a rash (about 5% of patients) or major, especially agranulocytosis (about 0.5% of patients). The rash can often be managed by administering antihistamines, and unless it is severe, it is not an indication for discontinuing the medication. Agranulocytosis requires immediate cessation of antithyroid drug therapy, institution of appropriate antibiotic therapy, and shifting to an alternative therapy, usually radioactive iodine. Agranulocytosis is usually heralded by a severe sore throat and fever. Thus, all patients receiving antithyroid drugs are instructed that if sore throat or fever develops, they should stop the drug, contact their physician, and obtain a white blood cell and differential count. If the white blood cell count is normal, the antithyroid drug can be resumed. Cholestatic jaundice with methimazole, hepatocellular toxicity and vasculitis with PTU, and acute arthritis with either drug are serious but rare side effects that also require cessation of drug therapy. As noted earlier, the severity of hepatotoxicity from PTU has led to the warning by the FDA that PTU be used only in special circumstances: in patients who are allergic to methimazole who are not candidates for radioiodine or surgery and in the first trimester of pregnancy. PTU may also be preferred in patients with thyroid storm, where the inhibition of T₄ to T₃ conversion may be clinically important.

**B. Radioactive iodine therapy** In the United States, sodium iodide ¹³¹I is the preferred treatment for most patients over age 21. In many patients without underlying heart disease, radioactive iodine may be given immediately in a dosage of 80 to 200 μCi/g of thyroid weight estimated on the basis of physical examination. The dosage is corrected for iodine uptake according to the following formula:
Dose = $\frac{80 - 200 \text{ microcuries}}{\text{Estimated gm thyroid tissue}} \times \frac{\text{Estimated gm thyroid tissue}}{\text{fractional 24-hour radioiodine uptake}}$

Following the administration of radioactive iodine, which typically is given orally as a single capsule, the gland will shrink, and the patient will usually become euthyroid over a period of 2 to 6 months.

In elderly patients and in those with underlying heart disease or other medical problems, severe thyrotoxicosis, or large glands (>100 g), it is desirable to achieve a euthyroid state prior to $^{131}$I therapy, because there may be occasional exacerbations of thyroid function in the weeks following radioiodine therapy. For this purpose, patients usually are treated with methimazole until they are euthyroid; medication is then stopped for 3 to 7 days, and the radioiodine therapy is given. Methimazole (or PTU) pretreatment have been associated with a diminished effectiveness of radioiodine therapy, which can be overcome by modestly increasing the dose of radioactive iodine.

Hypothyroidism is the almost inevitable complication of radioiodine therapy, ultimately developing in more than 80% of patients who are adequately treated. Hypothyroidism usually occurs in the first 6 to 12 months after therapy and is the best assurance that the patient will not have a recurrence of hyperthyroidism. Serum FT$_4$ and TSH levels should be followed every 6 to 8 weeks, and when hypothyroidism develops, prompt replacement therapy with T$_4$. 0.05 to 0.2 mg daily, is instituted. Long-term follow-up studies have shown that radioiodine therapy does not cause infertility, birth defects, or cancer later in life. Severe Graves eye disease is a relative contraindication to radioiodine therapy; several prospective studies have shown that radioiodine can exacerbate eye problems when they are severe at baseline. Patients with severe underlying hyperthyroidism and those patients who smoke cigarettes are particularly prone to an exacerbation following radioiodine treatment. However, potential worsening can be prevented by the administration of prednisone 30 to 60 mg daily for 1 to 2 months following the radioiodine treatment. Prednisone is typically used in patients with moderate to severe Graves eye disease, especially in those who smoke cigarettes.

Hypothyroidism may also occur as a late development after an earlier course of antithyroid drug therapy for Graves disease; in such patients, burned-out Graves disease is likely the end result of autoimmune thyroid destruction. Accordingly, all patients with Graves disease who have not become hypothyroid require lifetime follow-up to be certain that they remain euthyroid.

The patient is prepared with antithyroid drugs until euthyroid (about 6 weeks). In addition, starting 2 weeks before the day of operation, the patient may be given saturated solution of potassium iodide, five drops twice daily. This regimen is thought to diminish the vascularity of the gland and thereby decrease intraoperative blood loss.

An experienced surgeon is required and total thyroidectomy is recommended, because if too much thyroid tissue is left behind, the disease may recur. Hypoparathyroidism and recurrent laryngeal nerve injury occur as complications of surgery in about 1% of cases, with lower rates in the hands of high volume surgeons.

D. Other medical measures During the acute phase of thyrotoxicosis, $\beta$-adrenergic blocking agents are extremely helpful. Propranolol, 10 to 40 mg every 6 hours, or longer acting beta-blockers such as Inderal LA, nadolol, atenolol, or metoprolol control many adrenergic symptoms, tachycardia, hypertension, and atrial fibrillation. The drug is gradually withdrawn as serum FT$_4$ and T$_3$ levels return to normal. Adequate nutrition and rest are both essential. The oral cholecystographic dyes, sodium iopanoate and iopanoic acid (no longer available in the United States), have been shown to inhibit both thyroid hormone synthesis and release as well as peripheral conversion of T$_4$ to T$_3$. In a dosage of 1 g daily, these drugs may help to rapidly restore the euthyroid state in very ill patients. They leave the gland saturated with iodide, so they should not be used immediately before $^{131}$I therapy. Cholestyramine, 4 g orally three times daily, lowers serum T$_4$ by binding it in the gut, and may be useful in severely hyperthyroid patients.

Choice of Therapy

The choice of therapy varies with the nature and severity of the illness and prevailing customs. For example, in the United States, radioiodine therapy has been the preferred treatment for the average patient, whereas in Europe and Asia, primary antithyroid drug therapy is preferred. In general, antithyroid drugs are a reasonable initial therapy for children and adolescents and in adults with mild disease and small goiters. In all other patients, radioiodine is the treatment of choice. Nowadays, the role of surgery is limited to noncompliant patients who refuse radioiodine, patients with large goiters, and other unusual circumstances noted earlier.

C. Surgical treatment Total or near-total thyroidectomy is the treatment of choice for patients with very large glands or multinodular goiters, for patients with a concomitant suspicious or malignant thyroid nodule, for patients who are allergic to or noncompliant with antithyroid drugs, for patients who refuse radioactive iodine, and for pregnant women with severe Graves disease who are allergic or develop reactions to antithyroid drugs.

D. Other medical measures}

During the acute phase of thyrotoxicosis, $\beta$-adrenergic blocking agents are extremely helpful. Propranolol, 10 to 40 mg every 6 hours, or longer acting beta-blockers such as Inderal LA, nadolol, atenolol, or metoprolol control many adrenergic symptoms, tachycardia, hypertension, and atrial fibrillation. The drug is gradually withdrawn as serum FT$_4$ and T$_3$ levels return to normal. Adequate nutrition and rest are both essential. The oral cholecystographic dyes, sodium iopanoate and iopanoic acid (no longer available in the United States), have been shown to inhibit both thyroid hormone synthesis and release as well as peripheral conversion of T$_4$ to T$_3$. In a dosage of 1 g daily, these drugs may help to rapidly restore the euthyroid state in very ill patients. They leave the gland saturated with iodide, so they should not be used immediately before $^{131}$I therapy. Cholestyramine, 4 g orally three times daily, lowers serum T$_4$ by binding it in the gut, and may be useful in severely hyperthyroid patients.

Choice of Therapy

The choice of therapy varies with the nature and severity of the illness and prevailing customs. For example, in the United States, radioiodine therapy has been the preferred treatment for the average patient, whereas in Europe and Asia, primary antithyroid drug therapy is preferred. In general, antithyroid drugs are a reasonable initial therapy for children and adolescents and in adults with mild disease and small goiters. In all other patients, radioiodine is the treatment of choice. Nowadays, the role of surgery is limited to noncompliant patients who refuse radioiodine, patients with large goiters, and other unusual circumstances noted earlier.

Treatment of Complications

A. Thyrotoxic crisis Thyrotoxic crisis (thyroid storm) requires vigorous management. Propranolol, 1 to 2 mg slowly intravenously every 5 to 10 minutes for a total of 10 mg, or 40 to 80 mg every 6 hours orally, is helpful in controlling arrhythmias. Large doses of propranolol also have the ability to block T$_4$ to T$_3$ conversion. Esmolol, a very rapidly acting beta blocker, is given at a dose of 250 to 500 mg/kg/min as a loading dose followed by 50 $\mu$g/kg/min with cardiac monitoring. In the presence of severe heart failure or asthma and arrhythmia, where beta blockers may be contraindicated, cautious intravenous administration of
verapamil in a dose of 5 to 10 mg may be effective. Hormone synthesis is blocked by the administration of PTU, 250 mg every 6 hours. In thyroid storm, PTU may be preferable to methimazole because PTU blocks $T_4$ to $T_3$ conversion. If the patient is unable to take medication by mouth, methimazole in a dose of 60 mg every 24 hours or PTU, 400 mg every 6 hours, can be given by rectal suppository or enema. After administration of an antithyroid drug, hormone release is retarded by the oral administration of a saturated solution of potassium iodide, 10 drops twice daily. As noted above, the oral cholecystographic agents, sodium iopodate (Oragrafin) or iopanoic acid (Telepaque), provide a source of iodine and potentially block $T_4$ to $T_3$ conversion, but these drugs are not available currently in the United States. The administration of hydrocortisone hemisuccinate, or its equivalent, 50 mg intravenously every 6 hours, is usually recommended, but its role in thyroid storm management is uncertain. Supportive therapy includes a cooling blanket and acetaminophen to help control fever. Aspirin is contraindicated because of its tendency to bind to TBG and displace $T_4$, rendering more $T_4$ available in the free state. Proper fluid, electrolyte, and nutritional support are important. For sedation, phenobarbital may be useful because it accelerates the peripheral metabolism and inactivation of $T_4$ and $T_3$. Oxygen, diuretics, and digoxin are indicated for heart failure and/or atrial fibrillation. Finally, it is essential to treat the underlying disease process that may have precipitated the acute exacerbation. As an extreme measure (rarely needed) to control thyrotoxic crisis, plasmapheresis or peritoneal dialysis may be used to remove high levels of circulating free thyroid hormones (see Chapter 24).

B. Ophthalmopathy For mild disease, keeping the patient's head elevated at night and the administration of diuretics may help diminish periorbital edema. As noted above, prednisone begun immediately after radioiodine in a dose of 30 to 60 mg/d, reducing the dose by 10 mg every 2 weeks, protects against exacerbation of ophthalmopathy following $^{131}$I therapy. Management of severe ophthalmopathy due to Graves disease involves close cooperation between the endocrinologist and the ophthalmologist. For severe acute inflammatory reactions, a short course of high-dose corticosteroid therapy is frequently effective (eg, prednisone, 100 mg daily orally in divided doses for 7-14 days, then every other day in gradually diminishing dosage for 6-12 weeks). Alternatively, pulse therapy with high doses of intravenous methylprednisolone can be used. If corticosteroid therapy is not effective or if there is recurrence after the drug is tapered, external x-ray therapy to the retrobulbar area may be helpful. The dose is usually 2000 cGy in 10 fractions given over a period of 2 weeks. The lens and anterior chamber structures must be shielded.

In very severe cases where vision is threatened, orbital decompression can be used. One operation involves a transantral approach through the maxillary sinus, removing the floor and the lateral walls of the orbit. In the alternative anterior approach, the orbit is entered under the globe, and portions of the floor and the walls of the orbit are removed. Both approaches are effective, and exophthalmos can be reduced by 5 to 7 mm in each eye by these techniques. After the acute process has subsided, the patient is frequently left with double vision or lid abnormalities owing to muscle fibrosis and contracture or the postoperative position of the globe. These problems can be corrected by cosmetic lid surgery or eye muscle surgery.

C. Thyrotoxicosis and pregnancy Thyrotoxicosis during pregnancy presents a special problem. It is unusual, affecting approximately 0.1% of pregnancies. It is important to recall that serum TSH levels may be subnormal at the end of the first trimester in up to 20% of normal women. This is due to the effects of serum hCG, the levels of which normally peak at the end of the first trimester; hCG activates the TSH receptor. This is a transient phenomenon and is physiologic, not pathologic. Hyperemesis gravidarum may cause mild hyperthyroidism (so-called gestational thyrotoxicosis), which is likely due to extremely high serum levels of hCG, present in this condition, that stimulates the TSH receptor. However, no treatment is indicated, because the hyperthyroid state resolves when the hyperemesis resolves, usually by midgestation.

In pregnant patients with Graves disease, the patient is treated with antithyroid drugs throughout most of the pregnancy, postponing the decision regarding long-term management until after delivery. Radioactive iodine is absolutely contraindicated because it crosses the placenta freely and may injure the fetal thyroid. The dosage of antithyroid drugs must be kept to the minimum necessary to control symptoms, because both PTU and methimazole cross the placenta and may affect the function of the fetal thyroid gland. PTU is preferred over methimazole because methimazole has rare teratogenic effects (aplasia cutis and methimazole embryopathy [choanal atresia, tracheoesophageal fistulae, and other defects]). Current recommendations advise limiting PTU use to the first trimester, and then switching to methimazole. However, methimazole can be used when PTU allergy or a poor clinical response to PTU is present. If the disease can be controlled by initial doses of PTU of 250 mg/d (in divided doses) or less and maintenance doses of 25 to 100 mg/d, the likelihood of fetal hypothyroidism is extremely small. The FT₄ or FT₃ should be maintained in the upper range of normal for nonpregnant women by appropriately reducing the antithyroid drug dosage. In a significant minority of patients, the drug can be discontinued in the latter part of pregnancy because of spontaneous disappearance of TSAb. Serum levels of TSAb should be measured in the third trimester; high titers can be associated with neonatal Graves disease (see later). Breastfeeding is permissible with either antithyroid drug, because the low levels found in breast milk do not affect thyroid function in the neonate.

Graves disease may occur in the newborn infant (neonatal Graves disease) due to transplacental passage of TSAb. Although

---

1Preparation of rectal methimazole: Dissolve 1200 mg methimazole in 12 mL of water to which a mixture of two drops of Span 80 in 52 mL of cocoa butter warmed to 37°C has been added. Stir the mixture to form a water-oil emulsion, pour into 2.6 mL suppository molds, and cool. Each suppository supplies approximately 60 mg methimazole-absorbed dose (Naibel et al, 1982).

Preparation of rectal PTU: Dissolve 400 mg PTU in 60 mL of Fleer Mineral Oil for the first dose and then dissolve 400 mg PTU in 60 mL of Fleer Phospho-Soda for subsequent enemas.
most infants with this rare syndrome are born to mothers with active Graves disease, it occasionally can occur in infants born to hypothyroid mothers who have been treated for Graves disease with radiiodine in the past but who still retain circulating TSAb. The disease may not be evident at birth, because the antithyroid drugs used to treat the mother can cross the placenta and affect the infant’s thyroid as well. The child is born small, with weak muscles, tachycardia, fever, and frequently with distress or neonatal jaundice. Examination reveals an enlarged thyroid gland and occasionally prominent, puffy eyes. The heart rate is rapid, temperature is elevated, and heart failure may ensue. Laboratory studies reveal an elevated FT₄ or FT₃, a markedly elevated T₃, and usually a low TSH—in contrast to normal infants, who have elevated TSH at birth. Bone age may be accelerated. TSAb is usually found in the serum of both the infant and the mother. The pathogenesis of this syndrome is thought to involve transplacental transfer of TSAb from mother to fetus, with subsequent development of thyrotoxicosis. The disease is self-limited and subsides over a period of 4 to 12 weeks, coinciding with the fall in the child’s serum TSAb levels. Therapy for the infant includes PTU in a dose of 5 to 10 mg/kg/d (in divided doses at 8-hour intervals); Lugol solution, one drop (8 mg potassium iodide) every 8 hours; and propranolol, 2 mg/kg/d in divided doses. In addition, adequate nutrition, antibiotics for infection if present, sedatives if necessary, and supportive therapy are indicated. If the child is very thyrotoxic, corticosteroid therapy (prednisone, 2 mg/kg/d) partially blocks conversion of T₄ to T₃ and may be helpful in the acute phase. The above medications are gradually reduced as the child improves and can usually be discontinued by 6 to 12 weeks.

Maternal sera may also contain TSAb that functions as blocking antibodies that can cross the placenta to produce transient hypothyroidism in the infant. This condition may need to be treated with T₄ supplementation for a short time.

**Course and Prognosis**

In general, the course of Graves disease treated with antithyroid drugs is one of remissions and exacerbations over a protracted period of time, unless the gland is destroyed by surgery or radioactive iodine. Although some patients may remain euthyroid for long periods after antithyroid drug treatment, at least 25% eventually develop hypothyroidism. Lifetime follow-up is therefore indicated for all patients with Graves disease.

**2. OTHER FORMS OF THYROTOXICOSIS**

**Toxic Adenoma**

A functioning adenoma hypersecreting T₃ and T₄ causes hyperthyroidism. These lesions start out as a small autonomously functioning nodule that slowly increases in size to produce excessive quantities of thyroid hormones. This gradually supresses endogenous TSH secretion, which results in reduced function of the contralateral lobe of the gland (Figure 7-39). The typical patient is an older individual (usually >40) who has noted recent growth of a long-standing thyroid nodule. Symptoms of weight loss, weakness, shortness of breath, palpitations, tachycardia, and heat intolerance are noted. Infiltrative ophthalmopathy is never present.

Physical examination reveals a definite nodule on one side, with very little thyroid tissue on the other side. Laboratory studies usually reveal suppressed TSH and elevation in serum T₃ levels, often with only borderline elevation of FT₄ levels. A radionuclide scan reveals that the nodule is hot, with diminished or absent function of the contralateral lobe. Toxic adenomas are usually benign follicular adenomas and almost never malignant.

Treatment with radioactive iodine is generally effective and is attractive because the contralateral lobe can be spared the destructive effects of the radiation, and the patient should therefore remain euthyroid. Radiodine therapy in doses of 20 to 30 mCi is usually required to destroy the benign neoplasm. If antithyroid drugs are used to pretreat the patient, it is important that the serum TSH remain low, so that the contralateral lobe will not be stimulated to take up the radioiodine. Surgery is an option, if the nodule is very large and causing obstructive symptoms such as dysphagia, neck pressure, or difficulty breathing. Antithyroid drugs may be used to normalize thyroid function prior to radioiodine or surgery but are not a good long-term solution, because, unlike the situation with Graves disease, remissions do not occur.

**Toxic Multinodular Goiter (Plummer Disease)**

This disorder usually occurs in older patients with long-standing euthyroid multinodular goiter. The patient presents with tachycardia, heart failure, or arrhythmia and sometimes weight loss, nervousness, weakness, tremors, and sweats. Physical examination reveals a multinodular goiter that may be small or quite large and may even extend substernally. Laboratory studies reveal a suppressed TSH and elevation in serum T₃ levels, with less striking elevation of serum T₄. Radioiodine scan reveals multiple
functioning nodules in the gland or occasionally an irregular, patchy distribution of radioactive iodine (Figure 7-40).

Hyperthyroidism in patients with long-standing multinodular goiters can be precipitated by the administration of pharmacologic doses of iodide-containing drugs (called the Jod-Basedow phenomenon or iodide-induced hyperthyroidism). The pathophysiology of iodine-induced hyperthyroidism is unknown but likely involves the inability of some thyroid nodules to adapt to an iodide load, with resulting excess hormone production. This is one mechanism for the development of hyperthyroidism after administration of the iodine-containing antiarrhythmic drug amiodarone (see later).

The management of toxic nodular goiter may be difficult, because patients are often elderly with other comorbidities. Control of the hyperthyroid state with antithyroid drugs followed by radioiodine is the therapy of choice. If the goiter is very large, thyroidectomy can be contemplated if the patient is a good surgical candidate.

Amiodarone-Induced Thyrotoxicosis

Amiodarone is an antiarrhythmic drug that contains 37.3% iodine by weight. In the body, it is stored in fat, myocardium, liver, and lung and has a half-life of about 50 days. In the United States, about 2% of patients treated with amiodarone develop amiodarone-induced thyrotoxicosis. In some patients, the thyrotoxicosis is due to the excess iodine; in others, it is due to an amiodarone-induced thyroiditis, with inflammation and release of stored hormone into the bloodstream as the result of thyroidal inflammation. Thyroid ultrasound with Doppler examination of the thyroid circulation may be helpful in differentiating the two syndromes: the thyroidal blood flow is increased in iodide-induced hyperthyroidism and diminished in thyroiditis. Treatment is often difficult. Iodide-induced thyrotoxicosis can be controlled with methimazole, 40 to 60 mg/d, and β-adrenergic blockade. Although potassium perchlorate (250 mg every 6 hours) could be added to block further iodide uptake, long-term, high-dose treatment with this agent has been associated with aplastic anemia and requires careful monitoring. Also, this drug is no longer available in the United States. The drug-induced thyroiditis responds to prednisone therapy, which may need to be continued for several months. Some patients have what appears to be a mixed form of disease and respond to a combination of antithyroid drugs and prednisone. Total thyroidectomy is curative and may be needed in patients who are nonresponsive to pharmacologic therapy. Of course, surgery is feasible only if the patient can withstand the stress of surgery (see Chapter 24).

Subacute and Silent Thyroiditis

These entities will be discussed in a separate section, but it should be mentioned here that thyroiditis, either subacute or silent, may present with symptoms of mild to severe thyrotoxicosis following an acute release of T₄ and T₃ into the circulation. These illnesses can be differentiated from other forms of thyrotoxicosis in that the RAIU is markedly suppressed and the symptoms usually subside spontaneously over a period of weeks or months.

Thyrotoxicosis Factitia

This is a psychoneurotic disturbance in which the patient surreptitiously ingests excessive amounts of T₄ or thyroid hormone preparations, usually for purposes of weight control. The individual, usually a woman, is often someone connected with the health-care field who can easily obtain thyroid medication. Features of thyrotoxicosis, including weight loss, nervousness, palpitation, tachycardia, and tremor, may be present, but goiter and eye signs are absent. Characteristically, TSH is suppressed, serum FT₄ and T₃ levels are elevated, serum thyroglobulin is low, and RAIU is nil. Management requires careful discussion of the hazards of long-term thyroid hormone therapy, particularly cardiovascular damage, muscle wasting, and osteoporosis. Formal psychotherapy may be necessary.

Rare Forms of Thyrotoxicosis

A. Struma ovarii In this syndrome, a teratoma of the ovary contains thyroid tissue that becomes hyperactive. Mild features of thyrotoxicosis result, such as weight loss and tachycardia, but there is no evidence of goiter or eye signs. Serum FT₄ and T₃ are mildly elevated, serum TSH is suppressed, and RAIU over the neck is low. Total body scan reveals uptake of radioiodine in the pelvis, rather than in the neck. The disease is curable by removal of the teratoma.

B. Thyroid carcinoma Follicular carcinoma of the thyroid may concentrate radioactive iodine, but only rarely does it retain the ability to convert this iodide into active hormone. Only a few cases of metastatic thyroid cancer are described in which patients have presented with hyperthyroidism. The clinical picture consists
of weakness, weight loss, palpitations, and a thyroid nodule but no ophthalmopathy. Body scan with $^{131}$I reveals areas of uptake usually distant from the thyroid (e.g., bone or lung). Treatment with large doses of radioactive iodine may destroy the metastatic deposits and treat the hyperthyroidism.

C. Hydatidiform mole and choriocarcinoma  Hydatidiform moles and choriocarcinomas produce high levels of chorionic gonadotropin, which has intrinsic TSH-like activity. This may induce thyroid hyperplasia, increased radioiodine uptake, suppressed TSH, and mild elevation of serum T4 and T3 levels. It is rarely associated with overt thyrotoxicosis and is curable by removal of the mole or treatment of the tumor.

D. Hamburger thyrotoxicosis  In the 1970s an epidemic of thyrotoxicosis in the midwestern United States was traced to hamburger made from neck trim, the strap muscles from the necks of slaughtered cattle that contained beef thyroid tissue. The United States Department of Agriculture has now prohibited the use of this material for human consumption.

E. Syndrome of inappropriate TSH secretion  A group of patients have been reported with elevated serum FT$_4$ concentrations in association with elevated or inappropriately normal serum immunoreactive TSH levels. This has been called the syndrome of inappropriate TSH secretion. Two conditions may explain this unusual combination of laboratory values: (1) TSH-secreting pituitary adenoma, and (2) non-neoplastic pituitary hypersecretion of TSH.

Patients with TSH-secreting pituitary adenomas usually present with mild thyrotoxicosis and goiter and may have a concurrent pituitary hormonal deficiency, such as central hypogonadism causing amenorrhea or impotence. Rarely, a TSH-secreting tumor may cosecrete other pituitary hormones such as growth hormone or prolactin. There are no eye signs of Graves disease. Laboratory evaluation reveals elevated FT$_4$ and T$_3$ whereas serum TSH, usually undetectable in Graves disease, is within the normal range or even elevated. The TSH $\alpha$ subunit secretion from these tumors is markedly elevated; a molar ratio of $\alpha$ subunit:TSH greater than 5.7 is usually diagnostic of the presence of a TSH-secreting pituitary adenoma.$^4$

In addition, the increased serum TSH is not suppressible with high doses of exogenous thyroid hormones. Visual field examination may reveal a bitemporal defect, and CT or MRI of the sella usually reveals a pituitary tumor. Management usually involves control of the thyrotoxicosis with antithyroid drugs and removal of the pituitary tumor via transsphenoidal hypophysectomy. These tumors are often quite aggressive and may extend widely out of the sella. If the tumor cannot be completely removed, it may be necessary to treat residual tumor with radiation therapy and to control thyrotoxicosis with radioactive iodine. Long-acting somatostatin analog (octreotide) suppresses TSH secretion in many of these patients and may even inhibit tumor growth in some.

Non-neoplastic pituitary hypersecretion of TSH is essentially a form of tissue resistance to T$_3$ and T$_4$. This is discussed in the following section.

**Thyroid Hormone Resistance Syndromes**

Two forms of resistance to thyroid hormones are recognized: (1) generalized resistance to thyroid hormones (GRTH), (2) selective pituitary resistance to thyroid hormones (PRTH).

GRTH was first described in 1967 as a familial syndrome of deaf mutism, stippled epiphyses, goiter, and abnormally high thyroid hormone levels with normal TSH. The clinical presentation in more than 500 cases that have been reported has been variable; although most patients are clinically euthyroid, some present with goiter, stunted growth, delayed maturation, attention deficits, hyperactivity disorders, and resting tachycardia. Seventy-five percent of reported cases are familial. Inheritance is autosomal dominant. Laboratory tests reveal elevated T$_3$, FT$_4$, T$_3$, and normal or elevated TSH. Dynamic tests to distinguish generalized resistance to thyroid hormones from TSH-secreting adenomas usually reveal a fall in TSH with T$_3$ administration, and a molar ratio of $\alpha$ subunit:TSH of less than 1. In addition, in patients with GRTH, pituitary MRI fails to demonstrate a pituitary tumor. Molecular studies have revealed point mutations in the carboxyl terminal ligand-binding portion of the human TR$\beta$, which produces a defective TR that fails to bind T$_3$ but retains the ability to bind to DNA. In addition, the mutant TR occupies the TRE as an inactive dimer or heterodimer, perhaps inducing sustained gene repression (see Figures 7–20 and 7–21). Individual point mutations in different families may account in part for the differences in clinical expression of the syndrome. Furthermore, identification of the mutation in affected individuals may allow the use of molecular screening methods for the diagnosis of the syndrome in some families.

In most patients with GRTH, the increased levels of T$_3$ and T$_4$ compensate in part for the receptor defect, and treatment is not necessary. In fact, some patients are erroneously thought to have Graves disease and undergo inappropriate therapy with radioiodine or surgery. In some children, administration of thyroid hormones may be necessary to correct defects in growth or mental development.

Selective PRTH is less common and usually presents with symptoms of mild hyperthyroidism, goiter, elevated serum T$_3$ and T$_4$, and normal or elevated serum TSH. It is currently thought that selective PRTH is not a distinct syndrome, but rather the result of the poor sensitivity and specificity of the signs and symptoms of hyperthyroidism, and the fact that thyroid hormone resistance is not necessarily complete and may vary from tissue to tissue. In fact, identical mutations in the TR$\beta$ receptor have been found in patients with both variants of thyroid hormone resistance. If the hyperthyroid state is causing significant symptoms, therapy with beta-blocking drugs, antithyroid drugs, or radioactive iodine could be considered.

$^4$The $\alpha$ subunit-TSH molar ratio is calculated as follows: ($\alpha$ subunit in $\mu$g/L divided by TSH in mIU/L) x 10. Normal range (for a patient with normal TSH and gonadotrophins) is less than 1.
**TSH Receptor Gene Mutations**

Mutations in the TSH receptor (TSH-R) gene can produce a variety of clinical syndromes. Somatic mutations in the seven-transmembrane loop of the TSH-R may activate the receptor, producing solitary or multiple hyperfunctioning adenomas, whereas germline mutations may result in congenital hyperthyroidism in the newborn, that can mimic neonatal Graves disease. Mutations in the extracellular amino terminal portion of the TSH-R produce resistance to TSH with uncompensated or compensated hypothyroidism. Some patients may have normal serum FT4 and T3 levels and normal growth and development but persistently elevated serum TSH. Others may be severely hypothyroid (cretinoid), with low FT4 levels, elevated TSH, and no response to exogenous TSH. In this group, the defect may be in the coupling of TSH-R and the G, protein necessary for activation of adenylyl cyclase.

**NONTOXIC GOITER**

**Etiology**

Nontoxic goiter (ie, goiter not associated with hyperthyroidism) can be diffuse or nodular. In some circumstances, it results from TSH stimulation, which in turn results from inadequate thyroid hormone synthesis. Some goiters are due to mutations in genes involved in thyroid growth and/or thyroid function. In many patients, however, the cause of the goiter is obscure, because serum TSH levels are normal. Worldwide, iodine deficiency remains the most common cause of nontoxic goiter or endemic goiter. With the widespread use of iodized salt and the introduction of iodides into animal feeds, and food preservatives, iodide deficiency in developed countries has become relatively rare, and it probably does not exist in the United States. However, there are large areas such as central Africa, the mountainous areas of central Asia, the Andes of central South America, parts of central Europe, and Indonesia (particularly New Guinea), where iodine intake is still markedly deficient. Optimal iodine requirements for adults are in the range of 150 to 300 μg/d. In endemic goiter areas, the daily intake (and urinary excretion) of iodine falls below 50 μg/d; in areas where iodine is extremely scarce, excretion falls below 20 μg/d. It is in these areas that the great number of the population has goiters, and 5% to 15% of infants are born with myxedematous or neurologic changes of cretinism. The variability in the extent of goiter in these areas may be related to the presence of other, unidentified goitrogens such as goitrin, an organic compound found in cassava and cabbage, that release thiocyanate that can exacerbate the effects of iodide deficiency. In addition, compounds such as phenols, phthalates, pyridines, and polynuclear hydrocarbons found in industrial waste water are weakly goitrogenic.

The most common cause of thyroid enlargement in developed countries is chronic thyroiditis (Hashimoto thyroiditis; see later). The cause of goiter not due to autoimmune thyroid disease or iodine sufficiency is uncertain. In some patients, mild defects in thyroid hormone synthesis (dys hormonogenesis) (discussed above in the section on Hypothyroidism) may result in goiter with relatively normal thyroid function. Finally, thyroid enlargement can be due to gene mutations producing a benign lesion, such as adenoma, or to a malignant one, such as carcinoma.

**Pathogenesis**

The development of nontoxic goiter in patients with dys hormonogenesis or severe iodine deficiency involves impaired hormone synthesis and, secondarily, an increase in TSH secretion. TSH induces diffuse thyroid hyperplasia, followed by focal hyperplasia with necrosis and hemorrhage, and finally the development of new areas of focal hyperplasia. Focal or nodular hyperplasia usually involves a clone of cells that may or may not be able to concentrate iodine or synthesize thyroglobulin. Thus, the nodules vary from hot nodules that can concentrate iodine to cold ones that cannot, and from colloid nodules that can synthesize thyroglobulin to microfollicular ones that cannot. Initially, the hyperplasia is TSH dependent, but later the nodules become TSH independent, or autonomous. Thus, a diffuse nontoxic TSH-dependent goiter may progress over an extended period of time to become a toxic multinodular TSH-independent goiter.

The mechanism for the development of autonomous growth and function of thyroid nodules may involve mutations that activate the G, protein in the cell membrane. Mutations of this gene, called the gsp oncogene, have been found in a high proportion of nodules from patients with multinodular goiter. Chronic activation of the G, protein results in thyroid cell proliferation and hyperfunction even when TSH is suppressed.

In iodine-sufficient parts of the world such as the United States, euthyroid nontoxic goiter is a very common problem affecting up to 15% of women. The cause of goiter in the absence of iodine deficiency, autoimmunity, or obvious biosynthetic defects is unknown. In some kindreds with euthyroid multinodular goiter, mutations in the thyroglobulin gene have been identified, suggesting the presence of subclinical or mild defects in thyroid hormone synthesis that do not cause overt hypothyroidism or even elevation in serum TSH levels.

**Clinical Features**

**A. Symptoms and signs**  Patients with nontoxic goiter usually present with thyroid enlargement, which, as noted above, may be diffuse or multinodular. The gland may be relatively firm but is often soft or rubbery in consistency. Over a period of time, the gland may become progressively larger, so that in long-standing cases, huge goiters may develop and extend substernally to the level of the aortic arch. Facial flushing and dilation of cervical veins on lifting the arms over the head is a positive Pemberton sign and indicates obstruction to jugular venous flow (Figure 7-41). The patient may complain of pressure symptoms in the neck, particularly on moving the head upward or downward, and of difficulty in swallowing. Vocal cord paralysis due to recurrent laryngeal nerve involvement is rare. The vast majority of patients are euthyroid. Thyroid enlargement probably represents compensated hypothyroidism.
B. Laboratory findings  Laboratory studies reveal a normal FT₄ and, usually, normal levels of TSH. The increased mass of thyroid tissue may compensate for inefficient synthesis of hormone. RAIU may be high, normal, or low, depending on the iodide pool and the serum TSH level.

C. Imaging studies  Isotope scanning usually reveals a patchy uptake, frequently with focal areas of increased uptake corresponding to hot nodules and areas of decreased uptake corresponding to cold nodules. RAIU of the hot nodules may not be suppressible following administration of thyroid hormones such as liothyronine. Thyroid ultrasound is a simple way to follow the growth of the goiter and in addition may reveal cystic changes and coarse calcifications in one or more of the nodules, representing previous hemorrhage and necrosis.

Differential Diagnosis
The major problem in differential diagnosis is to rule out cancer. This will be discussed in the section on thyroid carcinoma.
Treatment

With the exception of those due to neoplasm, the current management of nontoxic goiters consists simply of observation, without any specific therapy. Nontoxic goiters are very slow growing and usually never cause compressive symptoms or thyroid dysfunction. Thyroid hormone suppression therapy rarely results in clinically significant decrements in goiter size. Also, long-standing goiters may have areas of necrosis, hemorrhage, and scarring as well as autonomously functioning nodules that will not regress on T4 therapy. Furthermore, to suppress the serum TSH level, doses of T4 are required that could cause harm, especially in elderly patients who are at risk of developing atrial fibrillation and osteoporosis. Also, many nontoxic goiters have areas of autonomy within them that do not depend on TSH for function, and therefore, will not decrease in size and may contribute to the iatrogenic hyperthyroidism.

Surgery is indicated for goiters that continue to grow or that produce obstructive symptoms. Substernal extension of a goiter is not, in and of itself, an indication for surgical removal. The gross appearance of a multinodular goiter at the time of surgery is presented in Figure 7-42. Note that the left lobe of the gland extends downward from the middle of the thyroid cartilage to just above the clavicle. The pressure of this enlargement has caused deviation of the trachea to the right. The surface of the gland is irregular, with many large and small nodules. Although multinodular goiters are rarely malignant, the size of the mass with resulting pressure symptoms may require subtotal thyroidectomy.

If the patient is not a suitable candidate for surgery, radioactive iodine ablation of functioning thyroid tissue may provide palliative relief of obstructive symptoms. An adequate dose of radioactive iodine reduces the size of the goiter about 30% to 50% and usually alleviates obstructive symptoms.

Course and Prognosis

Patients with nontoxic goiter should avoid pharmacologic doses of iodides, which may induce either hyperthyroidism or, in the presence of thyroid autoimmunity, hypothyroidism. Occasionally, single adenomas or several adenomas become hyperfunctional, producing a toxic nodular goiter (discussed earlier). Nontoxic goiter is often familial and other members of the family should be examined and observed for the possible development of goiter.

THYROIDITIS

1. SUBACUTE THYROIDITIS

Subacute thyroiditis (De Quervain thyroiditis or granulomatous thyroiditis) is an acute inflammatory disorder of the thyroid gland most likely due to viral infection. A number of viruses, including mumps virus, coxsackievirus, and adenoviruses, have been implicated, either by finding the virus in biopsy specimens taken from the gland or by demonstration of rising titers of viral antibodies in the blood during the course of the infection. Pathologic examination reveals moderate thyroid enlargement and a mild inflammatory reaction involving the capsule. Histologic features include destruction of thyroid parenchyma and the presence of many large phagocytic cells, including giant cells. Subacute thyroiditis is more common in the summer months, in women, and in individuals who are HLA-Bw35 positive.

Clinical Features

A. Symptoms and signs  Subacute thyroiditis usually presents with fever, malaise, and soreness in the anterior neck, which may extend up to the angle of the jaw or toward the ear lobes on one or both sides of the neck. Initially, the patient may have symptoms of hyperthyroidism, with palpitations, nervousness, and sweats. There is no ophthalmopathy. On physical examination, the gland is exquisitely tender, so that the patient objects to pressure on it. There are no signs of local redness or heat suggestive of abscess formation. Clinical signs of thyrotoxicosis, including tachycardia, tremor, and hyperreflexia, may be present.

B. Laboratory findings  Laboratory studies vary with the course of the disease (Figure 7-43). Initially, FT4 and T3 are elevated, whereas serum TSH and RAIU are extremely low. Because the thyroid hormone levels in the blood are a reflection of leakage of glandular hormonal stores, serum FT4 levels are elevated disproportionately to serum T3 levels. The erythrocyte sedimentation rate is markedly elevated, sometimes greater than 100 mm/h by the Westergren scale. Thyroid autoantibodies are usually not detectable in serum. As the disease progresses, FT4 and T3 drop, TSH rises, and symptoms of hypothyroidism may be noted. Later, RAIU rises, reflecting recovery of the gland from the acute insult.

Differential Diagnosis

Subacute thyroiditis can be differentiated from other viral illnesses by the involvement of the thyroid gland. It is differentiated from
2. CHRONIC THYROIDITIS

Chronic thyroiditis (Hashimoto thyroiditis, lymphocytic thyroiditis) is the most common cause of hypothyroidism and goiter in the United States. It is certainly the major cause of goiter in children and young adults and is the cause of idiopathic myxedema, which represents an end stage of Hashimoto thyroiditis, with total destruction of the gland. Riedel thyroiditis may be a very rare variant of Hashimoto thyroiditis, with extensive fibrosis extending outside the gland and involving overlying muscle and surrounding tissues. Riedel struma (struma is an old term for the thyroid) presents as a stony-hard mass that must be differentiated from thyroid cancer. It is also associated with fibrosis in other parts of the body including the mediastinum and retroperitoneum.

Etiology and Pathogenesis

Hashimoto thyroiditis is an immunologic disorder in which lymphocytes become sensitized to thyroidal antigens and autoantibodies are formed that react with these antigens (see thyroid autoimmunity, above). In Hashimoto thyroiditis, the three most important thyroid autoantibodies are thyroglobulin antibody, TPO Ab, and TSH-R-blocking antibody. During the early phases of Hashimoto thyroiditis, thyroglobulin antibody is markedly elevated, and TPO Ab is slightly elevated. Later, thyroglobulin antibody may disappear, but TPO Ab is present for many years. Blocking antibodies may be found in patients with atrophic thyroiditis and myxedema and, rarely, in mothers giving birth to infants with no detectable thyroid tissue (athyreotic cretins). The pathology of Hashimoto thyroiditis involves a heavy infiltration of lymphocytes totally destroying normal thyroidal architecture. Lymphoid follicles and germinal centers may be formed. The follicular epithelial cells are frequently enlarged and contain an eosinophilic cytoplasm laden with mitochondria (Hürthle cells). Destruction of the gland results in a fall in serum T3 and FT4 and a rise in TSH. Initially, TSH may maintain adequate hormonal synthesis by the development of thyroid enlargement or goiter, but often the gland fails, and hypothyroidism with or without goiter ensues.

Hashimoto thyroiditis is part of a spectrum of thyroid diseases that includes Graves disease at one end and idiopathic myxedema at the other (Figure 7–44). It is familial and may be associated with other autoimmune diseases, including pernicious anemia, adrenocortical insufficiency, idiopathic hypoparathyroidism, myasthenia gravis, and vitiligo. Schmidt syndrome consists of Hashimoto thyroiditis, idiopathic adrenal insufficiency, and, commonly, type 1 diabetes mellitus. This phenomenon has also been called the autoimmune polyglandular syndrome (see Chapter 2).

Course and Prognosis

Subacute thyroiditis usually resolves completely and spontaneously over weeks or months. Occasionally, the disease may begin to resolve and then suddenly become worse, sometimes involving first one lobe of the thyroid gland and then the other (migrating or creeping thyroiditis). Exacerbations may occur when the FT₄ levels have fallen, the TSH level has risen, and the gland is starting to recover function. Rarely, the course may extend over several years, with repeated bouts of inflammatory disease. Ninety percent of patients recover without any sequelae. In about 10% of patients, permanent hypothyroidism ensues, and long-term T₄ therapy is necessary.

A. Symptoms and signs

Hashimoto thyroiditis usually presents with goiter in a patient who is euthyroid or has mild hypothyroidism. The female: male sex distribution is about 4:1. The process is painless, and the patient may be unaware of the goiter unless it becomes very large. Older patients may present...
The major complication of Hashimoto thyroiditis is progressive nontoxic goiter by serum antibody studies and, if necessary, by hypothyroidism. Most patients with Hashimoto thyroiditis may be helpful is FNAB, which reveals lymphocytic infiltration as well as the presence of Hurthle cells. The most striking laboratory finding is the high titer of autoantibodies to thyroidal antigens in the serum. Serum tests for either thyroglobulin antibody or TPO Ab are positive in most patients with Hashimoto thyroiditis. Another diagnostic test that may be helpful is FNAB, which reveals lymphocytic infiltration as well as the presence of Hurthle cells.

### Differential Diagnosis
Hashimoto thyroiditis can be differentiated from other causes of nontoxic goiter by serum antibody studies and, if necessary, by FNAB.

### Complications and Sequelae
The major complication of Hashimoto thyroiditis is progressive hypothyroidism. Most patients with Hashimoto thyroiditis initially have a small goiter and subclinical hypothyroidism, which is defined as normal serum levels of FT4 and T3, but mildly elevated serum TSH levels, usually less than 10 mU/L. This is in contrast to overt hypothyroidism, in which FT4 levels are subnormal. Whether subclinical hypothyroidism is a significant health problem that warrants therapy is a matter of debate. Some patients may have mild symptoms of hypothyroidism as well as increased lipid levels and other risk factors for atherosclerotic cardiovascular disease. There may be progression to overt hypothyroidism over time, especially if serum levels of antithyroid antibodies are high. On the other hand, most patients are asymptomatic, especially when TSH serum levels are less than 10 mU/L, and the link between atherosclerosis is still controversial.

One variant of Hashimoto thyroiditis has been termed silent or painless thyroiditis. It has a predilection for occurring in the postpartum period, developing in about 5% of postpartum women. In this setting it is called postpartum thyroiditis. Most patients have symptoms and signs of mild hyperthyroidism that may be difficult to distinguish from mild Graves disease. There are no eye findings, and unlike subacute thyroiditis, the thyroid is not tender to palpation. The serum FT4 is elevated out of proportion to the serum T3, typical of most forms of thyroiditis, when there is leakage of stored hormone into the bloodstream. The erythrocyte sedimentation rate is normal, which distinguishes it from subacute thyroiditis, and TPO Ab titers are elevated. Importantly, the 24-hour RAIU is low, rather than elevated, which readily distinguishes this condition from postpartum Graves disease. Silent thyroiditis evolves with a triphasic course, similar to what is seen in subacute thyroiditis, with the hyperthyroid phase lasting 1 to 3 months, followed by a hypothyroid phase lasting several months as well. In postpartum thyroiditis, the hyperthyroid phase generally begins 3 to 4 months after delivery. Although recovery is the rule, about 25% of patients have permanent mild or subclinical hypothyroidism, which can progress with time to overt hypothyroidism. Long-term follow-up is required because permanent hypothyroidism can eventually develop in patients after many years. Also, recurrent episodes of silent thyroiditis can occur, and postpartum thyroiditis often develops following subsequent pregnancies.

Rarely, a patient with Hashimoto thyroiditis may develop lymphoma of the thyroid gland. Although the etiology of thyroid lymphoma is unknown, Hashimoto thyroiditis is a definite risk factor. It is possible that thyroid lymphoma may be the result of the expansion of an abnormal clone of an immortalized population of intrathyroidal lymphocytes. Thyroid lymphoma is characterized by rapid growth of the gland despite continued T4 therapy; the diagnosis of lymphoma can be made by FNAB and immunocytochemical analysis, looking for a monoclonal population of lymphocytes, but sometimes requires surgical biopsy (see later).

Whether adenocarcinoma of the thyroid gland occurs more frequently in patients with Hashimoto thyroiditis is controversial, but the two diseases—chronic thyroiditis and carcinoma—can coexist in the same gland. Recent studies have shown that the presence of thyroid cancer in thyroid nodules is more frequent in patients whose serum TSH is higher, even when it is within the normal range. Cancer must be suspected when a solitary nodule or thyroid mass grows or fails to regress while the patient is receiving doses of T4 that normalize or suppress the serum TSH. FNAB is critical in the differential diagnosis in this situation.

### Treatment
The indications for treatment of Hashimoto thyroiditis are goiter or overt hypothyroidism; a patient with a positive thyroid antibody test alone does not require therapy. Surgery is rarely indicated.
for Hashimoto thyroiditis but occasionally is performed if a goiter does not regress and continues to cause compressive symptoms. The treatment of subclinical hypothyroidism is a matter of debate but is often instituted because of (1) mild symptoms; (2) dyslipidemia which could be ameliorated by $T_4$ therapy; and (3) positive antithyroid antibody titers, which predicts a higher chance of progression to overt hypothyroidism over time. Sufficient $T_4$ is given to normalize TSH and allow regression of the goiter.

The treatment of silent or postpartum thyroiditis varies with the patient's thyroid status. During the hyperthyroid phase, $\beta$-adrenergic-blocking drugs can be used to treat the symptoms of tremor, palpitations, and nervousness. $T_4$ can be used in the hypothyroid phase, but it is usually not needed, because symptoms are usually mild.

**Course and Prognosis**

Without treatment, Hashimoto thyroiditis usually progresses from goiter and subclinical hypothyroidism to overt hypothyroidism over many years. In severe cases, myxedema and myxedema coma may be the end result of untreated disease. With $T_4$ therapy, the goiter usually resolves, although not necessarily completely, and hypothyroid symptoms are reversed.

Because Hashimoto thyroiditis may be part of a syndrome of multiple autoimmune diseases (see Chapter 2), the patient should be monitored for other autoimmune diseases such as pernicious anemia, adrenal insufficiency, and type 1 diabetes mellitus. Patients with Hashimoto thyroiditis may also develop true Graves disease, occasionally with severe ophthalmopathy or dermopathy (see Figure 7–44). The chronic thyroiditis may blunt the severity of the thyrotoxicosis, so that the patient may present with eye or skin complications of Graves disease without marked thyrotoxicosis, a syndrome often called euthyroid Graves disease. The ophthalmopathy and dermopathy are treated as if thyrotoxic Graves disease were present.

### 3. OTHER FORMS OF THYROIDITIS

The thyroid gland may be subject to acute abscess formation in patients with septicemia or acute infective endocarditis or from local extension of a pharyngeal infection. Immunocompromised hosts may develop opportunistic thyroidal infections, with involvement of organisms such as aspergillus, mycobacteria, and pneumocystis. Abscesses cause symptoms of pyogenic infection, with local pain and tenderness, swelling, and warmth and redness of the overlying skin. Needle aspiration confirms the diagnosis and identifies the organism. Treatment includes antibiotic therapy and occasionally incision and drainage. A thyroglossal duct cyst may become infected and present as acute suppurative thyroiditis. This too responds to antibiotic therapy and occasionally incision and drainage.

### EFFECTS OF IONIZING RADIATION ON THE THYROID GLAND

Ionizing radiation can induce both acute and chronic thyroiditis. Thyroiditis may occur acutely in patients treated with large doses of radioiodine and may be associated with release of thyroid hormones and an acute thyrotoxic crisis. Such an occurrence is extremely rare, however, and pretreatment with antithyroid drugs to bring the patient to a euthyroid state prior to $^{131}I$ therapy should prevent this complication. Radioiodine therapy, which exposes the thyroid to a dosage of around 10,000 rads (cGy), is not associated with the development of thyroid cancer, presumably because the thyroid gland is largely destroyed by high doses of radiation. Thus, although the incidence of postradiation hypothyroidism is high, the incidence of thyroid cancer is extremely low.

External radiation was used many years ago for the treatment of respiratory problems in the newborn, thought to be due to thymic hyperplasia, and for the treatment of benign conditions such as severe acne and chronic tonsillitis or adenoiditis. This treatment has been associated with the later development of nodular goiter, hypothyroidism, or thyroid cancer. Fortunately, such therapy has not been used since the early 1960s. In addition, high doses of therapeutic radiation in children with Hodgkin disease or other cancers have also been associated with the development of thyroid cancer later in life. Almost all radiation-related thyroid cancers have been of the papillary type. In some parts of the world, radiation exposure from fallout from atomic bomb testing or a nuclear reactor accident has been associated with nodular thyroid disease and thyroid cancer. Although the overall frequency of thyroid carcinoma in irradiated patients is low, data from several large series suggest that the incidence of cancer in a patient who presents with a solitary cold nodule of the thyroid gland and a history of therapeutic radiation of the head, neck, or chest is about 50%.

The most recent episode of large-scale radiation-induced thy­roid neoplasia was the Chernobyl disaster in April, 1986, at which time huge amounts of radioactive material, especially radioiodine, were released. As early as 4 years later, a striking increase in the incidence of thyroid nodules and thyroid cancer was noted in children in Gomel, an area in the Republic of Belarus that is close to Chernobyl and was heavily contaminated by the accident. A high proportion of the cancers arose in very young children and developed after a very short latency period. The sex distribution was equal. Most of the cancers have been papillary carcinomas and have been more aggressive than typical papillary cancer, with intraglandular, capsular, local, and lymph node invasion.

Patients who have been exposed to ionizing radiation should be followed carefully for life. Annual studies should include physical examination of the neck for goiter or nodules and FT$_4$ or TSH determinations to rule out hypothyroidism. Periodic thyroid ultrasound may detect nodules that are not palpable. If a nodule is found and is greater than 1 cm in diameter, FNAB should be performed. If the nodule is malignant, the patient should have total thyroidectomy. If it is benign, follow-up with periodic thyroid ultrasound is recommended. If the nodule enlarges, repeat biopsy or surgery should be considered.

### THYROID NODULES AND THYROID CANCER

Thyroid nodules are extremely common, particularly among women. The prevalence of palpable thyroid nodules in the United States

8. Rare: teratoma, lipoma, hemangioma

1. BENIGN THYROID NODULES

Etiology

Benign conditions that can produce nodularity in the thyroid gland are listed in Table 7-10. They include focal areas of chronic thyroiditis; colloid-filled or hyperplastic cellular nodules within a multinodular goiter; a cyst involving thyroid tissue; rarely parathyroid tissue or thyroglossal duct remnants; and agenesis of one lobe of the thyroid, with hypertrophy of the other lobe presenting as a mass in the neck and mimicking a nodule. It is usually the left lobe of the thyroid that fails to develop, and the hypertrophy occurs in the right lobe. Finally, benign areas of hyperplasia and neoplasms in the thyroid, including follicular adenomas and Hürthle cell adenomas (also called oxyphil adenomas) present as thyroid nodules. Rare benign thyroidal lesions include teratomas, lipomas, and hemangiomas.

thyroid nodule on physical examination, and the presence of a multinodular goiter. Individuals at higher risk of thyroid cancer include children, young adults, and older males. A solitary firm or dominant nodule that is clearly different from the rest of the gland signifies an increased risk of malignancy. Vocal cord paralysis, enlarged cervical lymph nodes, and suspected metastases are strongly suggestive of malignancy.

C. Serum factors A serum TSH level should be the initial laboratory study in the evaluation of a thyroid nodule. If the serum TSH level is normal, which is the case for most patients, no further blood tests are needed. If the serum TSH is below normal, a radionuclide thyroid scan should be considered to see whether the nodule is hot or autonomously functioning (see later). A high normal or elevated serum TSH has been associated with modestly higher risk of thyroid cancer. In the presence of a firm thyroid gland or other clinical features of Hashimoto thyroiditis (eg, positive family history of hypothyroidism), serum antithyroid antibodies should be assessed. A high titer of thyroid autoantibodies in serum suggests chronic thyroiditis as the cause of thyroid enlargement and nodules, but does not rule out an associated malignancy. Measurement of serum calcitonin is not routinely advised. However, an elevated serum calcitonin in patients with a family history of medullary carcinoma strongly suggests the presence of medullary thyroid cancer. Elevated serum thyroglobulin following total thyroidectomy for papillary or follicular thyroid cancer usually indicates residual or metastatic disease, but serum thyroglobulin is not helpful in determining the nature of a thyroid nodule.

D. Imaging studies Thyroid ultrasound has become an important tool in the confirmation and differential diagnosis of thyroid nodules. Ultrasound is used to confirm that a cervical mass is within the thyroid; measure a nodule's size precisely; detect other nonpalpable nodules elsewhere in the gland; and distinguish cystic from solid lesions, as a small pure cyst is almost never malignant. Cystic lesions that have internal septa or solid lesions on ultrasound may be benign or malignant. Certain ultrasound characteristics can suggest that a nodule is more likely to be malignant, including microcalcifications, irregular borders, and high internal blood flow on Doppler imaging. Other ultrasound characteristics, such as the so-called comet tail artifact due to the presence of colloid within the nodule favor a benign nodule.

In patients with low serum TSH levels, radionuclide thyroid scanning with ¹²³Iodine or ⁹⁹ᵐTc pertechnetate can be used to identify a hot or cold nodule (ie, a nodule that takes up more or less radioactive iodine than surrounding tissue). Hot nodules are almost never malignant, and although 5% to 10% of cold nodules may be malignant, 90% to 95% of cold nodules are benign (Figure 7-45).

E. Needle biopsy Fine-needle aspiration biopsy (FNAB) of thyroid nodules to obtain cytological material for pathological examination is the principal test to distinguish benign from malignant lesions. The technique of FNAB is relatively simple, safe, reliable, and well tolerated. FNAB is now generally performed under sonographic guidance and definitely should be done so if the nodule is nonpalpable, difficult to localize by palpation, or is cystic. FNAB separates thyroid nodules into three groups:

1. Cytologically benign thyroid nodules (70%-80% of all biopsy specimens), which exclude cancer with a negative predictive value of 95%-98%.
2. Cytologically malignant thyroid nodules (3%-5% of all biopsy specimens), which have a positive predictive value for cancer of 95% for all types of thyroid malignancies.
3. Cytologically indeterminate or suspicious thyroid nodules (10%-15% of all biopsy specimens), among which 15% ultimately prove to be malignant and 85% benign.

There are several subcategories of cytologically indeterminate lesions, including suspicions for malignancy (60%-75% risk of cancer) and follicular neoplasm (15%-30% risk of cancer). In the

FIGURE 7-45 Demonstration of resolution obtained utilizing different scanning techniques: A. ¹²³I scintiscan with rectilinear scanner. B. Fluorescent scan with rectilinear scanner. C. ⁹⁹ᵐTc pertechnetate scan with the pinhole collimated gamma camera. Note the presence of two cold nodules, one in each lobe of the thyroid, easily detected in C but not clearly delineated in the other two scans. The lesion in the right lobe was palpable, about 1 cm in diameter, and was shown to be follicular carcinoma on needle biopsy. The lesion in the left lobe was either a metastatic tumor or a second primary follicular carcinoma. (Courtesy of Dr. M.D. Okerlund.)
future, assessment of genetic and molecular markers of malignancy (eg, BRAF mutational analysis, galectin-3 immunostaining) in FNAB specimens may assist in distinguishing benign from malignant indeterminate nodules. These markers of malignancy, and others, are currently being studied to see whether they may provide increased sensitivity and specificity for predicting malignancy in suspicious nodules, beyond what can be ascertained by traditional cytopathology.

Management of Thyroid Nodules

A decision tree for management of a thyroid nodule is presented in Figure 7-46. A patient with a thyroid nodule should have a serum TSH performed. If TSH is low, thyroid scanning should be done to avoid performing FNAB in a patient with a hot nodule. If the serum TSH is normal or elevated, ultrasound should be performed to document the presence of the nodule and to see whether other nodules are present. If one or more nodules are confirmed, FNAB should be performed on those nodules that are larger than 1.0 to 1.5 cm or that have suspicious ultrasound characteristics. If the nodule is cytologically malignant, the patient is generally referred for thyroid surgery unless there are other serious medical problems associated with high operative risk and/or a prognosis much greater than thyroid cancer. If the nodule is cytologically benign and neither local compressive symptoms nor hyperthyroidism are present, only reassessment of nodule size in 6 to 12 months by physical examination and/or ultrasound is required. If the nodule grows, defined as an increase of 20% or more in two of three dimensions, repeat FNAB and cytological examination are indicated to verify the benign diagnosis.

In patients with cytologically indeterminate nodules, those with lesions categorized as suspicious for malignancy are generally best referred for surgery. In those with a cytological follicular neoplasm, a radionuclide scan may be obtained. If the scan reveals the nodule to be hot (ie, functioning and suppressing the remainder of the gland), the patient can be observed to detect future overt hyperthyroidism. If the lesion is cold and ≥2 cm in diameter, has suspicious ultrasound features, or is present in a younger patient, surgery is usually preferable. On the other hand, if the nodule is <1 cm in diameter, soft, or present in an older patient, observation with serial sonography and surgery only if the lesion grows is an alternative.

2. THYROID CANCER

Pathology

The types and approximate frequency of malignant thyroid tumors are listed in Table 7–12.

A. Papillary carcinoma Papillary carcinoma of the thyroid gland typically presents as a nodule that is firm and solid on thyroid ultrasound, sometimes with internal calcifications. In multinodular goiter, the cancer is usually a dominant nodule—larger, firmer, and/or with ultrasound characteristics more suspicious than other nodules in the gland. About 10% of papillary carcinomas, especially in children, present with enlarged cervical nodes. Careful examination then often also reveals a nodule in the thyroid. Sometimes, there is hemorrhage, necrosis, and cyst formation in the malignant nodule, but on thyroid ultrasound of these lesions, a defined solid component is an indication for FNAB of this nodule component. Finally, papillary carcinoma may be found incidentally as a microscopic focus of cancer in a gland removed for other reasons, such as another indeterminate nodule, multinodular goiter, or Graves disease. Microscopically, papillary cancer typically consists of single layers of thyroid cells arranged in vascular stalks, with papillary projections extending into microscopically cystlike spaces. The nuclei of the cells are large and pale and frequently contain clear, glassy intranuclear inclusion bodies. About 40% of papillary carcinomas form laminated calcified spheres—often at the tip of a papillary projection—called psammoma bodies. Most papillary thyroid cancers grow slowly and

remains confined to the thyroid gland and local lymph nodes. However, these cancers can exhibit intraglandular metastasis and lymph node spread. In some children with papillary thyroid cancer, there are extensive lymph node and pulmonary micrometastases. In older patients, papillary cancer can be aggressive and invade locally into adjacent muscles, nerves, and trachea. In later stages, these tumors may spread to the lung, bone, brain, and other organs. Death is usually due to local disease, with invasion of deep tissues in the neck; less commonly, death may be due to extensive distant metastases. In some older patients, a long-standing, slowly growing papillary carcinoma begins to grow rapidly and converts to undifferentiated or anaplastic carcinoma.

Most papillary carcinomas secrete thyroglobulin, which can be used as a marker for recurrence or metastasis of the cancer. Some papillary cancers concentrate radioiodine, albeit less efficiently than normal thyroid tissue. In such patients, radioiodine is an effective tool for identification and treatment of extrathyroidal disease.

B. Follicular carcinoma Follicular carcinoma is characterized histologically by the presence of small follicles with poor colloid formation. Follicular carcinoma is distinguished from benign follicular adenoma microscopically by the presence of the capsule and/or vascular invasion within the tumor capsule. When only the capsule is involved, follicular cancer is categorized as minimally invasive, a tumor that typically has an indolent course similar to low-grade papillary cancers. When capsular blood vessels are also invaded, follicular cancers are categorized as invasive and have the potential for distant metastatic spread to bone, lung, and other sites. These tumors often retain the ability to concentrate radioactive iodine, form thyroglobulin, and, rarely, synthesize T₃ and T₄. This may render these tumors responsive to radioactive iodine therapy. When death occurs, it is attributable to local extension or distant metastases with extensive involvement of bone, lungs, and viscera.

A variant of follicular carcinoma is the Hurthle cell or oxyphil cell carcinoma, characterized by large individual cells with pink-staining cytoplasm filled with mitochondria. They behave like follicular cancer except that they rarely take up radioiodine.

C. Medullary carcinoma Medullary thyroid cancer is a disease of the C cells (parafollicular cells) derived from the ultimobranchial body. These cells are capable of secreting calcitonin, calcitoninogen, and other peptides (see Chapters 8 and 22). Microscopically, these tumors consist of sheets of cells separated by a pink-staining substance that stains with Congo red, typical of amyloid.

Medullary thyroid carcinoma is typically more aggressive than papillary or follicular carcinoma, extending locally to cervical lymph nodes and into surrounding tissues. It may also invade lymphatics and blood vessels and metastasize to lungs, liver, and other viscera. The calcitonin and CEA secreted by the tumor are clinically useful markers for diagnosis and follow-up.

Eighty percent of medullary carcinomas are sporadic, and the remainder are familial. There are three familial patterns: (1) familial medullary cancer without associated endocrine disease; (2) multiple endocrine neoplasia 2A (MEN 2A), consisting of medullary thyroid carcinoma, pheochromocytoma, and hyperparathyroidism; and (3) MEN 2B, consisting of medullary thyroid cancer, pheochromocytoma, multiple mucosal neuromas, as well as intestinal ganglioneuromatosis simulating Hirschsprung disease. There is also a variant of MEN 2A with cutaneous lichen amyloidosis, a pruritic skin lesion located on the upper back. These familial syndromes are due to ret protooncogene mutations, most commonly in exons 10, 11, or 16 (see later and Chapter 22).

If medullary thyroid cancer is diagnosed by FNAB or at surgery, it is essential that the patient be screened for one of the familial medullary thyroid carcinoma syndromes by DNA analysis for mutations in the ret protooncogene. If screening is negative, the tumor is almost certainly sporadic, and no investigation of family members is required. If a mutation is found, family members should then be screened.

D. Undifferentiated (anaplastic) carcinoma Undifferentiated thyroid gland cancer include small cell, giant cell, and spindle cell carcinomas. They usually occur in older patients, who often have a long history of goiter with sudden gland enlargement over weeks or months, causing pain, dysphagia, hoarseness, and/or dyspnea. Death from aggressive local extension and metastatic disease typically occurs within 6 to 36 months. These tumors are very resistant to all currently available therapies.

E. Miscellaneous types

1. Lymphoma—Thyroid lymphoma may develop as part of a generalized lymphoma or may be primary in the thyroid gland. Primary thyroid lymphoma usually develops in patients with long-standing Hashimoto thyroiditis. It may be difficult to distinguish from chronic thyroiditis histologically. There is a monoclonal lymphocyte population with invasion of thyroid follicles and blood vessel walls. If there is no systemic involvement, the tumor may respond dramatically to combined radiation and chemotherapy.

2. Cancer metastatic to the thyroid—Systemic cancers can metastasize to the thyroid gland. Common primary cancers responsible for these metastases include breast, kidney, lung carcinomas, and malignant melanoma. The primary site of involvement is usually obvious. Occasionally, the diagnosis is made by biopsy of an enlarging cold thyroid nodule. The prognosis is that of the primary tumor.

F. Molecular biology of thyroid neoplasms Extensive studies have revealed frequent gene mutations in both benign and malignant thyroid neoplasms (Figure 7-47). Activating mutations in the gsp oncogene, encoding Gₛα or the TSH receptor in thyroid cells have been associated with increased growth and function in benign hot or toxic thyroid nodules. Activating mutations of the nɛ oncogene and loss of function of PTEN a tumor suppressor gene, are common in benign follicular adenomas. Progression to follicular carcinoma may occur after another genetic event involving a chromosomal translocation forming a fusion gene between the thyroid transcription factor PAX8 gene and the PPARγ gene (PAX8-PPARγ). Further loss of the suppressor gene PS3 may allow
progression to an anaplastic carcinoma. Papillary cancer is likely caused by mutations in genes in the MAP kinase–signaling pathway, especially **BRAF**. Another common finding in papillary thyroid cancers, especially after radiation exposure, are gene rearrangements in which a portion of the **RET** gene, a receptor tyrosine kinase not normally expressed in the thyroid, is linked to a portion of one of several unrelated genes at its 5′ end, producing a constitutively active chimeric RET receptor. Subsequent loss of **P53** suppressor gene may allow progression to anaplastic carcinoma. As noted above, activating mutations of the **RET** protooncogene on chromosome 10 have been shown to be associated with MEN 2A, MEN 2B, and familial medullary thyroid cancer. About 85% to 90% of the mutations found in MEN 2A and familial medullary thyroid cancer occur in exons 10 and 11, whereas about 95% of the mutations associated with MEN 2B are found in codon 918 in exon 16 of the **RET** oncogene. These mutations can be demonstrated in DNA from peripheral white blood cells utilizing the polymerase chain reaction and DNA sequencing. In patients with MEN 2 or familial medullary thyroid cancer who do not demonstrate a mutation in **RET**, family unit linkage analysis may be used to identify gene carriers. Thus, families can be screened for the carrier state, and early diagnosis and treatment can be instituted (Figure 7–48). Somatic mutations in the **ret** oncogene occur in about 30% of sporadic medullary thyroid cancer cells, but this does not occur in white blood cells and does not represent a germline mutation (see also Chapter 22).

**Management of Thyroid Cancer (Figure 7–49)**

**A. Papillary and follicular carcinoma: treatment** Because both papillary and follicular cancers arise from thyroid epithelial cells and sometimes respond to TSH and concentrate iodine, they are grouped together as **differentiated thyroid cancers**. These patients may be classified loosely into low-risk and high-risk groups. The low-risk group includes patients under age 45 with primary lesions under 2 cm and no evidence of intra- or extraglandular spread. For these patients, total thyroidectomy is generally recommended, although lobectomy is probably adequate therapy for small (<1 cm) tumors. All other patients should be considered high-risk, and for these, total thyroidectomy and—if there is preoperative evidence of lymphatic spread—central compartment neck dissection are indicated. In the absence of evidence of lymphatic spread, prophylactic neck dissection may not be necessary, but can be considered for larger tumors (>4 cm).

For many low-risk patients and all high-risk patients, postoperative radioidine ablation of residual thyroid remnant is recommended to decrease the likelihood of recurrent disease. To achieve maximal uptake of radioidine into the remnant, an elevated serum TSH level is required. This can be achieved using injections of recombinant human TSH (rhTSH) given to patients in the euthyroid state. Alternatively, TSH stimulation can be achieved by withdrawing the patient from thyroxine therapy, which causes transient clinical hypothyroidism. If the latter method is employed, T₃ is often prescribed temporarily at a dose of 25 to 50 μg daily in divided doses for 2 to 4 weeks; the medication is then stopped for 2 weeks, and, because of its 1-day half-life, patients quickly become hypothyroid prior to radioiodine therapy. In general, rhTSH is preferred, since clinical hypothyroidism is avoided and whole body radiation exposure is lower as the radioiodine is cleared from the body more rapidly because renal function is preserved. Regardless of how the patient achieves an elevated serum TSH level, a low-iodine diet is prescribed for 1 to 2 weeks to enhance uptake of the radioisotope. Following either rhTSH stimulation or thyroid hormone withdrawal, the serum thyroglobulin level is determined, and the patient is scanned 24 to
FNAB positive for medullary carcinoma (Confirm with serum calcitonin)

72 hours after a low dose of radioiodine (ie, 1-4 mCi of \(^{131}\)I or 1-2 mCi \(^{123}\)I). If there is evidence of residual radioactive iodine uptake in the neck or elsewhere, or if there is a rise in serum thyroglobulin to detectable levels, radioactive iodine \(^{131}\)I is administered in a dose of 30 to 200 mCi, depending on the size and invasiveness of the primary tumor. A whole body radioiodine scan is then repeated 4 to 7 days later (called a posttherapy scan) to be sure no additional areas of radioiodine uptake are revealed. Nine to 12 months later, rhTSH is administered or thyroid hormone therapy is withdrawn, and a radioiodine scan and serum thyroglobulin are repeated to document ablation of all functioning thyroid tissue. An undetectable serum thyroglobulin level at a time when the serum TSH is elevated is the most sensitive evidence that all thyroid tissue has been eradicated. Indeed, a repeat whole body radioiodine scan may not be needed in low-risk patients. For the first year, patients are typically maintained on doses of T4 that are adequate to suppress serum TSH to levels that are less than 0.1 mU/L. Once it has been established that the patient is free of disease, the dose of T4 can be increased to allow the serum TSH to rise into the low-normal range (0.3-2 mU/L).

rhTSH, rather than thyroid hormone withdrawal, is usually employed for follow-up evaluations. When using rhTSH, the patient continues to take his T4 avoiding the adverse effects of hypothyroidism. If the patient's TSH-stimulated serum thyroglobulin is less than 1 ng/mL and the whole-body radioiodine scan, if obtained, is negative, the patient is likely free of disease. On the other hand, if the serum thyroglobulin concentration rises above 2 ng/mL and/or if the radioiodine scan is positive, the patient is likely to have either persistent thyroid remnant tissue or residual thyroid cancer. Neck sonography, CT, or MRI should be considered in this circumstance to look for evidence of residual thyroid cancer. If disease is localized anatomically and proven to be thyroid cancer, additional surgery may be warranted. If the stimulated thyroglobulin is greater than 20 ng/mL and other anatomic imaging studies are negative, some experts recommend empiric radioiodine therapy because of the high suspicion of residual disease that might then be visualized on the posttreatment scan.

Follow-up at intervals of 6 to 12 months should include careful examination of the neck, sometimes including neck ultrasound, looking for recurrent masses, which typically develop in ipsilateral cervical nodes. If an abnormal lymph node is discovered, FNAB is...
FNAB positive for malignancy

Papillary/follicular

Under 1-1.5 cm
Age <45 years

Lobectomy or thyroidectomy

Thyroxine for life

T3 (liothyronine (lcl)) 25-50 μg/d for 4 weeks, stop for 2 weeks

Local removal to preserve airway (palliative) + RT

Thyroxine for life

Anaplastic

>1-1.5 cm
Age >45 years

Total thyroidectomy

D/C thyroxine

Low-iodine diet

administer rhTSH

Scan with 131I or 123I

Serum Tg

Negative scan; undetectable Tg

Thyroxine for life; monitor PE, Tg, ultrasound of neck, rhTSH stimulated Tg periodically

Positive scan; detectable Tg

Give 30-100 mCi 131I***

Recurrence

Consider additional surgery, radioiodine, radiotherapy

6-12 months:

FIGURE 7-49 Decision matrix for the management of papillary, follicular, or anaplastic thyroid carcinoma. Some experts recommend radioiodine therapy following total thyroidectomy for tumors >1.0 cm and for multifocal disease. Some patients have a negative scan but detectable serum Tg and require further evaluation. See text for details. (FNAB, fine-needle aspiration biopsy; PE, physical examination; RT, radiotherapy; rhTSH, recombinant human TSH [Thyrogen]; Tg, thyroglobulin.)

indicated to confirm or rule out cancer. The patient’s serum TSH should be checked to be certain it is adequately suppressed. The serum thyroglobulin should be periodically assessed to be certain it is undetectable. A rise in serum thyroglobulin to detectable levels while TSH is suppressed suggests tumor recurrence, and imaging studies such as neck ultrasound, CT, and MRI are necessary. PET scanning may also be useful to localize residual disease, especially in patients with very high serum thyroglobulin levels (>50 ng/mL) when conventional imaging studies have been unrevealing.

Thyroglobulin autoantibodies present in 20% of patients interfere with accurate measurement of thyroglobulin in radioimmunometric assays which are used in the majority of commercial laboratories and hospitals, causing falsely low values. Patients with thyroglobulin autoantibodies must be followed with periodic imaging studies, such as thyroid ultrasound or CT scan.

The patient with a rising thyroglobulin and a negative 131I scan presents a common and difficult problem. Serial anatomic imaging, especially with cervical sonography, can sometimes identify the site of residual cervical disease. Administration of large empiric 131I doses has not been shown to be of significant benefit. For patients with noniodine-avid metastatic disease that is progressive, recent studies have shown that several kinase-inhibiting drugs, including sorafenib and sunitinib, can be effective in halting further tumor growth for 1 to 2 years. The kinases involved include the vascular endothelial growth factor receptor family (VEGF), RET, and BRAF. For patients with bone or brain metastases, combined external radiation and 131I therapy may be effective.

B. Differentiated thyroid cancer: course and prognosis

Staging of cancer usually relies on the tumor-nodes-metastases (TNM) system for staging thyroid cancer (Table 7-13). Papillary and follicular thyroid carcinomas are grouped together, and staging is related to the age of the patient at the time of diagnosis. The cause-specific 5-year mortality rates are for stage 1, 0%; stage 2, 1%; stage 3, 5%; and stage 4, 77%. The TNM system may underestimate the risk of recurrence and death in younger patients with
TABLE 7-13 Tumor (T), lymph node (N), and distant metastasis (M) classification and staging of thyroid cancer.

**DEFINITION of TNM**

**Primary Tumor (T)**
- All categories may be subdivided: (s) solitary tumor and (m) multifocal tumor (the largest determines the classification).
- **TX** Primary tumor cannot be assessed
- **T0** No evidence of primary tumor
- **T1** Tumor 2 cm or less in greatest dimension limited to the thyroid
  - **T1a** Tumor 1 cm or less, limited to the thyroid
  - **T1b** Tumor more than 1 cm but not more than 2 cm in greatest dimension, limited to the thyroid
- **T2** Tumor more than 2 cm but not more than 4 cm in greatest dimension, limited to the thyroid
- **T3** Tumor more than 4 cm in greatest dimension limited to the thyroid, or any tumor with minimal extrathyroid extension (e.g., extension to sternothyroid muscle or perithyroid soft tissues)
- **T4a** Moderately advanced disease.
  - Tumor of any size extending beyond the thyroid capsule to invade subcutaneous soft tissues, larynx, trachea, esophagus, or recurrent laryngeal nerve
- **T4b** Very advanced disease.
  - Tumor invades prevertebral fascia or encases carotid artery or mediastinal vessels

**Regional Lymph Nodes (N)**
- **NX** Regional lymph nodes cannot be assessed.
- **NO** No regional lymph node metastasis
- **N1** Regional lymph node metastasis
  - **N1a** Metastasis to Level VI (pretracheal, paratracheal, and prelaryngeal/Delphian lymph nodes)
  - **N1b** Metastasis to unilateral, bilateral, or contralateral cervical (Levels I, II, III, IV or V) or retropharyngeal or superior mediastinal lymph nodes (Level VII)

**Distant Metastasis (M)**
- **MO** No distant metastasis (no pathologic MO; use clinical M to complete stage group)
- **M1** Distant metastasis

**All anaplastic carcinomas are considered T4 tumors**
- **T4a** Intrathyroidal anaplastic carcinoma
- **T4b** Anaplastic carcinoma with gross extrathyroid extension

**STAGE GROUPING**

**Clinical**

Separate stage groupings are recommended for papillary or follicular, medullary, and anaplastic (undifferentiated) carcinoma.

aggressive disease. An optimal outcome is also dependent on adequate therapy. There has been controversy over the extent of initial surgery for papillary and follicular thyroid cancer. As noted above, lesions under 1 cm with no evidence of local or distant metastases (T1, N0, M0) can probably be treated with lobectomy alone. However, in all other groups, total thyroidectomy and modified regional neck dissection (if gross evidence of spread is noted at the time of surgery) is indicated for two reasons: (1) it removes all local disease, and (2) it sets the stage for $^{131}$I therapy and follow-up utilizing serum thyroglobulin measurements. Total or near-total thyroidectomy must be performed by an experienced thyroid surgeon to minimize the complications of surgery. The improvement in outcome following total thyroidectomy is presented in Figure 7–50.

A second factor in survival is the use of radioiodine for ablation of residual thyroid tissue after thyroidectomy and the treatment of residual or recurrent disease. Low doses of 30 to 50 mCi $^{131}$I are used to ablate residual thyroid tissue, but larger doses of 100 to 200 mCi are necessary for the treatment of invasive or metastatic disease. Acute adverse effects of the larger doses include radiation sickness, sialadenitis, gastritis, and transient oligospermia. Cumulative doses of $^{131}$I above 500 mCi may be associated with transient infertility in females and azoospermia in males, pancytopenia in about 4% of patients, and leukemia in about 0.3%. Radiation pneumonitis may occur in patients with diffuse pulmonary metastases, but this is minimized by utilization of high-dose treatment no more than once a year. The effectiveness of $^{131}$I therapy in reducing cancer mortality is presented in Figure 7–51.

A third factor in survival is the adequate use of TSH suppression therapy. T$_4$ in a dose of 2.2 μg/kg/d (1 μg/lb/d) usually suppresses TSH to 0.1 mU/L or less, which removes a major growth factor for papillary or follicular thyroid cancer (see Figure 7–51). However, high-dose T$_4$ therapy is not without risk: there may be angina, tachycardia, or heart failure in older patients or tachycardia and nervousness in younger patients. In addition, there is an increased risk of osteoporosis in postmenopausal women. Estrogen or bisphosphonate therapy may prevent bone loss in these patients, but the treatment program must be individualized.

C. Medullary carcinoma Early and adequate initial thyroidectomy and cervical node dissection is the best therapy for medullary cancer. Once the disease has metastasized, it is very difficult to control, though the more favorable tumor types often progress very slowly. Patients with medullary cancer should be followed postoperatively with periodic measurement of serum markers (eg, calcitonin and CEA) that indicate residual disease. Family members of patients with an RET oncogene mutation should be screened for the mutation as noted above (Figure 7–48). If a patient has a persistently elevated serum calcitonin concentration after total thyroidectomy and regional node dissection, neck ultrasound, CT, MRI, and/or selective venous catheterization and sampling for serum calcitonin may reveal the location of the metastases. Metastatic foci of medullary cancer may also be revealed by PET, indium-labeled somatostatin (octreotide), or sestamibi scans. If these studies fail to localize the lesion (as is often the case), the patient must be followed until the metastatic lesions become evident by physical examination or imaging studies. External x-ray therapy may be useful in the treatment of some metastatic lesions. Chemotherapy with tyrosine kinase inhibitors,
especially the experimental RET inhibitor vandetanib (ZD 6474), has recently been shown to be highly effective in preventing disease progression in many patients with medullary cancer. Metastatic medullary cancer cannot be treated with $^{131}$I, and TSH-suppressive doses of T4 are not required.

Medullary thyroid cancer is most aggressive in patients with MEN 2B, less aggressive in the sporadic type, and least aggressive in MEN 2A and familial medullary thyroid cancer.

D. Anaplastic carcinoma Anaplastic carcinoma of the thyroid has a very poor prognosis. Treatment consists of minimal surgery to biopsy the tumor and establish the diagnosis, and sometimes to debulk the tumor and prevent tracheal compression. Standard treatment incorporates combined radiotherapy and chemotherapy with doxorubicin, which is sometimes combined with other agents (see Figure 7-49). Occasionally, patients have prolonged survival, but most succumb to their disease within 1 year.

CELLULAR AND EXTRACELLULAR CALCIUM METABOLISM

The calcium ion plays a critical role in intracellular and extracellular events in human physiology. Extracellular calcium levels in humans are tightly regulated within a narrow physiologic range to provide for proper functioning of many tissues: excitation-contraction coupling in the heart and other muscles, synaptic transmission and other functions of the nervous system, platelet aggregation, coagulation, and secretion of hormones and other regulators by exocytosis. The level of intracellular calcium is also tightly controlled, at levels about 10,000-fold lower than extracellular calcium, in order for calcium to serve as an intracellular second messenger in the regulation of cell division, muscle contractility, cell motility, membrane trafficking, and secretion.

It is the concentration of ionized calcium ([Ca\(^{2+}\)]\(\text{ion}\)) that is regulated in the extracellular fluid. The ionized calcium concentration averages 1.25 ± 0.07 mmol/L (Table 8–1). However, only about 50% of the total calcium in serum and other extracellular fluids is present in the ionized form. The remainder is bound to albumin (about 40%) or complexed with anions such as phosphate and citrate (about 10%). The protein-bound and complexed fractions of serum calcium are metabolically inert and are not regulated by hormones; only the ionized [Ca\(^{2+}\)]\(\text{ion}\) serves a regulatory role, and only this fraction is itself regulated by the calciotropic hormones parathyroid hormone (PTH) and 1,25 dihydroxyvitamin D [1,25(OH)\(_2\)D]. Large increases in the serum concentrations of phosphate or citrate can, however, by mass action, markedly increase the complexed fraction of calcium. For example, massive transfusions of blood, in which citrate is used as an anticoagulant, can reduce the ionized [Ca\(^{2+}\)]\(\text{ion}\) enough to produce tetany. In addition, because calcium and phosphate circulate at concentrations close to saturation, a substantial rise in the serum concentration of either calcium or phosphate can lead to the precipitation of calcium phosphate salts in tissues. This is a source of major clinical problems in patients with severe hypercalcemia (eg, malignant tumors) and in those with severe hyperphosphatemia (eg, in renal failure or rhabdomyolysis).

What is remarkable about calcium metabolism is that the serum-ionized [Ca\(^{2+}\)]\(\text{ion}\), which represents a tiny fraction of the total body calcium, can be so tightly regulated in the face of the rapid fluxes of calcium through body compartments that take place during the course of calcium metabolism (Figure 8–1). The total calcium in extracellular fluid amounts to about 1% of total body calcium, with most of the remainder sequestered in bone. Yet from the extracellular fluid compartment, which contains about 900 mg of calcium, 10,000 mg/d is filtered at the glomerulus and 500 mg/d is added to a labile pool in bone; and to the extracellular fluid compartment are added about 200 mg absorbed from the diet, 9800 mg reabsorbed by the renal tubule, and 500 mg from bone.

The challenge of calcium homeostasis, then, is to maintain a constant level of ionized [Ca\(^{2+}\)]\(\text{ion}\) in the extracellular fluid, simultaneously providing adequate amounts of calcium to cells, to bone, and for renal excretion—and all the while compensating, on an hourly basis, for changes in daily intake of calcium, bone metabolism, and renal function. It is scarcely surprising that this homeostatic task requires two hormones, PTH and 1,25(OH)\(_2\)D, or that the secretion of each hormone is exquisitely sensitive to small changes in the serum calcium, or that each hormone is able to regulate calcium exchange across all three interfaces of the extracellular fluid: the gut, the bone, and the renal tubule. We will reexamine the integrated roles of PTH and 1,25(OH)\(_2\)D in calcium homeostasis after their actions and secretory control have been described.

The challenge of the cellular calcium economy is to maintain a cytosolic [Ca\(^{2+}\)], or [Ca\(^{2+}\)]\(\text{cyt}\), of about 100 nmol/L, about 10,000-fold less than what is present outside cells (~1.0 mmol/L), providing for rapid fluxes through the intracellular compartment as required for regulation while maintaining a large gradient across the cell membrane. The calcium gradient across the cell membrane is maintained by ATP-dependent calcium pumps, Na\(^+\)-Ca\(^{2+}\) exchangers, and the storage of calcium within intracellular sites. Calcium can enter cells through several types of calcium channels, some of which are voltage operated or receptor operated, to provide for rapid influx in response to depolarization or receptor stimulation. The cell also maintains large stores of calcium in microsomal and mitochondrial pools and in some cells the Golgi apparatus. Calcium can be released from microsomal stores rapidly by cellular signals such as 1,4,5-inositol trisphosphate (IP\(_3\)). Reuptake mechanisms are also present, so that cytosolic calcium transients can be rapidly terminated by returning calcium to storage pools or pumping it across the plasma membrane.

PARATHYROID HORMONE

Anatomy and Embryology of the Parathyroid Glands

PTH is secreted from four glands located adjacent to the thyroid gland in the neck. The glands weigh an average of 40 mg each. The two superior glands are usually found near the posterior aspect of the thyroid capsule; the inferior glands are most often located near the inferior thyroid margin. However, the exact location of the glands is variable, and 12% to 15% of normal persons have a fifth parathyroid gland. The parathyroid glands arise from...
the third and fourth branchial pouches. The inferior glands are actually those derived from the third branchial pouches. Beginning cephalad to the other pair, they migrate further caudad, and one of them sometimes follows the thymus gland into the superior mediastinum. The small size of the parathyroids and the vagaries of their location and number make parathyroid surgery a challenging enterprise for all but the expert surgeon.

The parathyroid glands are composed of epithelial cells and stromal fat. The predominant epithelial cell is the chief cell. The chief cell is distinguished by its clear cytoplasm from the oxyphil cell, which is slightly larger and has eosinophilic granular cytoplasm. Both cell types contain PTH, and it is not known whether their secretory regulation differs in any fundamental way.

**Secretion of Parathyroid Hormone**

To regulate the extracellular calcium concentration \([\text{Ca}^{2+}]\), PTH is under tight control by the serum calcium concentration. Thus, the negative feedback relationship of PTH with serum \([\text{Ca}^{2+}]\) is steeply sigmoidal, with the steep portion of the curve corresponding exactly to the normal range of serum calcium—precisely the relationship to create a high "gain" controller and ensure maintenance of the normal serum-ionized \([\text{Ca}^{2+}]\) by PTH (Figure 8–2).

To sense the ionized \([\text{Ca}^{2+}]\) and thereby regulate the secretion of PTH, the parathyroid cell relies on relatively high levels of expression of the extracellular calcium-sensing receptor (CaSR). CaSR is a 120-kDa G protein–coupled receptor belonging to family C of this superfamily (see Chapter 1). The CaSR has sequence homologies to the metabotropic glutamate receptors of the central nervous system, the type B gamma-aminobutyric acid receptor, and a large family of pheromone receptors. The large extracellular domain of the CaSR mediates the sensing of calcium and other ions. Like other G protein–coupled receptors, the CaSR has seven membrane-spanning domains. The intracellular loops that connect these domains are directly involved in coupling the receptor to G proteins.

Shortly after the identification of the CaSR, it was shown that mutations in this receptor were responsible for familial benign hypocalciuric hypercalcemia (FBHH), a disorder of calcium sensing by the parathyroid glands and kidney. The CaSR is not unique to the parathyroid. CaSRs are widely distributed in the brain, skin, growth plate, intestine, stomach, C cells, and other tissues. This receptor regulates the responses to calcium in thyroid C cells, which secrete calcitonin in response to high extracellular \([\text{Ca}^{2+}]\), and in the distal nephron of the kidney, where the receptor regulates calcium excretion. The function of CaSRs in many other sites is still unclear.

The primary cellular signal by which an increased extracellular \([\text{Ca}^{2+}]\) inhibits the secretion of PTH appears to be an increase in \([\text{Ca}^{2+}]\). The CaSR is directly coupled by \(G_q\) to the enzyme phospholipase C, which hydrolyzes the phospholipid phosphatidylinositol 4,5-bisphosphate (PIP\(_2\)) to liberate the intracellular messengers IP\(_3\) and diacylglycerol (see Chapter 1). IP\(_3\) binds to a receptor in endoplasmic reticulum that releases calcium from membrane stores. The release of stored calcium raises the \([\text{Ca}^{2+}]\), rapidly and is followed by a sustained influx of extracellular calcium, through channels that produce a rise and sustained plateau in \([\text{Ca}^{2+}]\). Increased \([\text{Ca}^{2+}]\) may be sufficient for inhibition of PTH release, but it is unclear whether calcium release from intracellular stores or sustained calcium influx from the cell exterior is more important. The other product of phospholipase C action is the lipid diacylglycerol, an activator of the calcium- and phospholipid-sensitive protein kinases in the protein kinase C family. The effects of protein kinase C isoenzymes on the release of PTH from the gland are complex. CaSRs also couple to the inhibition of cyclic adenosine-3',5'-monophosphate (cAMP) generation, which also may play a role in setting the response of parathyroid cells to ambient calcium levels.

The initial effect of high extracellular calcium is to inhibit the secretion of preformed PTH from storage granules in the gland by blocking the fusion of storage granules with the cell membrane and release of their contents. In most cells, stimulation of exocytosis (stimulus-secretion coupling) is a calcium-requiring process, which is inhibited by depletion of extracellular calcium. The parathyroid cell is necessarily an exception to this rule, because this cell must increase secretion of PTH when the ionized \([\text{Ca}^{2+}]\) is low. In the parathyroids, intracellular magnesium may serve the role in stimulus-secretion coupling that calcium does in other cells. As discussed later in the section on hypoparathyroidism, depletion of magnesium stores can paralyze the secretion of PTH, leading to reversible hypoparathyroidism.

Besides calcium, there are several regulators of PTH secretion. Hypermagnesemia inhibits PTH, and during the treatment of premature labor with infusions of magnesium sulfate, reductions
in PTH levels and occasionally hypocalcemia are observed. Conversely, moderate hypomagnesemia can stimulate PTH secretion, even though prolonged depletion of magnesium will paralyze it. On a molar basis, magnesium is less potent in controlling secretion than calcium. Catecholamines, acting through β-adrenergic receptors and cAMP, stimulate the secretion of PTH. This effect does not appear to be clinically significant. The hypercalcemia sometimes observed in patients with pheochromocytoma usually has another basis—secretion of parathyroid hormone–related protein (PTHrP) by the tumor.

Not only do changes in serum calcium regulate the secretion of PTH—they also regulate the synthesis of PTH at the level of stabilizing preproPTH mRNA levels. It is estimated that glandular stores of PTH are sufficient to maintain maximal rates of secretion for no more than 1.5 hours, so increased synthesis is required to meet sustained hypocalcemic challenges.

Transcription of the PTH gene is also regulated by vitamin D: high levels of 1,25(OH)2D inhibit PTH gene transcription. This is one of many ways that the calciotropic hormones cooperatively regulate calcium homeostasis, and it has therapeutic implications. Vitamin D analogs are used to treat secondary hyperparathyroidism in dialysis patients with renal osteodystrophy.

Synthesis and Processing of Parathyroid Hormone

PTH is an 84-amino-acid peptide with a molecular weight of 9300. Its gene is located on chromosome 11. The gene encodes a precursor called preproPTH with a 29-amino-acid extension added at the amino terminus of the mature PTH peptide (Figure 8–3). This extension includes a 23-amino-acid signal sequence (the presequence) and a 6-residue prohormone sequence. The signal sequence in preproPTH functions precisely as it does in most other secreted protein molecules, to allow recognition of the peptide by a signal recognition particle, which binds to nascent peptide chains as they emerge from the ribosome and guides them to the endoplasmic reticulum, where they are inserted through the membrane into the lumen (Figure 8–4).

In the lumen of the endoplasmic reticulum, a signal peptidase cleaves the signal sequence from preproPTH to leave proPTH, which exits the endoplasmic reticulum and travels to the Golgi apparatus, where the prosequence is cleaved from PTH by an enzyme called furin. Whereas preproPTH is evanescent, proPTH has a life span of about 15 minutes. The processing of proPTH is quite efficient, and proPTH, unlike other prohormones

![FIGURE 8-3 Primary structure of human preproparathyroid hormone. The arrows indicate sites of specific cleavages which occur in the sequence of biosynthesis and peripheral metabolism of the hormone. McGraw-Hill; 1995.)](image-url)
FIGURE 8-4 Biosynthetic events in the production of PTH within the parathyroid cell. PreproPTH gene is transcribed to its mRNA, which is translated on the ribosomes to preproPTH (amino acids –29 to +84). The presequence is removed within the endoplasmic reticulum, yielding proPTH (–6 to +84). Mature PTH (1-84) released from the Golgi is packaged in secretory granules and released into the circulation in the presence of hypocalcemia. The CaSR, or CaR, senses changes in extracellular calcium that affect both the release of PTH and the transcription of the preproPTH gene. (Reproduced, with permission, from McPhee SJ, et al, ed. Pathophysiology of Disease: An Introduction to Clinical Medicine. Originally published by Appleton & Lange. Copyright 1995 by The McGraw-Hill Companies, Inc.)

Clearance and Metabolism of PTH

PTH secreted by the gland has a circulating half-life of 2 to 4 minutes. Intact PTH (1-84) is predominantly cleared in the liver and kidney. There, PTH is cleaved at the 33 to 34 and 36 to 37 positions to produce an amino terminal fragment and a carboxyl terminal fragment. Amino terminal fragments of PTH do not circulate to the same extent as carboxyl terminal fragments. The latter are cleared from blood by renal filtration, and they accumulate in chronic renal failure. Although the classic activities of PTH are encoded in the amino terminal portion of the molecule, mid region and carboxyl terminal fragments of the hormone may not be metabolically inert. Recent evidence suggests that they may have their own receptors and biologic actions.

Assays of PTH

Current assays of intact PTH (1-84) employ two-site immunoradiometric assay (IRMA) or immunochemiluminescent assay (ICMA) techniques, in which the normal range for PTH is approximately 10 to 60 pg/mL (1-6 pmol/L). By utilizing antibodies to two determinants, one near the amino terminal end of the PTH molecule and the other near the carboxyl terminal end of PTH, these assays are designed to measure the intact, biologically active hormone species (Figure 8-5). In practice, such assays have sufficient sensitivity and specificity to detect not only increased levels of PTH in patients with hyperparathyroid disorders but also suppressed levels of PTH in patients with nonparathyroid hypercalcemia. The ability to detect suppression of PTH makes these assays powerful tools for the differential diagnosis of hypercalcemia. If hypercalcemia results from a form of hyperparathyroidism, then the serum PTH level will be high; if hypercalcemia has a nonparathyroid basis, then PTH will be suppressed.
The central function of PTH is to regulate ionized \[Ca^{2+}\] levels by mucosa, and kidney. The effect of PTH on intestinal calcium absorption is indirect, resulting from increased renal production of the intestinally active vitamin D metabolite \(1,25(OH)_2D\). By its integrated effects on the kidney, gut, and bone, PTH acts to increase the inflow of calcium into the extracellular fluid and thus defend against hypocalcemia. Removal of the parathyroid glands results in profound hypocalcemia and ultimately in tetany and death.

In the kidney, PTH has direct effects on the tubular reabsorption of calcium, phosphate, and bicarbonate. Although the bulk of calcium is resorbed from tubule fluid together with sodium in the proximal convoluted tubule, the fine tuning of calcium excretion occurs in the distal nephron. There, PTH markedly increases the reabsorption of calcium, predominantly in the distal convoluted tubule. Although calcium is actively transported against an electrochemical gradient, the precise nature of the calcium transport process that is regulated by PTH is controversial. However, from a physiologic standpoint, the ability to limit renal losses of calcium is one important means by which PTH defends the serum calcium level.

PTH inhibits the reabsorption of phosphate in the renal proximal tubule. In this nephron segment, phosphate is transported across the apical membrane of the tubule cell by specific sodium-phosphate cotransporters, with phosphate influx driven by the energy of the sodium gradient. PTH inhibits sodium-phosphate reabsorption by reducing the rate of insertion of transporters from a sequestered cytoplasmic pool into the apical membrane. The phosphaturic effect of PTH is profound. It is best quantified by calculating the tubular reabsorption of phosphate (TRP) from the clearances of phosphate and creatinine \(\left(\text{TRP} = 1 - \frac{C_{\text{ph}}}{C_{\text{cre}}}, \text{normal range 80\%-97\%}\right)\), or by calculating the renal phosphate threshold \((\text{TRP/creatinine})\) from a standard nomogram. Because it is primarily the renal phosphate threshold that sets the level of serum phosphate, the phosphaturic effect of PTH is mirrored in the serum phosphorus level (eg, hypophosphatemia in hyperparathyroidism). Hyperparathyroid states may also be characterized by impaired bicarbonate reabsorption and a mild hyperchloremic metabolic acidosis, because of inhibition of \(\text{Na}^+\text{-H}^+\) antipporter activity by PTH.

Although the hypocalciuric effect of PTH is readily understood as part of the concerted actions of the hormone to defend the serum \([\text{Ca}^{2+}]\), the utility of the phosphaturic effect of PTH is less obvious. One consideration is that the phosphaturic effect tends to prevent an increase in serum phosphate, which would otherwise result from the obligatory release of phosphate with calcium during bone resorption and would tend to dampen the homeostatic increase in serum calcium by complexing calcium in blood. An example is renal osteodystrophy. When phosphate clearance is impaired by renal failure, the hypocalcemic effect of phosphate released during bone remodeling is an important contributor to progressive secondary hyperparathyroidism as part of a positive feedback loop—the more that bone resorption is stimulated and phosphate released, the more hyperparathyroidism is induced.

### Biologic Effects of PTH

The central function of PTH is to regulate ionized \([\text{Ca}^{2+}]\) levels by concerted effects on three principal target organs: bone, intestinal mucosa, and kidney. The effect of PTH on intestinal calcium absorption is indirect, resulting from increased renal production of the intestinally active vitamin D metabolite \(1,25(OH)_2D\). By its integrated effects on the kidney, gut, and bone, PTH acts to increase the inflow of calcium into the extracellular fluid and thus defend against hypocalcemia. Removal of the parathyroid glands results in profound hypocalcemia and ultimately in tetany and death.

In the kidney, PTH has direct effects on the tubular reabsorption of calcium, phosphate, and bicarbonate. Although the bulk of calcium is resorbed from tubule fluid together with sodium in the proximal convoluted tubule, the fine tuning of calcium excretion occurs in the distal nephron. There, PTH markedly increases the reabsorption of calcium, predominantly in the distal convoluted tubule. Although calcium is actively transported against an electrochemical gradient, the precise nature of the calcium transport process that is regulated by PTH is controversial. However, from a physiologic standpoint, the ability to limit renal losses of calcium is one important means by which PTH defends the serum calcium level.

PTH inhibits the reabsorption of phosphate in the renal proximal tubule. In this nephron segment, phosphate is transported across the apical membrane of the tubule cell by specific sodium-phosphate cotransporters, with phosphate influx driven by the energy of the sodium gradient. PTH inhibits sodium-phosphate reabsorption by reducing the rate of insertion of transporters from a sequestered cytoplasmic pool into the apical membrane. The phosphaturic effect of PTH is profound. It is best quantified by calculating the tubular reabsorption of phosphate (TRP) from the clearances of phosphate and creatinine \(\left(\text{TRP} = 1 - \frac{C_{\text{ph}}}{C_{\text{cre}}}, \text{normal range 80\%-97\%}\right)\), or by calculating the renal phosphate threshold \((\text{TRP/creatinine})\) from a standard nomogram. Because it is primarily the renal phosphate threshold that sets the level of serum phosphate, the phosphaturic effect of PTH is mirrored in the serum phosphorus level (eg, hypophosphatemia in hyperparathyroidism). Hyperparathyroid states may also be characterized by impaired bicarbonate reabsorption and a mild hyperchloremic metabolic acidosis, because of inhibition of \(\text{Na}^+\text{-H}^+\) antipporter activity by PTH.

Although the hypocalciuric effect of PTH is readily understood as part of the concerted actions of the hormone to defend the serum \([\text{Ca}^{2+}]\), the utility of the phosphaturic effect of PTH is less obvious. One consideration is that the phosphaturic effect tends to prevent an increase in serum phosphate, which would otherwise result from the obligatory release of phosphate with calcium during bone resorption and would tend to dampen the homeostatic increase in serum calcium by complexing calcium in blood. An example is renal osteodystrophy. When phosphate clearance is impaired by renal failure, the hypocalcemic effect of phosphate released during bone remodeling is an important contributor to progressive secondary hyperparathyroidism as part of a positive feedback loop—the more that bone resorption is stimulated and phosphate released, the more hyperparathyroidism is induced.

### Mechanism of Action of Parathyroid Hormone

There are two mammalian receptors for PTH. The first receptor to be identified recognizes PTH and PTHrP and is designated the PTH/PTHrP receptor, or the PTH-1 receptor (PTH-1R). The
PTH-2R is activated by PTH only. These receptors also differ in their tissue distribution. The PTH-1R in kidney and bone is an 80,000-MW glycoprotein and member of the G protein receptor superfamily. It has the canonical architecture of such receptors, with a large first extracellular domain, seven consecutive membrane-spanning domains, and a cytoplasmic tail (see Chapter 1). PTH binds to sites in the large extracellular domain of the receptor. The hormone-bound form of the receptor then activates associated G proteins via several determinants in the intracellular loops. PTH receptors are closely related to a small subfamily of peptide hormone receptors, which includes those for secretin, vasoactive intestinal polypeptide (VIP), adrenocorticotropin (ACTH), and calcitonin.

PTH itself has a close structural resemblance to a sister protein, PTHrP, and also resembles the peptides secretin, VIP, calcitonin, and ACTH. As noted above, the receptors for these related ligands are themselves members of a special family. These peptide hormones are characterized by an amino terminal alpha helical domain, thought to be directly involved in receptor activation, and an adjacent alpha helical domain that seems to be the primary receptor-binding domain. In the case of PTH, residues 1 to 6 are required for activation of the receptor; truncated analogs without these residues (eg, PTH[7-34]) can bind the receptor but cannot efficiently activate it and thus serve as competitive antagonists of PTH action. The primary receptor-binding domain consists of PTH(18-34). Although the intact form of PTH is an 84-amino-acid peptide, PTH(35-84) does not seem to have any important role in binding to the bone-kidney receptor. However, a separate PTH(35-84) receptor may exist; the carboxyl terminal PTH receptor could mediate an entirely different set of actions of PTH.

The PTH-1 receptor binds PTH and PTHrP with equal affinity. Physiologic activation of the receptor by binding of either PTH or PTHrP induces the active, GTP-bound state of two receptor-associated G proteins. Gi couples the receptor to the effector adenyl cyclase and thereby to the generation of cAMP as a cellular second messenger. Gs couples the receptor to a separate effector system, phospholipase C, and thereby to an increase in [Ca2+], and to activation of protein kinase C (see Chapter 1). Although it is not clear which of the cellular messengers, cAMP, intracellular calcium, or diacylglycerol is responsible for each of the various cellular effects of PTH, there is evidence from an experiment of nature that cAMP is the intracellular second messenger for maintaining calcium homeostasis and renal phosphate excretion. The experiment is pseudohypoparathyroidism (PHP), in which null mutations in one allele of the stimulatory G protein subunit Gs alpha (GNAS1) cause hypocalcemia and unresponsiveness of renal phosphate excretion to PTH.

**PTHrP**

When secreted in abundance by malignant tumors, PTHrP produces severe hypercalcemia by activating the PTH-1 receptor. However, the physiologic roles of PTHrP are quite different from those of PTH. PTHrP is produced in many fetal and adult tissues. Based on gene knockout experiments and overexpression of PTHrP in individual tissues, we now know that PTHrP is required for normal development as a regulator of the proliferation and mineralization of chondrocytes and as a regulator of placental calcium transport. In postnatal life, PTHrP also appears to regulate epithelial-mesenchymal interactions that are critical for development of the mammary gland, skin, and hair follicle. In most physiologic circumstances, PTHrP carries out local rather than systemic actions. PTHrP is discussed fully in Chapter 21.

**CALCITONIN**

Calcitonin (CT) is a 32-amino-acid peptide whose principal function is to inhibit osteoclast-mediated bone resorption. CT is secreted by parafollicular C cells of the thyroid. These are neuroendocrine cells derived from the ultimobranchial body, which fuses with the posterior lobes of the thyroid to become the C cell mass (about 0.1% of the thyroid gland).

The secretion of CT is under the control of the ionized [Ca2+]i. The C cell uses the same CaSR as the parathyroid cell to sense changes in the ambient ionized [Ca2+]i. In contrast to parathyroid cells, C cells increase secretion of CT in response to hypercalcemia and shut off hormone secretion during hypocalcemia.

CT is a member of the CT gene-related peptide (CGRP) superfamily that includes: CT, CGRP, CT-receptor-stimulating peptide (CRSP), adrenomedullin, and amylin. CT and CGRP are encoded by one gene, and the respective peptides are generated from alternative splicing of primary RNA transcripts in a tissue-selective manner with CT made predominantly in the thyroid C cells. The genomic structure of the CT/CGRP/CRSP gene family is shown in Figure 8–6. In humans, there are two genes (CALCA and CALCB) that encode CGRPs and CT and one pseudogene. PTHrP, which plays a crucial role in bone remodeling, is discussed in Chapter 21.

Copyright 1995 by The McGraw-Hill Companies, Inc.)

(CALCP). Transcription of CALCA produces CT and CGRP in a tissue-specific manner by alternative splicing. The CALCB gene has a coding CGRP-beta exon and an exon that codes for CT but in which there is an in-frame stop codon. Thus, CALCB generates only CGRP-beta. In the thyroid C cell, mature CT (Figure 8-7) is incorporated within a 141-amino-acid precursor. In neurons of the central nervous system, CGRP is produced from a 128-amino-acid precursor. CGRP is a 37-amino-acid peptide with considerable homology to CT. The amino termini of both peptides incorporate a seven-member disulfide-bonded ring (see Figure 8-7). Acting through its own receptor, CGRP is among the most potent vasodilator substances known. When administered intravenously, CT produces a rapid and dramatic decline in levels of serum calcium and phosphate, primarily through actions on bone. The major effect of the hormone is to inhibit osteoclastic bone resorption. After exposure to CT, the morphology of the osteoclast changes rapidly. Within minutes, the cell withdraws its processes, shrinks in size, and retracts the ruffled border, the organelle of bone resorption, from the bone surface. Osteoclasts and cells of the proximal renal tubule express CT receptors. Like the PTH receptor, this is a G protein–coupled receptor with seven membrane-spanning regions that is coupled by G, alpha to adenylyl cyclase and thereby to the generation of cAMP in target cells. CT also has renal effects. In the kidney, CT inhibits the reabsorption of phosphate, thus promoting renal phosphate excretion. CT also induces a mild natriuresis and increases the renal excretion of calcium. The renal effects of CT are not essential for its acute effect on serum calcium levels, which results from blockade of bone resorption.

Although its secretory control by calcium and its antiresorptive actions enable CT to counter PTH in the control of calcium homeostasis, thus engendering bihormonal regulation, it is actually unlikely that CT plays an essential physiologic role in humans and other terrestrial animals. This is supported by two lines of evidence. First, removal of the thyroid gland—the major if not the only source of CT in mammals—has no perceptible impact on calcium handling or bone metabolism in postnatal life. Second, secretion of extremely high CT levels by medullary carcinoma of the thyroid (MCT), a malignancy of the C cell, likewise has no apparent effect on mineral homeostasis. Thus, in humans, CT is a hormone in search of a function. It plays a much more obvious homeostatic role in saltwater fish, in which the major challenge is maintenance of blood calcium levels in the sea, where the ambient calcium concentration of sea water is very high.

CT is of clinical interest for two reasons. First, CT is important as a tumor marker in MCT. Second, CT has therapeutic uses as an inhibitor of osteoclastic bone resorption. CT can be administered either parenterally or as a nasal spray and is used in the treatment of Paget disease of bone, hypercalcemia, and osteoporosis.

VITAMIN D

Nomenclature

The term vitamin D (calciferol) refers to two secosteroids: vitamin D₂ (ergocalciferol) and vitamin D₃ (cholecalciferol) (Figure 8–8). Both are produced by photolysis from naturally occurring sterol precursors. Vitamin D₂ is the principal form of vitamin D available for pharmaceutical purposes other than as dietary supplements (Table 8–2). Vitamin D₃ is produced from 7-dehydrocholesterol, a precursor of cholesterol found in high concentration in the skin. Although vitamin D₃ is metabolized somewhat differently than vitamin D₂, the active metabolites of vitamin D₂ and vitamin D₃ have equivalent biologic activity so the term vitamin D₃, unless otherwise qualified, will be understood here to denote both. Vitamins D₂ and D₃ differ in their side chains: vitamin D₂ has a methyl group at C24 and a double bond at C22 to C23. These features alter the metabolism of vitamin D₃ compared with vitamin D₂; however, both are converted to 25-hydroxyvitamin D (25[OH]D) and 1,25-dihydroxyvitamin D (1,25(OH)₂D).

In the process of forming vitamins D₂ and D₃, the B ring of the sterol precursor is cleaved, and the A ring is rotated around the C5 to C6 double bond so that the 3β-hydroxyl group is positioned below the plane of the A ring. By convention, this hydroxyl group retains its designation as 3β, and the one position above the plane of the A ring is designated 1α. Hydroxylations in the side chain can lead to stereoisomers

Nomenclature

Vitamin D

The term vitamin D (calciferol) refers to two secosteroids: vitamin D₂ (ergocalciferol) and vitamin D₃ (cholecalciferol) (Figure 8–8). Both are produced by photolysis from naturally occurring sterol precursors. Vitamin D₂ is the principal form of vitamin D available for pharmaceutical purposes other than as dietary supplements (Table 8–2). Vitamin D₃ is produced from 7-dehydrocholesterol, a precursor of cholesterol found in high concentration in the skin. Although vitamin D₃ is metabolized somewhat differently than vitamin D₂, the active metabolites of vitamin D₂ and vitamin D₃ have equivalent biologic activity so the term vitamin D₃, unless otherwise qualified, will be understood here to denote both. Vitamins D₂ and D₃ differ in their side chains: vitamin D₂ has a methyl group at C24 and a double bond at C22 to C23. These features alter the metabolism of vitamin D₃ compared with vitamin D₂; however, both are converted to 25-hydroxyvitamin D (25[OH]D) and 1,25-dihydroxyvitamin D (1,25(OH)₂D).

In the process of forming vitamins D₂ and D₃, the B ring of the sterol precursor is cleaved, and the A ring is rotated around the C5 to C6 double bond so that the 3β-hydroxyl group is positioned below the plane of the A ring. By convention, this hydroxyl group retains its designation as 3β, and the one position above the plane of the A ring is designated 1α. Hydroxylations in the side chain can lead to stereoisomers
FIGURE 8-8 The photolysis of ergosterol and 7-dehydrocholesterol to vitamin D$_2$ (ergocalciferol) and vitamin D$_3$ (cholecalciferol), respectively. An intermediate is formed after photolysis, which undergoes a thermal-activated isomerization to the final form of vitamin D. The rotation of the A-ring puts the 3-beta-hydroxyl group into a different orientation with respect to the plane of the A-ring during production of vitamin D.

designated R and S. The natural position for the C24 hydroxyl group is R. Both the R and the S positions can be hydroxylated at C25 in the formation of 25,26(OH)$_2$D.

Because vitamin D can be formed in vivo (in the epidermis) in the presence of adequate amounts of ultraviolet light, it is more properly considered a hormone (or prohormone) than a vitamin. To be biologically active, vitamin D must be metabolized further. The liver is the major but not the only organ that can metabolize vitamin D to its principal circulating form, 25(OH)D. The kidney and other tissues metabolize 25(OH)D to a variety of other metabolites, the most important of which are 1,25(OH)$_2$D and, perhaps, 24,25(OH)$_3$D. A large number of other metabolites have been identified, but their physiologic roles are unclear. They may represent products destined only for elimination. Normal circulating levels of the principal metabolites are listed in Table 8–3. The recommended daily allowance for vitamin D in adults is 400 units (1 unit = 0.025 µg vitamin D), although recent data indicate that is inadequate especially in older individuals.

*Values differ somewhat from laboratory to laboratory depending on the methodology used, sunlight exposure, and dietary intake of vitamin D in the population study. Children tend to have higher 1,25(OH)$_2$D levels than do adults.

Cutaneous Synthesis of Vitamin D

Vitamin D$_3$ is formed in the skin from 7-dehydrocholesterol, which is distributed throughout the epidermis and dermis but has its highest concentration in the lower layers of the epidermis, the stratum spinosum, and stratum basale. These epidermal layers also account for the highest production of vitamin D. The cleavage of the B ring of 7-dehydrocholesterol to form previtamin D$_3$ (see Figure 8-8) requires ultraviolet light with a spectrum of 280 to 320 nm (UVB). Following cleavage of the B ring, the previtamin D$_3$ undergoes thermal isomerization to vitamin D$_3$ but also to the biologically inactive compounds lumisterol and tachysterol. Formation of pre-D$_3$ is rapid and reaches a maximum within hours during exposure to solar or ultraviolet irradiation. The degree of epidermal pigmentation, the age of the skin, and the intensity of exposure all affect the time required to reach the maximum pre-D$_3$ concentration but do not alter that maximum. Continued ultraviolet light exposure then results in continued formation of the inactive compounds from pre-D$_3$. The formation of lumisterol is reversible, so lumisterol can be converted back to pre-D$_3$ as pre-D$_3$ levels fall. Short exposure to sunlight causes prolonged release of vitamin D$_3$ from the exposed skin because of the slow conversion of pre-D$_3$ to vitamin D$_3$ and the conversion of lumisterol to tachysterol. Prolonged exposure to sunlight does not produce toxic quantities of vitamin D$_3$ because of the photoconversion of pre-D$_3$ to lumisterol and tachysterol.

Vitamin D$_3$ transport from the skin into the circulation has not been thoroughly studied. Vitamin D$_3$ is carried in the bloodstream primarily bound to vitamin D-binding protein (DBP), an $\alpha$-globulin produced in the liver. DBP has a lower affinity for vitamin D$_3$ than other vitamin D metabolites such as 25(OH)D and 24,25(OH)$_2$D. 7-Dehydrocholesterol, pre-D$_3$, lumisterol, and tachysterol bind to DBP even less well. Therefore, vitamin D$_3$ could be selectively removed from skin by the gradient established by selective binding to DBP. Because the deepest levels of the epidermis make the most vitamin D$_3$ when the skin is irradiated, the distance over which vitamin D$_3$ must diffuse to reach the circulation is short. However, simple diffusion is an unlikely means for so hydrophobic a molecule to enter the bloodstream. Epidermal lipoproteins may play a role in transport, but this remains to be established.

Dietary Sources and Intestinal Absorption

Dietary sources of vitamin D are clinically important because exposure to ultraviolet light may not be sufficient to maintain adequate production of vitamin D in the skin. The farther away from the equator one lives, the shorter the period of the year during which the intensity of sunlight is sufficient to produce vitamin D$_3$. Most milk products in the United States are supplemented with vitamin D. Unfortified milk products contain little or no vitamin D. Although plants and mushrooms contain ergosterol, their content of vitamin D$_3$ is limited unless they are irradiated with ultraviolet light during processing. Vitamin D is found in moderate to high concentrations in fish oils and fish liver and in lesser concentrations in eggs. Vitamin D is absorbed from the diet in the small intestine with the help of bile salts. Drugs that bind bile salts such as colestipol and various malabsorption syndromes reduce vitamin D absorption. Most of the vitamin D passes into the lymph in chylomicrons, but a significant amount is absorbed directly into the portal system. The presence of fat in the lumen decreases vitamin D absorption. 25(OH)D and calcitriol are preferentially absorbed into the portal system and are less influenced by the amount of fat in the lumen. Biliary conjugates of the vitamin D metabolites have been identified, and an enterohepatic circulation of these metabolites has been established. Vitamin D is taken up rapidly by the liver and is metabolized to 25(OH)D. 25(OH)D is also transported in the blood bound to DBP. Little vitamin D is stored in the liver. Excess vitamin D is stored in adipose tissue and muscle.

Binding Proteins for Vitamin D Metabolites

As noted above, vitamin D metabolites are transported in the blood bound principally to DBP (85%) and albumin (15%). DBP binds 25(OH)D and 24,25(OH)$_2$D with approximately 30 times greater affinity than it binds 1,25(OH)$_2$D and vitamin D. DBP circulates at a concentration ($5 \times 10^{-6}$ mol/L) approximately
50 times greater than the total concentrations of the vitamin D metabolites. DBP levels are reduced in liver disease and in the nephrotic syndrome and increased during pregnancy and with estrogen administration, but are not altered by states of vitamin D deficiency or excess. The high affinity of DBP for the vitamin D metabolites and the large excess-binding capacity maintain the free and presumed biologically active concentrations of the vitamin D metabolites at very low levels—approximately 0.03% and 0.4% of the total 25(OH)D and 1,25(OH)₂D levels, respectively. Liver disease reduces the total level of the vitamin D metabolites commensurate with the reduction in DBP and albumin levels, but the free concentrations of the vitamin D metabolites remain normal in most subjects. This fact must be borne in mind when evaluating a patient with liver disease to determine whether such a patient is truly vitamin D deficient. Pregnancy, on the other hand, increases both the free and total concentrations by increasing DBP levels, altering the binding of the metabolites to DBP, and increasing the production of 1,25(OH)₂D. The binding of the vitamin D metabolites to DBP appears to occur at the same site, and saturation of this site by one metabolite can displace the other metabolites. This is an important consideration in vitamin D toxicity because the very high levels of 25(OH)D that characterize this condition displace the often normal levels of 1,25(OH)₂D, leading to elevated free and biologically active concentrations of 1,25(OH)₂D. This phenomenon at least partially explains the hypercalcemia and hypercalciuria that mark vitamin D intoxication even in patients with normal total 1,25(OH)₂D levels.

At present, it is not clear whether DBP functions just to maintain a circulating reservoir of vitamin D metabolites or whether DBP participates in transporting the vitamin D metabolites to their target tissues. A different set of proteins related to heat shock proteins are found within the cell that bind the vitamin D metabolites and appear to facilitate their further metabolism. These proteins are distinct from DBP and the nuclear hormone receptors for calcitriol, which will be discussed subsequently.

**Metabolism**

The conversion of vitamin D to 25(OH)D occurs principally in the liver (Figure 8–9). Both mitochondria and microsomes have the capacity to produce 25(OH)D but with different kinetics and with different enzymes. The mitochondrial enzyme has been identified as the 5β-cholestane-3α,7α,12α-triol-27(26)-hydroxylase (CYP27A1), a cytochrome P450 mixed-function oxidase, and its cDNA has been isolated. A number of microsomal P450 enzymes have been shown to have 25-hydroxylase activity with variable preference for D₂ or D₃ and their 1-hydroxylated metabolites. The microsomal 25-hydroxylase that has received the most attention is CYP2R1. Like the mitochondrial enzyme, these are not specific

---

**FIGURE 8-9** The metabolism of vitamin D. The liver converts vitamin D to 25(OH)D. The kidney converts 25(OH)D to 1,25(OH)₂D and 24,25(OH)₂D. Control of metabolism is exerted primarily at the level of the kidney where low serum phosphate, low serum calcium, and high parathyroid hormone (PTH) levels favor production of 1,25(OH)₂D whereas FGF23; high serum calcium and phosphate, and 1,25(OH)₂D inhibit 1,25(OH)₂D production while increasing 24,25(OH)₂D production. Plus (+) and minus (−) signs denote the stimulatory and inhibitory enzymatic reactions, respectively, driving the metabolic steps indicated.
for vitamin D. Regulation of 25(OH)D production is difficult to demonstrate. Drugs such as phenytoin and phenobarbital reduce serum 25(OH)D levels, primarily by increased catabolism of 25(OH)D and vitamin D. Liver disease leads to reduced total (but not necessarily free) serum 25(OH)D levels, primarily because of reduced DBP and albumin synthesis and not reduced synthesis of 25(OH)D. Vitamin D deficiency is marked by low blood levels of 25(OH)D, primarily because of lack of substrate for the 25-hydroxylase. Vitamin D intoxication, on the other hand, leads to increased levels of 25(OH)D because of the lack of feedback inhibition on the 25-hydroxylases.

Control of vitamin D metabolism is exerted principally in the kidney (see Figure 8–9). 1,25(OH)₂D and 24,25(OH)₂D are produced by cytochrome mixed-function oxidases in mitochondria of the proximal tubules. CDNAs encoding these enzymes have both been identified and show substantial homology to each other and to the mitochondrial 25-hydroxylase (CYP27A1). Their homology to other mitochondrial steroid hydroxylases is considerable but not as high. Although the 24-hydroxylase is widely distributed, the 1-hydroxylase is more limited, being found primarily in the epidermis, placenta, bone, macrophages, and prostate in addition to kidney, although low levels of expression have been observed in a number of other tissues such as breast, lung, testes, T and B lymphocytes, dendritic cells, heart, and brain.

The kidney remains the principal source of circulating 1,25(OH)₂D. Production of 1,25(OH)₂D in the kidney is stimulated by PTH and insulin-like growth factor-1 (IGF-1) and is inhibited by fibroblast-derived growth factor 23 (FGF23) and high blood levels of calcium and phosphate. Production of FGF23, a recently identified cytokine, occurs primarily in bone and is regulated by the levels of serum phosphate and 1,25(OH)₂D (Figure 8–10). FGF23 inhibits 1,25(OH)₂D production, blocks renal phosphate reabsorption, and acts to lower serum phosphate (see Figure 8–10 and Chapter 21).

**Mechanisms of Action**

The main function of vitamin D metabolites is the regulation of calcium and phosphate homeostasis, which occurs in conjunction with PTH. The gut, kidney, and bone are the principal target tissues for this regulation. The major pathologic complication of vitamin D deficiency is rickets (in children with open epiphyses) or osteomalacia (in adults), which results mainly from the deficiency of calcium and phosphate required for bone mineralization. 1,25(OH)₂D is the most biologically active, if not the only vitamin D metabolite involved in maintaining calcium and phosphate homeostasis.

Most of the cellular processes regulated by 1,25(OH)₂D involve the nuclear vitamin D receptor (VDR), a 50-kDa protein related by structural and functional homology to a large class of nuclear hormone receptors including the steroid hormone receptors, thyroid hormone receptors (TRs), retinoic acid and retinoid X receptors (RARs, RXRs), and endogenous metabolite receptors, including peroxisome proliferation activator receptors (PPARs), liver X receptors (LXRs), and farnesoid X receptors (FXRs) (see Chapter 1). These receptors are transcription factors. The VDR, as is the case with TRs, RARs, PPARs, LXRs, and FXRs, generally acts by forming heterodimers with RXRs. The VDR–RXR complex then binds to specific regions within the regulatory portions of the genes whose expression is controlled by 1,25(OH)₂D (Figure 8–11). The regulatory regions are called vitamin D response elements (VDREs) and are generally composed of two stretches of six nucleotides (each called a half-site) with a specific and nearly identical sequence separated by three nucleotides with a less specific sequence (a direct repeat with three base-pair separation; DR3). Numerous exceptions to this rule can be found such as a VDR–RAR complex binding to a DR6 (direct repeat with six
base-pair separation) or inverted palindromes (repeat elements going in opposite directions) with various degrees of spacing (eg, IP9). Other nuclear hormone receptors bind to similar elements but with different spacing or orientation of the half-sites. The binding of the VDR–RXR complex to the VDRE then attracts a complex of proteins termed coactivators to the VDR–RXR complex, some of which open up the gene for transcription by acetylating the histones and other proteins which communicate with and activate the RNA polymerase II complex. Transcription of the gene is initiated to produce the corresponding mRNA, which leaves the nucleus for the cytoplasm to be translated to the corresponding protein.

A. Intestinal calcium transport

Intestinal calcium transport is the best-understood target tissue response of 1,25(OH)2D. Calcium transport through the intestinal epithelium proceeds by at least three distinct steps: (1) entrance into the cell from the lumen across the brush border membrane down a steep electrochemical gradient; (2) passage through the cytosol, probably within subcellular organelles such as mitochondria and endosomes; and (3) removal from the cell against a steep electrochemical gradient at the basolateral membrane. Each of these steps is regulated by 1,25(OH)2D. At the brush border, 1,25(OH)2D induces a change in the binding of calmodulin to brush border myosin 1, a unique form of myosin found only in the intestine, where it resides primarily in the microvillus bound to actin and to the plasma membrane. The calmodulin-myosin 1 complex may provide the mechanism for removing calcium from the brush border after it crosses the membrane into the cell. Changes in the phospholipid composition of the brush border may explain the increased flux of calcium across this membrane after calcitriol administration. None of these changes requires new protein synthesis. However, evidence now indicates that a calcium channel, the transient receptor potential cation channel 6 (TRPV6) in the brush border membrane is induced by 1,25(OH)2D and is likely the major mechanism by which calcium enters the intestinal epithelial cell. The transport of calcium through the cytosol requires a vitamin D-inducible protein called calbindin. Calbindin exists either in a 28-kDa or 9-kDa form, depending on the species and tissue. Calbindin has a high affinity for calcium. If its synthesis is blocked, the calcium content of the cytosol and mitochondria increases, and efficiency of transport is reduced. At the basolateral membrane, calcium is removed from the cell by an ATP-driven pump, the Ca2+-ATPase (PMC Alb), a protein also induced by 1,25(OH)2D. Recent studies, however, in which calbindin or TRPV6 expression is deleted show surprisingly little impact on intestinal calcium transport (calbindin knockout) or only a partial reduction (TRPV6 knockout) suggesting that there is more to learn about the mechanisms governing intestinal calcium transport. Nevertheless in mice in which the VDR is rendered nonfunctional (VDR knockout), intestinal calcium transport is markedly impaired, indicating the importance of VDR function—presumably via regulation of gene expression—in governing intestinal calcium transport.

B. Actions of vitamin D in bone

The critical role of 1,25(OH)2D in regulating bone formation and resorption is evidenced by the development of rickets in children who are vitamin D-deficient, have inactivating mutations in CYP27B1 (the 1-hydroxylase) (pseudovitamin D-deficient rickets), or lack a functioning VDR (hereditary 1,25(OH)2D-resistant rickets). The histologic and radiologic appearance of bone in these genetic conditions is quite similar to that in patients with severe vitamin D deficiency.

Patients with inactivating mutations in the 1-hydroxylase gene can be treated successfully with calcitriol (but not with vitamin D), whereas those with mutations in the VDR are resistant to calcitriol as well as to vitamin D. These experiments of nature, however, do not exclude the possibility that other vitamin D metabolites, in combination with 1,25(OH)2D, are essential for normal bone metabolism.

In vitamin D deficiency, all vitamin D metabolites are reduced, but 25(OH)D and 24,25(OH)2D tend to be reduced out of proportion to 1,25(OH)2D, which may be maintained in the low normal range despite clear abnormalities in bone mineralization. Thus, it is reasonable to ask whether 1,25(OH)2D is the only vitamin D metabolite of consequence for the regulation of skeletal homeostasis. In fact, a number of studies point to unique actions of 24,25(OH)2D that cannot be replicated by 1,25(OH)2D, especially in cartilage, although this remains controversial. Studies in
mice, in which the 24-hydroxylase gene has been inactivated (knocked out), support the concept that 24,25(OH)2D has a role in bone formation that is not replaced by 1,25(OH)2D. At least some of the skeletal abnormalities in 24-hydroxylase-null animals may be explained by their inability to regulate 1,25(OH)2D levels. Nevertheless, the need for more than just 1,25(OH)2D is an important concept in the treatment of vitamin D deficiency; this is best done with vitamin D or 25(OH)D rather than calcitriol alone, because vitamin D serves as a precursor for both 1,25(OH)2D and 24,25(OH)2D.

The mechanisms by which 1,25(OH)2D regulates skeletal homeostasis remain uncertain. Provision of adequate calcium and phosphate for mineralization is clearly important. The rickets present in patients with defective VDRs can be cured with calcium and phosphate infusions. Similarly, in mice in which the VDR is rendered nonfunctional (knocked out), rickets is prevented with diets high in calcium and phosphate. Thus, even though the osteoblast, the cell responsible for forming new bone, contains a VDR and the transcription of a number of proteins in bone is regulated by 1,25(OH)2D, it is not clear how essential the direct actions of 1,25(OH)2D on bone are for bone formation and mineralization. Thus, the bone is a good example of the paradoxical appearance of osteomalacia—can be understood in the context of these differential effects of 1,25(OH)2D on the osteoblast as it differentiates. Excess 1,25(OH)2D can disrupt the differentiation pathway.

C. Actions of vitamin D in kidney

The kidney expresses VDRs, and 1,25(OH)2D stimulates the expression of calbindin, TRPV5 (the renal homolog of the intestinal TRPV6), and Ca2+ ATPase (PMCA) in the distal tubule as well as 24,25(OH)2D production in the proximal tubule. However, the role of 1,25(OH)2D in regulating calcium and phosphate transport across the renal epithelium remains controversial. 25(OH)D may be more important than 1,25(OH)2D in acutely stimulating calcium and phosphate reabsorption by the kidney tubules. In vivo studies are complicated by the effect of 1,25(OH)2D on other hormones, particularly PTH, which appears to be more important than the vitamin D metabolites in regulating calcium and phosphate handling by the kidney.

D. Actions of vitamin D in other tissues

An exciting observation is that VDRs are found in a large number of tissues beyond the classic target tissues—gut, bone, and kidney—and these tissues respond to 1,25(OH)2D. Furthermore, many of these tissues contain CYP27B1 (the 1-hydroxylase) and so are capable of producing their own 1,25(OH)2D from circulating 25(OH)D. These tissues include elements of the hematopoietic and immune systems; cardiac, skeletal, and smooth muscle; and brain, liver, breast, endothelium, skin (keratinocytes, melanocytes, and fibroblasts), and endocrine glands (pituitary, parathyroid, pancreatic islets [B cells], adrenal cortex and medulla, thyroid, ovary, and testis). Furthermore, malignancies developing in these tissues often contain VDRs and respond to the antiproliferative actions of 1,25(OH)2D.

The responses of these tissues to 1,25(OH)2D are as varied as the tissues themselves. 1,25(OH)2D regulates hormone production and secretion, including stimulation of insulin secretion from the pancreas and prolactin from the pituitary, but inhibiting PTH secretion from the parathyroid gland, renin secretion from the kidney, and atrial natriuretic peptides from the heart. 1,25(OH)2D enables the innate immune system by inducing antimicrobial peptides such as cathelicidin but suppresses the adaptive immune response by blocking the maturation of dendritic cells and shifting the balance of T-helper cell differentiation from Th1 and Th17 to Th2 and Treg. Myocardial contractility and vascular tone are modulated by 1,25(OH)2D. 1,25(OH)2D reduces the rate of proliferation of many cell lines, including normal keratinocytes, fibroblasts, lymphocytes, and thymocytes as well as abnormal cells of mammary, skeletal, intestinal, lymphatic, and myeloid origin. Differentiation of numerous normal cell types, including keratinocytes, lymphocytes, hematopoietic cells, intestinal epithelial cells, osteoblasts, and osteoclasts as well as abnormal cells of the same lineage is enhanced by 1,25(OH)2D. Thus, the potential for manipulating a vast array of physiologic and pathologic processes with calcitriol and its analogs is enormous. This promise is starting to be realized in that vitamin D analogs are being used to treat psoriasis, uremic hyperparathyroidism, and osteoporosis.
Epidemiologic and animal studies indicate a role for vitamin D in the prevention and treatment of both type 1 and type 2 diabetes mellitus, autoimmune diseases such as multiple sclerosis and inflammatory bowel disease, and infections such as tuberculosis. Trials of vitamin D analogs in the treatment of a variety of cancers are also being conducted. Thus, although regulation of bone mineral homeostasis remains the major physiologic function of vitamin D and its metabolites, clinical applications for these compounds and their analogs are being found outside the classic target tissues.

**HOW VITAMIN D AND PTH CONTROL MINERAL HOMEOSTASIS**

Consider a person who switches from a high normal to a low normal intake of calcium and phosphate—from 1200 mg/d to 300 mg/d of calcium (the equivalent of leaving three glasses of milk out of the daily diet). The net absorption of calcium falls sharply, causing a transient decrease in the serum calcium level. The homeostatic response to this transient hypocalcaemia is led by an increase in PTH, which stimulates the release of calcium and phosphate from bone and the retention of calcium by the kidney. The phosphaturic effect of PTH allows elimination of phosphate, which is resorbed from bone together with calcium. In addition, the increase in PTH, along with the fall in serum calcium and serum phosphate, activates renal 1,25(OH)₂D synthesis. In turn, 1,25(OH)₂D increases the fractional absorption of calcium and further increases bone resorption. External calcium balance is thus restored by increased fractional absorption of calcium and increased bone resorption at the expense of higher steady state levels of PTH and 1,25(OH)₂D.

**MEDULLARY CARCINOMA OF THE THYROID**

MCT, a neoplasm of thyroidal C cells, accounts for 5% to 10% of all thyroid malignancies. Approximately 75% of MCTs are sporadic. The remainder is familial and associated with one of three heritable syndromes: familial isolated MCT; multiple endocrine neoplasia 2A (MEN 2A), consisting of MCT, pheochromocytoma, and primary hyperparathyroidism; or multiple endocrine neoplasia 2B (MEN 2B), consisting of MCT, pheochromocytoma, multiple mucosal neuromas, and, rarely, primary hyperparathyroidism (Table 8–4). The MEN syndromes are more extensively discussed in Chapter 22.

Understanding the pathogenesis of MCT has been greatly enhanced by the identification of causative mutations in the RET proto-oncogene located on chromosome 10q11.2. The RET gene encodes a membrane tyrosine kinase receptor whose ligands belong to the glial cell line-derived neurotrophic factor (GDNF) family. This receptor is expressed developmentally in migrating neural crest cells that give rise to hormone-secreting neuroendocrine cells (eg, C cells and adrenal medullary cells) and to the parasympathetic and sympathetic ganglia of the peripheral nervous system. Remarkably, different mutations in RET can produce five distinct diseases (see Table 8–4). Inheritance of certain activating mutations is responsible for MEN 2A and familial MCT. Inheritance of a different set of activating mutations causes MEN 2B. In over half of sporadic MCTs, the tumor has a clonal somatic mutation (present in the tumor but not in genomic DNA), which is identical to one of the mutations that is responsible for the familial forms of MCT. These somatic mutations clearly play a causative role in sporadic MCT. Mutations in the RET gene can also produce Hirschsprung disease, a congenital absence of the enteric parasympathetic ganglia, that can lead to a disturbance in intestinal motility, resulting in megacolon.

MCT is usually located in the middle or upper portions of the thyroid lobes. It is typically unilateral in sporadic cases but often multicentric and bilateral in familial forms of the disease. The natural history of MCT is variable. Sporadic tumors may be quite aggressive or very indolent; the mean 5-year survival rate is about 50%. The behavior of familial forms varies among syndromes. MEN 2B has the most aggressive form of MCT, with a 2-year survival of about 50%; MEN 2A has a course similar to that of sporadic forms of this tumor, and familial MCT has the most indolent course of all MCT. The natural history of the tumor in familial MCT, MEN 2A, and MEN 2B syndromes has been dramatically impacted by early prophylactic total thyroidectomy that is now advised in most carriers of disease-causing RET mutations. MCT may spread to regional lymph nodes or undergo hematogenous spread to the lungs and other viscera. When metastatic, this tumor is sometimes associated with a chronic diarrhea syndrome. The pathogenesis of the diarrhea is unclear. In addition to CT, these tumors secrete a variety of other bioactive products, including prostaglandins, serotonin, histamine, and peptide hormones (ACTH, somatostatin, corticotropin-releasing hormone). In some

cases, the associated diarrhea responds dramatically to treatment with long-acting somatostatin analog such as octreotide, which blocks secretion of these bioactive products.

CT is a tumor marker for MCT. It is most sensitive for this purpose when secretion is stimulated with provocative agents. The standard provocative tests use pentagastrin (0.5 μg/kg intravenously over 5 seconds) or a rapid infusion of calcium gluconate (2 mg calcium/kg over 1 minute). Blood samples are obtained at baseline and 1, 2, and 5 minutes after the stimulus. For maximal sensitivity, both tests are usually combined, with the calcium infusion immediately followed by administration of pentagastrin. Although basal CT levels are often normal in early tumors, CT levels may be many times higher than normal in patients with disseminated MCT. Despite this, the patients are uniformly normocalcemic. Although tumors secrete larger molecular weight forms of CT with decreased biologic activity, monomeric CT levels are often high as well. RET oncogene analysis has replaced provocative testing in most cases, although basal CT levels are still used to follow disease burden postoperatively and during chemotherapy trials.

Members of families carrying RET mutations must be screened for MCT and, if positive, for the associated tumors that occur in MEN 2A and MEN 2B (see Table 8–4 and Chapter 22). In the case of MCT, the presence of the RET mutation in an individual generally leads to the recommendation for a total thyroidectomy prior to the development of frank malignancy or abnormal CT levels. It is recommended in a kindred with a known RET mutation that children be screened at birth for the carrier state. Total thyroidectomy with or without central compartment lymph node dissection can be performed in mutation carriers, and further testing can be discontinued in genetically normal family members. The timing of prophylactic thyroidectomy in carriers of RET mutations, however, depends on the genotype present (ie, codon mutated in RET) (Table 8–5). As supported by the genotype-phenotype correlations in these diseases, surgery is recommended in certain high-risk cases before 1 year of age, in cases of intermediate risk before 5 years of age, and in lower-risk patients later in childhood usually by 10 years of age. Because a limited number of mutations in RET cause more than 95% of hereditary MCT and up to 25% of sporadic disease, it is possible to screen the majority of patients using commercial reference laboratories.

Apparent sporadic MCT also calls for genetic testing and family studies. Up to 25% of new cases of MCT may actually be probands of families who harbor one of the familial syndromes. It has been noted in some kindreds after careful and lengthy follow-up that some individuals develop pheochromocytomas or primary hyperparathyroidism. Therefore, patients with apparent familial MCT should be followed indefinitely for one of these components of MEN 2A. Screening of family members can be accomplished by genetic testing, once the index case is identified. Identification of a mutation that is present only in tumor tissue would establish the mutation as somatic and the tumor as a sporadic one. Identification of the same RET mutation in tumor and genomic DNA would make the diagnosis of a familial form of the disorder and would mandate careful screening of the family.

**HYPERCALCEMIA**

### Clinical Features

A number of symptoms and signs accompany hypercalcemia. They include central nervous system effects such as lethargy, depression, psychosis, ataxia, stupor, and coma; neuromuscular effects such as weakness, proximal myopathy, and hypertonatremia; cardiovascular effects such as hypertension, bradycardia (and eventually asystole), and a shortened QT interval; renal effects such as stones, decreased glomerular filtration, polyuria, hyperchloremic acidosis, and nephrocalcinosis; gastrointestinal effects such as nausea, vomiting, constipation, and anorexia; eye findings such as band keratopathy; and systemic metastatic calcification. Primary hyperparathyroidism, one of the most common etiologies for hypercalcemia, has the mnemonic for recalling its signs and symptoms as stones, bones, abdominal groans, and psychic moans (Figure 8–12).

Mechanisms

Although many disorders are associated with hypercalcemia (Table 8–6), they produce it by a limited number of mechanisms: (1) increased bone resorption, (2) increased gastrointestinal absorption of calcium, or (3) decreased renal excretion of calcium. Although any of these mechanisms can be involved in a given patient, the common feature of virtually all hypercalcemic disorders is accelerated bone resorption. The only hypercalcemic disorder in which bone resorption does not play a part is the milk-alkali syndrome.

The central feature of the defense against hypercalcemia is suppression of PTH secretion. This reduces bone resorption, renal production of 1,25(OH)₂D, and, thereby, intestinal calcium absorption and increases urinary calcium losses. The kidney plays a key role in the adaptive response to hypercalcemia as the only route of net calcium elimination. The level of renal calcium excretion is markedly increased by the combined effects of an increased filtered load of calcium and the suppression of PTH. However, the patient who relies on the kidneys to excrete an increased calcium load is in precarious balance. Glomerular filtration is impaired by hypercalcemia; the urinary concentrating ability is diminished, predisposing to dehydration; poor mentation may interfere with access to fluids; and nausea and vomiting may further predispose to dehydration and renal azotemia. Renal insufficiency, in turn, compromises calcium clearance, leading to a downward spiral (Figure 8–13). Thus, once established, many hypercalcemic states are self-perpetuating or aggravated through the vicious cycle of hypercalcemia. The only alternative to the renal route for elimination of calcium from the extracellular fluid is deposition of calcium phosphate and other salts in bone and soft tissues. Soft tissue calcification is observed with massive calcium loads, with massive phosphate loads (as in tumor lysis syndrome, crush injuries and compartment syndromes), and when renal function is markedly impaired and the calcium-phosphate product rises.

**FIGURE 8–12** Signs and symptoms of primary hyperparathyroidism.
Differential Diagnosis

As a practical matter, the categories for differential diagnosis are primary hyperparathyroidism and everything else (see Table 8–6). Hyperparathyroidism is by far the most common cause of hypercalcemia and has distinctive pathophysiologic features. Thus, the first step in the differential diagnosis is determination of intact PTH (Figure 8–14). If the PTH level is high, and thus inappropriate for hypercalcemia, little further workup is required except to consider the variant forms of hyperparathyroidism that are discussed later. If the PTH level is suppressed, then a search for other entities must be conducted. Most other entities in Table 8–6 are readily diagnosed by their distinctive features, as discussed later.

DISORDERS CAUSING HYPERCALCEMIA

1. PRIMARY HYPERPARATHYROIDISM

Primary hyperparathyroidism results from the excessive secretion of PTH and typically produces frank hypercalcemia. With the advent of multiphasic screening of serum chemistries, we have come to recognize that primary hyperparathyroidism is a common and usually asymptomatic disorder. Its incidence is approximately 42 per 100,000, and its prevalence is up to 4 per 1000 in women over age 60. Primary hyperparathyroidism is approximately 2 to 3 times more common in women than in men.

Etiology and Pathogenesis

Primary hyperparathyroidism is caused by a single parathyroid adenoma in about 80% of cases and by primary hyperplasia of the parathyroids in 10% to 15%. Parathyroid carcinoma is a rare cause of hyperparathyroidism, accounting for 1% to 2% of cases. Parathyroid carcinoma is often recognizable preoperatively because it presents with severe hypercalcemia or a palpable neck mass.

Sporadic parathyroid adenomas have a clonal origin, indicating that they can be traced back to an oncogenic mutation in a single progenitor cell. A few of these genetic alterations have been identified and/or assigned to chromosomal loci. About 25% of sporadic parathyroid adenomas have chromosomal deletions involving...
implicated in approximately 4% of sporadic parathyroid adenomas involves the **cyclin D1** gene. In the initial elucidation of this pathogenic mechanism, a chromosomal rearrangement was found in a parathyroid tumor. Breakage and then inversion of a piece of chromosome 11 led to the expression of cyclin D1, a cell-cycle regulatory protein, under the control of the PTH promoter. As expected, this promoter is highly active in parathyroid cells, resulting in marked overexpression of cyclin D1 in these tumor cells. Cyclin D1 is normally expressed at high levels in the G1 phase of the cell cycle and permits entry of cells into the mitotic phase of the cycle. Thus, a parathyroid-specific disorder of cell-cycle regulation leads to abnormal cell proliferation and ultimately excessive PTH production.

Parathyroid hyperplasia accounts for 12% to 15% of cases of primary hyperparathyroidism and is the pathologic basis for these inherited conditions: MEN 1, MEN 2A, the hyperparathyroidism-jaw tumor (HPT-JT) syndromes, and familial hyperparathyroidism. In all of these instances four or fewer glands may be involved at the time of presentation. Inheritance of all of these conditions is autosomal dominant.

Parathyroid hyperplasia was traditionally viewed as an example of true hyperplasia, a polyclonal expansion of cell mass. This occurs in other endocrine tissues when a trophic hormone present in excess (eg, ACTH excess) induces bilateral adrenal hyperplasia. Molecular analysis, however, has revised this view. Parathyroid hyperplasia appears to share similar pathogenic mechanisms with parathyroid adenomas. The MEN 1 syndrome illustrates this. MEN 1 is due to the inherited inactivation of one allele of the **MENIN** gene, which encodes a tumor suppressor. Acquired post-natal somatic mutations in the remaining **MENIN** gene result in loss of the other allele's function. This leads to tumors in those endocrine tissues in which the gene is expressed. In this view, multicentric somatic mutations would account for the occurrence of four-gland hyperparathyroidism.

Kindreds with a presentation like MEN 1 but without mutations in **MENIN** have been investigated for germline mutations in cyclin-dependent kinase inhibitors (CDKIs) of which there are seven known genes. In an analysis of 196 consecutive cases of MEN 1 or other tumor states without germline mutations in **MENIN**, one laboratory found seven probable pathologic mutations in these genes. Three of the seven mutations were in p27 with the remainder in three other CDKIs (p15, p18, and p27). These mutations are thought to be disease causing because abnormalities in CDKI–protein interaction were uncovered in the majority of these mutations tested. The CDKIs negatively control the cell cycle through interaction with and inhibition of cyclins D, E, and A. The germline mutations in these kindreds would, therefore, involve loss of function in known inhibitors of cell growth and cell cycle activity.

In MEN 2A, the occurrence of parathyroid hyperplasia is also a consequence of expression of activating mutations of the **RET** gene in the four glands. These and other studies clearly indicate that parathyroid hyperplasia is typically monoclonal in its origin, implying that cell hyperproliferation arose from a single progenitor cell in each gland.

In addition to hyperparathyroidism, as one part of classical MEN 1, it is now clear that a subset of cases of familial isolated hyperparathyroidism is due to germline mutations in the **MENIN** gene. This observation established the concept that isolated familial hyperparathyroidism can be an allelic variant of the MEN 1 syndrome. The variation from MEN 1 lies in the absence of tumors in the other endocrine glands.

Other cases of familial isolated hyperparathyroidism are explained, albeit rarely, by mutations in the gene that causes the HPT-JT syndrome (see later). Additional families with isolated hyperparathyroidism have, as yet, no identified mutations.

In contrast to MEN 1 and MEN 2A, both benign and malignant parathyroid tumors occur in the HPT-JT syndrome. This is an autosomal dominant disorder that includes primary hyperparathyroidism (90%), jaw tumors (ossifying fibromas of the mandible or maxilla) (30%), renal cysts (10%), and less frequently renal hamartomas and Wilms tumor. Linkage analysis originally determined the locus for this syndrome, which had been designated as **HRPT2** or **HPT2** to be at 1q24-q32. Inactivating mutations in **HRPT2** gene, encoding the protein parafibromin, have been identified in HPT-JT kindreds. Mutations in the **HRPT2** gene inactivate parafibromin. This protein like menin normally functions as a tumor suppressor. Its function(s) in parathyroid cells have not yet been elucidated.

Inactivating mutations in the **HRPT2** gene have also been identified in kindreds with isolated familial hyperparathyroidism. Both single- and multiple-gland disease have been noted. It was further noted that approximately 15% of affected individuals with HPT-JT syndrome develop parathyroid cancer, instead of adenomas or hyperplasia, suggesting that reduced parafibromin function also contributes to a malignant phenotype. Several groups have shown that a large percentage (70%) of patients with sporadic parathyroid cancer harbor somatic mutations in the **HRPT2** gene. Surprisingly, approximately 30% of individuals with isolated parathyroid cancer have also been found to have germline mutations in **HRPT2** without the other manifestations of the HPT-JT syndrome. It is now thought that the majority of sporadically occurring parathyroid cancers are due to somatic mutations in the coding region of the **HRPT2** gene. It is anticipated that mutations in the noncoding regulatory regions of this gene may explain additional cases. A pathologic study of more than 50 cases of parathyroid cancer indicates that the loss of parafibromin immunoreactivity is a specific and key feature of malignancy with a sensitivity of 96% (CI, 85%-99%) and specificity of 99% (CI, 92%-100%).

**Clinical Features**

**A. Symptoms and signs** The typical clinical presentation of primary hyperparathyroidism has evolved considerably over the
past few decades. As the disease continues to be detected primarily by multiphasic screening that includes determination of serum calcium levels, there has been a marked reduction in the frequency of the classic signs and symptoms of primary hyperparathyroidism. Renal disease (stones, decreased renal function, and occasionally nephrocalcinosis) and the classic hyperparathyroid bone disease osteitis fibrosa cystica are decidedly rare today. In fact, about 85% of patients presenting today have neither bone nor renal manifestations of hyperparathyroidism and are regarded as asymptomatic or at most minimally symptomatic. At the same time, we have begun to recognize more subtle manifestations of hyperparathyroidism. This has presented a number of questions about the role of parathyroid surgery in primary hyperparathyroidism, which are discussed later (see Treatment).

1. **Hyperparathyroid bone disease**—The classic bone disease of hyperparathyroidism is osteitis fibrosa cystica. Formerly common, this disorder now occurs in less than 10% of patients. Clinically, osteitis fibrosa cystica causes bone pain and sometimes pathologic fractures. The most common laboratory finding is an elevation of the alkaline phosphatase level, reflecting high bone turnover. Histologically, there is an increase in the number of bone-resorbing osteoclasts, marrow fibrosis, and cystic lesions that may contain fibrous tissue (brown tumors). The most sensitive and specific radiologic finding of osteitis fibrosa cystica is subperiosteal resorption of cortical bone, best seen in high-resolution films of the phalanges (Figure 8-15A). A similar process in the skull leads to a salt-and-pepper appearance (Figure 8-15B). Bone cysts or brown tumors may present as osteolytic lesions. Dental films may disclose loss of the lamina dura of the teeth, but this is a nonspecific finding also seen in periodontal disease.

The other important skeletal consequence of hyperparathyroidism is osteoporosis. Unlike other osteoporotic disorders, hyperparathyroidism often results in the preferential loss of cortical bone (Figure 8-16). In general, both the mass and mechanical strength of trabecular bone are relatively maintained in mild primary hyperparathyroidism. Patients who are followed medically with this disease generally do not experience progressive bone loss for as long as 8 years after diagnosis (Figure 8-17). This may be due to the fact that mild PTH excess has an anabolic effect on the skeleton to maintain or even increase bone mass. Although osteoporosis, defined by bone mineral density (BMD) T-scores by dual-energy x-ray

![Figure 8-15](image1.png) **A**: Magnified x-ray of index finger on fine-grain industrial film showing classic subperiosteal resorption in a patient with severe primary hyperparathyroidism. Note the left (radial) surface of the distal phalanx, where the cortex is almost completely resorbed, leaving only fine wisps of cortical bone. **B**: Skull x-ray from a patient with severe secondary hyperparathyroidism due to end-stage renal disease. Extensive areas of demineralization alternate with areas of increased bone density, resulting in the “salt and pepper” skull x-ray. (Both films courtesy of Dr. Harry Genant.)

![Figure 8-16](image2.png) **FIGURE 8–16** Bone mineral density at several sites in primary hyperparathyroidism shown as the percentage of expected for age. (Reproduced, with permission, from Silverberg SJ, et al. Nephrolithiasis and bone involvement in primary hyperparathyroidism. *Am J Med*. 1990;89:327.)
FIGURE 8-17  Mean changes in bone mineral density (BMD) measurements by dual-energy x-ray absorptiometry (DXA) in patients who underwent parathyroidectomy compared with medical follow-up during a 15-year observational study. BMD changes are reported compared with baseline and were statistically different from baseline as shown (*P < .05, **P < .01, ***P < 0.001). The number of patients whose measurements are included are shown underneath each time point. Either just before (distal 1/3 radius) or after 10 years of conservative follow-up (femoral neck) BMD measurements began to fall significantly, while lumbar spine BMD remained unchanged (Panel A). Patients who underwent parathyroidectomy demonstrated improved BMD which persisted during 15 years of follow-up (Panel B). (Reproduced and modified, with permission, from Rubin MR, et al. The natural history of primary hyperparathyroidism with or without parathyroid surgery after 15 years. J Clin Endocrinol Metab. 2008;93:3462. Copyright 2008 by The Endocrine Society. All rights reserved.)
absorptiometry (DXA) of –2.5 or lower, is generally considered to be an indication for surgical treatment of primary hyperparathyroidism, the impact of low bone mass on morbidity is difficult to corroborate clinically (see Treatment of Hypercalcemia).

2. **Hyperparathyroid kidney disease**—Once common in primary hyperparathyroidism, kidney stones now occur in 10% to 20% of cases depending on the series. These are usually calcium oxalate stones. From the perspective of a stone clinic, only about 7% of calcium stone formers prove to have primary hyperparathyroidism. They are difficult to manage medically, and stones constitute one of the agreed indications for parathyroidectomy. Clinically evident nephrocalcinosis rarely occurs, but a gradual loss of renal function is not uncommon. Renal function is stabilized after a successful parathyroidectomy, and otherwise unexplained renal insufficiency (defined as an estimated glomerular filtration rate [eGFR] <60 mL/min) in the setting of primary hyperparathyroidism is also considered to be an indication for surgery because of the risk of progression. Chronic hypercalcemia can also compromise the renal concentrating ability, giving rise to polydipsia and polyuria.

3. **Nonspecific features of primary hyperparathyroidism**—Although stupor and coma occur in severe hypercalcemia, the degree to which milder impairments of central nervous system function affect the typical patient with primary hyperparathyroidism is unclear. Lethargy, fatigue, depression, difficulty in concentrating, and personality changes may occur; however, some patients appear to benefit from parathyroidectomy. Frank psychosis also responds to surgery on occasion. Muscle weakness with characteristic electromyographic changes is also seen, and there is evidence from controlled clinical trials that surgery can improve muscle strength. A number of studies have examined quality of life (QOL) and psychological function in patients with primary hyperparathyroidism pre- and post-parathyroid surgery, compared to a medically followed group. Results vary as to whether QOL improves with surgery. It was formerly thought that the incidence of hypertension was increased in primary hyperparathyroidism, but more recent evidence suggests that it is probably no greater than in age-matched controls, and parathyroidectomy appears to be of no benefit. Dyspepsia, nausea, and constipation all occur, probably as a consequence of hypercalcemia, but there is probably no increase in the incidence of peptic ulcer disease. The articular manifestations of primary hyperparathyroidism include chondrocalcinosis in up to 5% of patients. Acute attacks of pseudogout, however, are less frequent.

**B. Laboratory findings** Hypercalcemia is virtually universal in primary hyperparathyroidism, although the serum calcium sometimes fluctuates into the upper normal range. In patients with subtle hyperparathyroidism, repeated serum calcium measurements over a period of time may be required to establish the pattern of intermittent hypercalcemia. Both total and ionized calcium are elevated, and in most clinical instances there is no advantage to measuring the ionized calcium level. Patients with normocalcemic primary hyperparathyroidism, in whom subtle vitamin D deficiency and malabsorption have been eliminated, are being recognized more frequently. In patients with primary hyperparathyroidism, the serum phosphorus level is low-normal (<3.5 mg/dL) or low (<2.5 mg/dL) because of the phosphaturic effect of PTH. A mild hyperchloremic metabolic acidosis may also manifest itself.

The diagnosis of primary hyperparathyroidism in a hypercalcemic patient can be made by determining the intact PTH level. As shown in Figure 8–14, an elevated or even upper-normal level of PTH is clearly inappropriate in a hypercalcemic patient and establishes the diagnosis of hyperparathyroidism or one of its variants—FBHH or lithium-induced hypercalcemia. The reliability of the two-site intact PTH assay allows for the definitive diagnosis of primary hyperparathyroidism. In a patient with a high PTH level, there is no need to screen for such disorders as metastatic cancer or sarcoidosis. Determinations of BMD, renal function, and a plain abdominal radiograph for renal stones are often obtained for clinical decision-making reasons. A determination of urinary calcium concentration and urinary creatinine excretion should always be obtained to exclude FBHH.

**Treatment**

The definitive treatment of primary hyperparathyroidism is parathyroidectomy. The surgical strategy (ie, minimally invasive vs bilateral neck exploration) depends on the ability of localizing studies such as sestamibi scanning to identify one clearly abnormal gland and the availability of intraoperative PTH determinations to verify that the disease-producing lesion has been removed during surgery. If multiple enlarged glands are suspected, the likely diagnosis is parathyroid hyperplasia or double adenoma. In patients with hyperplasia, the preferred operation is a 3/4 gland parathyroidectomy, leaving a remnant sufficient to prevent hypocalcemia. Double parathyroid adenomas are both removed in affected patients. The pathologist is of little help in distinguishing among normal tissue, parathyroid adenoma, and parathyroid hyperplasia: these in essence are surgical diagnoses, based on the size and appearance of the glands. The recurrence rate of hypercalcemia is high in patients who have parathyroid hyperplasia—particularly in those with MEN 1 or allelic variants of MEN 1 or the HPT-JT syndromes, because of the inherited propensity for tumor growth. In such cases, the parathyroid remnant can be removed from the neck and implanted in pieces in forearm muscles to allow for easy subsequent removal of some parathyroid tissue if hypercalcemia recurs.

In experienced hands, the cure rate for a single parathyroid adenoma is more than 95%. The success rate in primary parathyroid hyperplasia is somewhat lower, because of missed glands and recurrent hyperparathyroidism in patients with MEN syndromes. There is a 20% incidence of persistent or recurrent hypercalcemia. However, parathyroidectomy is difficult surgery: the normal parathyroid gland weighs only about 40 mg and may be located throughout the neck or upper mediastinum. It is mandatory in this situation not only to locate a parathyroid adenoma, but also to find the other gland or glands and determine whether or not they are normal in size. Complications of surgery include damage to the recurrent laryngeal nerve, which passes close to the posterior thyroid capsule, and inadvertent removal or devitalization of all parathyroid tissue, producing permanent hypoparathyroidism. In skilled hands, the incidence of these complications is less than 1%.
It is critical that parathyroid surgery be performed by someone with specialized skill and experience (see Chapter 26).

Localization studies of the parathyroid glands in patients with primary hyperparathyroidism and intraoperative PTH testing are critical components in the contemporary surgical management of patients presenting for minimally invasive surgical procedures. If localizing studies clearly indicate a single abnormal gland and if intraoperative PTH testing is available, surgical management generally consists of unilateral exploration with the removal of the single abnormal gland. Localization studies continue to be essential in the management of patients with recurrent or persistent hyperparathyroidism. The most successful procedures are ⁹⁹mTc-sestamibi scanning, computed tomography, magnetic resonance imaging, and ultrasound. Individually, each has a sensitivity of 60% to 80% in experienced hands. Used in combination, they are successful in at least 80% of reoperated cases. Invasive studies, such as angiography and venous sampling, are reserved for the most difficult cases.

There is no definitive medical therapy for primary hyperparathyroidism. In postmenopausal women, estrogen therapy in high doses (1.25 mg of conjugated estrogens or 30-50 μg of ethinyl estradiol) produces an average decrease of 0.5 to 1 mg/dl in the serum calcium and an increase in BMD. The effects of estrogen are on the skeletal responses to PTH. PTH levels do not fall. Small series of patients provide experience with oral bisphosphonates (e.g., alendronate) and the selective estrogen response modulator (SERM) raloxifene in these patients. Treatment with alendronate for 1 or 2 years reduces biochemical markers of bone turnover and improves BMD by DXA, especially in the spine and also in the femoral neck, compared to baseline values prior to treatment. Studies have shown that raloxifene, administered over several weeks, to postmenopausal women with mild primary hyperparathyroidism also reduces bone turnover markers significantly. Neither alendronate nor raloxifene have significant and or persistent effects on serum calcium or intact PTH levels, nor is either agent approved for treatment of primary hyperparathyroidism by the U.S. Food and Drug Administration (FDA). Calcimetic agents that activate the parathyroid CaSR, currently under investigation, may offer an alternative to surgery. The calcimetic cinacalcet is FDA-approved for the management of secondary hyperparathyroidism in patients on dialysis (see later). In small clinical trials, cinacalcet was shown to normalize serum [Ca²⁺] and raise serum phosphate with modest lowering of PTH levels in patients with mild asymptomatic primary hyperparathyroidism for up to 5 years of therapy. No significant changes in BMD by DXA were seen. This therapy, therefore, is most effective at controlling hypercalcemia in these patients. The relatively asymptomatic status of most patients with primary hyperparathyroidism today presents a dilemma. Which of them should be subjected to surgery? To answer this question definitively, it is necessary to know more about the natural history of untreated primary hyperparathyroidism. Most observational studies lack long-term follow-up and appropriate control groups. However, one observational study of 15 years duration showed modest increases in serum [Ca²⁺] (after 10 years) and slow but consistent downward trends in BMD at cortical sites (femoral neck and distal radius) (after 8-10 years of follow-up) (see Figure 8–17A). This study has challenged the skeletal safety of long-term observation of otherwise asymptomatic patients. On the other hand, surgery is usually curative. In experienced hands, surgery has a low morbidity rate. Although parathyroid surgery has a substantial initial cost, over the long term, the cost-benefit ratio may be favorable when compared with a lifetime of medical follow-up. Moreover, there is a marked improvement in BMD after surgery (see Figure 8–17B), with sustained increases over 15 years postoperatively. Consensus Development Conferences or International Workshops in 1990, 2002, and 2008 examined evidence and published recommendations for surgery in mild asymptomatic primary hyperparathyroidism and for conservative management. Current recommendations are for surgery (1) if the serum calcium is greater than 1 mg/dl above the upper limits of normal; (2) if there had been a previous episode of life-threatening hypercalcemia; (3) if the eGFR is <60 mL/min; (4) if a kidney stone is present; (5) if the BMD by DXA at the lumbar spine, hip, or distal radius is substantially reduced (≥2.5 SD below peak bone mass; T-score ≤−2.5); (6) if the patient is young (<50 years of age); or (7) if long-term medical surveillance is not desired or possible. Patients with a coexisting illness complicating the management of hypercalcemia should also be referred for surgery.

The expert panel also considered neuropsychiatric dysfunction, impending onset of menopause, older age and functional status, biochemical markers of bone turnover, and nonclassical symptoms of primary hyperparathyroidism (e.g., gastrointestinal and cardiovascular manifestations) in their recommendations. The participants thought that there was sufficient uncertainty regarding these factors that firm recommendations for surgical referral based on these factors alone was not warranted. This panel agreed, however, that these clinical issues should be carefully considered in making decisions regarding surgery and/or long-term follow-up in individual patients.

### Variants of Primary Hyperparathyroidism

#### A. Familial benign hypocalciuric hypercalcaemia

Inherited as an autosomal dominant trait, this disorder is responsible for lifelong asymptomatic hypercalcaemia, first detectable in cord blood. Hypercalcaemia is usually mild (10.5-12 mg/dL [2.7-3 mmol/L]) and is often accompanied by mild hyperphosphataemia and hypermagnesaemia. The PTH level is normal or slightly elevated, indicating that this is a PTH-dependent form of hypercalcaemia. The parathyroid glands are normal in size or slightly enlarged. The most notable laboratory feature of the disorder is hypocalciuria. The urinary calcium level is usually less than 50 mg/24 h, and the calcium/creatinine clearance ratio is less than 0.01 and calculated as follows:

\[
\text{Urine calcium} \times \text{Serum creatinine} \quad \frac{\text{Serum calcium}}{\text{Urine creatinine}}
\]

Hypocalciuria is an intrinsic renal trait; it persists even in patients who have undergone total parathyroidectomy and become hypercalcemic.
Because FBHH is asymptomatic and benign, the most important role of diagnosis is to distinguish it from primary hyperparathyroidism and avoid an unnecessary parathyroidectomy. If subtotal parathyroidectomy is performed, the serum calcium invariably returns to preoperative levels; these persons resist attempts to lower the serum calcium while functioning parathyroid tissue remains. Unfortunate patients with this condition who have undergone total parathyroidectomy are rendered hypoparathyroid and are dependent on calcium and vitamin D supplementation.

The diagnosis must be considered in patients with asymptomatic mild hypercalcemia who are relatively hypocalciuric. However, an unequivocal diagnosis cannot be made biochemically because the serum and urinary calcium and PTH levels all overlap with typical primary hyperparathyroidism. Family screening or sequencing of the CaSR gene in an affected individual is necessary to make the diagnosis and can be obtained commercially. The penetrance of the phenotype is essentially 100%, and affected family members are hypercalcemic throughout life, so if the proband has the disorder, each first-degree relative who is screened has a 50% chance of being hypercalcemic.

Most cases of FBHH are caused by loss-of-function mutations in the CaSR. Loss of the functional output of one CaSR allele shifts the set point for inhibition of PTH release to the right, producing hypercalcemia. The same receptor is expressed in the kidney, where it regulates renal calcium excretion. A variety of point mutations in different exons of the CaSR produce the phenotype. Acquired hypocaliuric hypercalcemia has been described in association with antibodies that interact with the parathyroid CaSRs and block the ability of high [Ca\(^{2+}\)] to suppress PTH.

A child of two parents with FBHH may inherit a mutant allele from each parent, producing neonatal severe hypercalcemia, a life-threatening disorder in which failure to sense extracellular calcium causes severe hyperparathyroidism, requiring total parathyroidectomy soon after birth.

**B. MEN syndromes**  
As noted above, primary hyperparathyroidism is a feature of both MEN 1 and MEN 2A (see also Chapter 22). The penetrance of primary hyperparathyroidism in MEN 1 is over 90% by age 40. Patients with the MEN 1 syndrome inherit a loss-of-function germline mutation in the tumor suppressor gene MENIN on chromosome 11q12-13. Menin is a nuclear protein that appears to interact with JunD, a member of the AP1 family of transcription factors. A mutation during mitosis of a parathyroid cell that resulted in loss of function in the remaining allele in that cell would abrogate the cell's growth control mechanism and permit clonal expansion of its progeny ultimately to generate the parathyroid tumor. A similar mechanism appears also to operate in a small fraction of sporadic parathyroid adenomas with 11q12-13 deletions.

The penetrance of primary hyperparathyroidism in MEN 2A is about 30%. As discussed in the above section on MCT, the disorder is caused by activating mutations in the RET gene, a tyrosine kinase growth factor receptor. Evidently, the RET gene product is less important for growth of the parathyroids than for thyroid C cells, because the penetrance of primary hyperparathyroidism is fairly low and because (in MEN 2B) a separate class of activating RET mutations produces MCT and pheochromocytoma and very rarely primary hyperparathyroidism. The treatment for parathyroid hyperplasia in MEN 1 or MEN 2 is subtotal parathyroidectomy. The recurrence rate is higher than in sporadic parathyroid hyperplasia and may approach 50% in MEN 1.

**C. Lithium therapy**  
Both in patients and in isolated parathyroid cells, exposure to extracellular lithium shifts the set point for inhibition of PTH secretion to the right. Clinically, this results in hypercalcemia and a detectable or elevated level of PTH. Lithium treatment also produces hypocaliuria and is thus a virtual phenocopy of FBHH. Most patients with therapeutic lithium levels for bipolar affective disorder have a slight increase in the serum calcium level, and up to 10% become mildly hypercalcemic, with PTH levels that are high normal or slightly elevated. Lithium treatment can also unmask underlying primary hyperparathyroidism. It is difficult to diagnose primary hyperparathyroidism in a lithium-treated patient, particularly when temporary cessation of lithium therapy is difficult. However, the likelihood of underlying primary hyperparathyroidism is high when the serum calcium is greater than 11.5 mg/dL, and the decision to undertake surgery must be based on clinical criteria. Unfortunately, surgical cure of hyperparathyroidism rarely ameliorates the underlying psychiatric condition.

**2. MALIGNANCY-ASSOCIATED HYPERCALCEMIA**

Malignancy-associated hypercalcemia is the second most common form of hypercalcemia, with an incidence of 15 cases per 100,000 per year—about one-half the incidence of primary hyperparathyroidism. It is, however, much less prevalent than primary hyperparathyroidism, because most patients have a very limited survival. Nonetheless, malignancy-associated hypercalcemia is the most common cause of hypercalcemia in hospitalized patients. The clinical features and pathogenesis of malignancy-associated hypercalcemia are presented in Chapter 21. The treatment of nonparathyroid hypercalcemia is presented later.

**3. SARCOIDOSIS AND OTHER GRANULOMATOUS DISORDERS**

Hypercalcemia is seen in up to 10% of subjects with sarcoidosis. A higher percentage has hypercalciuria. This is due to inappropriately elevated 1,25(OH)\(_2\)D levels and abnormal vitamin D metabolism. Lymphoid tissue and pulmonary macrophages from affected individuals contain 25(OH)D 1-hydroxylase activity that is not seen in normal individuals. The 1-hydroxylase enzyme, responsible for the overproduction of 1,25(OH)\(_2\)D in sarcoidosis, is the same as that in the kidney (CYP27B1). 1-Hydroxylase activity in these cells is not readily inhibited by calcium or 1,25(OH)\(_2\)D, indicating a lack of feedback inhibition. Macrophages expressing the 1-hydroxylase in these patients do not express a normally functioning 24-hydroxylase so that the catabolism and clearance of 1,25(OH)\(_2\)D in these cells are lacking. This makes these subjects vulnerable to
suppress the inflammation, and subsequently 1-hydroxylase activity (which makes such subjects more vulnerable to altered calcium homeostasis when their disease is active). Glucocorticoids, on the other hand, suppress the inflammation, and subsequently 1-hydroxylase activity, and antagonize 1,25(OH)\(_2\)D action, providing effective treatment for both the disease and this complication of it.

Other granulomatous diseases are associated with abnormal vitamin D metabolism, resulting in hypercalcemia and/or hypercalciuria. These disorders include tuberculosis, berylliosis, disseminated coccidioidomycosis, histoplasmosis, leprosy, and pulmonary eosinophilic granulomatosis. Furthermore, a substantial number of subjects with Hodgkin or non-Hodgkin lymphomas develop hypercalcemia associated with inappropriately elevated 1,25(OH)\(_2\)D levels. Although most such patients are normocalcemic on presentation, they may be hypercalcemic, and this should be evaluated as part of the workup. Hypercalcemia and hypercalciuria may not become apparent until situations such as increased sunlight exposure or vitamin D and calcium ingestion are experienced. Thus, one should remain alert to this complication even when the initial evaluation of serum calcium is within normal limits.

4. ENDOCRINOPATHIES

**Thyrotoxicosis**

Mild hypercalcemia is found in about 10% of patients with thyrotoxicosis. The PTH level is suppressed, and the serum phosphate is in the upper normal range. The serum alkaline phosphatase and biochemical markers of bone turnover may be mildly increased. Significant hypercalcemia may develop in patients with thyrotoxicosis, particularly if it is severe and if patients are temporarily immobilized. Thyroid hormone has direct bone-resorbing properties causing a high turnover state, which often eventually progresses to mild osteoporosis.

**Adrenal Insufficiency**

Hypercalcemia can be a feature of acute adrenal crisis and responds rapidly to glucocorticoid therapy. Animal studies suggest that hemoconcentration is a critical factor. In experimental adrenal insufficiency, ionized [Ca\(^{2+}\)] is normal.

5. ENDOCRINE TUMORS

Hypercalcemia in patients with pheochromocytoma is most often a manifestation of the MEN 2A syndrome, but hypercalcemia is found occasionally in uncomplicated pheochromocytoma, where it appears to result from secretion of PTHrP by the tumor. About 40% of tumors secreting VIP (V1Pomas) are associated with hypercalcemia. The cause is unknown. It is known, however, that high levels of VIP may activate PTH/PTHrP receptors.

6. THIAZIDE DIURETICS

The administration of thiazides and related diuretics such as chlorthalidone, metolazone, and indapamide can produce an increase in the serum calcium that is not fully accounted for by hemoconcentration. Hypercalcemia is mild and usually transient, lasting for days or weeks, but occasionally it persists. Thiazide administration can also exacerbate the effects of underlying primary hyperparathyroidism; in fact, thiazide administration was formerly used as a provocative test for hyperparathyroidism in patients with borderline hypercalcemia. Most patients with persistent hypercalcemia while receiving thiazides prove to have primary hyperparathyroidism.

7. VITAMIN D AND VITAMIN A

**Hypervitaminosis D**

Hypercalcemia may occur in individuals ingesting large doses of vitamin D either therapeutically or accidentally (eg, irregularities in milk product supplementation with vitamin D have been reported). The initial signs and symptoms of vitamin D intoxication include weakness, lethargy, headaches, nausea, and polyuria and are attributable to hypercalcemia and hypercalciuria. Ectopic calcification may occur, particularly in the kidneys, resulting in nephrolithiasis or nephrocalcinosis; other sites include blood vessels, heart, lungs, and skin. Infants appear to be quite susceptible to vitamin D intoxication and may develop disseminated atherosclerosis, supraavalvular aortic stenosis, and renal acidosis.

Hypervitaminosis D is readily diagnosed by the very high serum levels of 25(OH)\(_2\)D, because the conversion of vitamin D to 25(OH)\(_2\)D is not tightly regulated. In contrast, 1,25(OH)\(_2\)D levels are often normal, but not suppressed. This reflects the expected feedback regulation of 1,25(OH)\(_2\)D production by the elevated calcium and reduced PTH levels. Levels of free 1,25(OH)\(_2\)D when measured have been found to be increased. This is in part caused by the high levels of 25(OH)\(_2\)D that displace 1,25(OH)\(_2\)D from DBP, raising the ratio of free:total 1,25(OH)\(_2\)D. The elevated free concentration of 1,25(OH)\(_2\)D, plus the intrinsic biologic effects of the elevated 25(OH)\(_2\)D concentration, combine to increase intestinal calcium absorption and bone resorption. The hypercalciuria, which is invariably seen, may lead to dehydration and coma as a result of hyposthenuria, prerenal azotemia, and worsening hypercalcemia due, in part, to decreased renal clearance.

The dose of vitamin D required to induce toxicity varies among patients, reflecting differences in absorption, storage, and subsequent metabolism of the vitamin as well as in target tissue response to the active metabolites. For example, an elderly patient is likely to have reduced intestinal calcium transport and renal production of 1,25(OH)\(_2\)D. Such an individual may be able to tolerate 50,000 to 100,000 units of vitamin D daily (although these levels far exceed daily requirements). However, patients with unsuspected hyperparathyroidism receiving such doses for the treatment of osteoporosis are more likely to experience hypercalcemia. Treatment consists of withdrawing the vitamin D, rehydration, reducing calcium intake, and administering glucocorticoids, which antagonize the ability of 1,25(OH)\(_2\)D to stimulate intestinal calcium absorption. Excess vitamin D is slowly cleared from the body (weeks to months), so treatment is prolonged.
Hypervitaminosis A
Excessive ingestion of vitamin A, usually from self-medication with vitamin A preparations, causes a number of abnormalities, including gingivitis, cheilitis, erythema, desquamation, and hair loss. Bone resorption is increased, leading to osteoporosis and fractures, hypercalcemia, and hyperostosis. Excess vitamin A causes hepatosplenomegaly with hypertrophy of fat storage cells, fibrosis, and sclerosis of central veins. Many of these effects can be attributed to the effects of vitamin A on cellular membranes. Under normal circumstances, such effects are prevented because vitamin A is bound to retinol-binding protein (RBP), and its release from the liver is regulated. In vitamin A toxicity, however, these protective mechanisms are overcome, and retinol and its retinyl esters appear in blood unbound to RBP. The mechanism by which vitamin A stimulates bone resorption is not clear.

8. MILK-ALKALI SYNDROME
The ingestion of large quantities of calcium together with an absorbable alkali can produce hypercalcemia with alkalosis, renal fibrosis, and sclerosis of central veins. Many of these effects can be attributed to the effects of vitamin A on cellular membranes. Under normal circumstances, such effects are prevented because vitamin A is bound to retinol-binding protein (RBP), and its release from the liver is regulated. In vitamin A toxicity, however, these protective mechanisms are overcome, and retinol and its retinyl esters appear in blood unbound to RBP. The mechanism by which vitamin A stimulates bone resorption is not clear.

9. MISCELLANEOUS CONDITIONS
Immobilization
In immobilized patients there is a marked increase in bone resorption, which often produces hypercalcemia and occasionally hypercalciuria, mainly in individuals with a preexisting high bone turnover state, such as adolescents and patients with thyrotoxicosis or Paget disease. Intact PTH and PTHrP levels are suppressed. The disorder remits with the restoration of activity. If acute treatment is required, bisphosphonates appear to be the treatment of choice.

Acute Renal Failure
Hypercalcemia is often seen when renal failure is precipitated by rhabdomyolysis and usually occurs during the early recovery stage, presumably as calcium deposits are mobilized from damaged muscle tissue. It typically resolves over a few weeks.

TREATMENT OF HYPERCALCEMIA
Initial management of hypercalcemia consists of assessing the hydration state of the patient and rehydrating as necessary with saline. The first goal is to restore renal function, which is often impaired in hypercalcemia because of reduced glomerular filtration and dehydration. Hypercalcemia impairs the urinary concentrating ability, leading to polyuria, and at the same time impairs the sensorium, diminishing the sense of thirst. Once renal function is restored, excretion of calcium can be further enhanced by inducing a saline diuresis. Because most of the filtered calcium is reabsorbed by bulk flow in the proximal tubule along with sodium chloride, a saline diuresis markedly increases calcium excretion. However, a vigorous saline diuresis also induces substantial urinary losses of potassium and magnesium, and these must be monitored and replaced as necessary.

After these initial steps, attention should be given to finding a suitable chronic therapy. It is important to start chronic therapy soon after hospitalization, because several of the most useful agents take up to 5 days to have their full effect. Intravenous bisphosphonates (pamidronate or zoledronic acid) are the first choice for most patients. Bisphosphonates act by inhibiting osteoclastic bone resorption. The initial dose of pamidronate is 60 to 90 mg by intravenous infusion over 1 hour, and the dose of zoledronic acid is 4 mg infused over 15 minutes. In two large trials, 88% and 70% of patients with malignancy-associated hypercalcemia normalized their serum calcium values after infusions of zoledronic acid (4 mg) and pamidronate (90 mg), respectively. Zoledronic acid produced a longer duration of response when treating hypercalcemia of malignancy—32 days versus 18 days for pamidronate. The nadir of serum calcium does not occur until 4 to 5 days after administration of either agent. Retreatment with either agent can be conducted after recurrence of hypercalcemia. Transient fever and myalgia occur in between 10 and 20% of patients who undergo intravenous bisphosphonate therapy. Increases in serum creatinine of ≥0.5 mg/dL occur in about 15% of patients. Intravenous bisphosphonates should be used cautiously (if at all) and at reduced doses when the baseline serum creatinine exceeds 2.5 mg/dL.

In patients with severe hypercalcemia and in those with renal insufficiency that is refractory to rehydration, it may be necessary to use an alternative second-line antiresorptive agent for a few days while awaiting the full therapeutic effect of intravenous bisphosphonates. For this purpose, synthetic salmon CT may be administered at a dose of 4 to 8 IU/kg subcutaneously every 12 hours. This is a useful adjunct acutely, but most patients become totally refractory to CT within days to weeks, so it is not suitable for chronic use. The use of an antiresorptive agent together with saline diuresis provides for a two-pronged approach to hypercalcemia. Other agents besides bisphosphonates may be considered (eg, plicamycin or gallium nitrate), but their toxicity and lack of superior efficacy discourage their use. Both agents act to inhibit osteoclastic bone resorption.

Glucocorticoid administration is first-line treatment for hypercalcemia in patients with multiple myeloma, lymphoma, sarcoidosis, or intoxication with vitamin D or vitamin A. Glucocorticoids are also beneficial in some patients with breast carcinoma. However, they are of little use in most other patients with solid tumors and hypercalcemia.

HYPOCALCEMIA
Classification
Both PTH and 1,25(OH)2D maintain a normal serum calcium and are thus central to the defense against hypocalcemia.
Hypocalcemic disorders are best understood as failures of the adaptive response. Thus, chronic hypocalcemia can result from a failure to secrete PTH, altered responsiveness to PTH, a deficiency of vitamin D, or a resistance to vitamin D (Table 8–7). Acute hypocalcemia is most often the consequence of an overwhelming challenge to the adaptive response such as rhabdomyolysis, in which a flood of phosphate from injured skeletal muscle inundates the extracellular fluid.

**Clinical Features**

Most of the symptoms and signs of hypocalcemia occur because of increased neuromuscular excitability (tetany, paresthesias, seizures, organic brain syndrome) or because of deposition of calcium in soft tissues (cataract, calcification of basal ganglia).

**A. Neuromuscular manifestations** Clinically, the hallmark of severe hypocalcemia is tetany. Tetany is a state of spontaneous tonic muscular contraction. Overt tetany is often heralded by tingling paresthesias in the fingers and around the mouth, but the classic muscular component of tetany is carpal spasm. This begins with adduction of the thumb, followed by flexion of the metacarpophalangeal joints, extension of the interphalangeal joints, and flexion of the wrists to produce the *main d’accouchement* posture (Figure 8–18). These involuntary muscle contractions are painful. Although the hands are most typically involved, tetany can involve other muscle groups, including life-threatening spasm of laryngeal muscles. Electromyographically, tetany is typified by repetitive motor neuron action potentials, usually grouped as doublets. Tetany is not specific for hypocalcemia. It also occurs with hypomagnesemia and metabolic alkalosis, and the most common cause of tetany is respiratory alkalosis from hyperventilation.

Lesser degrees of neuromuscular excitability (eg, serum [Ca] 7.5-8.5 mg/dL) produce latent tetany, which can be elicited by testing for Chvostek and Trousseau signs. Chvostek sign is elicited by tapping the facial nerve about 2 cm anterior to the earlobe, just below the zygoma. The response is a contraction of facial muscles ranging from twitching of the angle of the mouth to hemifacial contractions. The specificity of the test is low; about 25% of normal individuals have a mild Chvostek sign. Trousseau sign is elicited by inflating a blood pressure cuff to about 20 mm Hg above systolic pressure for 3 minutes. A positive response is carpal spasm. Trousseau sign is more specific than Chvostek, but 1% to 4% of normal individuals have positive Trousseau signs.

Hypocalcemia predisposes to focal or generalized seizures. Other central nervous system effects of hypocalcemia include pseudotumor cerebri, papilledema, confusion, lassitude, and organic brain syndrome. Twenty percent of children with chronic hypocalcemia develop mental retardation. The basal ganglia are often calcified in patients with long-standing hypoparathyroidism or PHP. This is usually asymptomatic but can produce a variety of movement disorders.

**B. Other manifestations of hypocalcemia**

1. **Cardiac effects**—Repolarization is delayed, with prolongation of the QT interval. Excitation-contraction coupling may be impaired, and refractory congestive heart failure is sometimes
observed, particularly in patients with underlying cardiac disease.

2. **Ophthalmologic effects**—Subcapsular cataract is common in chronic hypocalcemia, and its severity is correlated with the duration and level of hypocalcemia.

3. **Dermatologic effects**—The skin is often dry and flaky and the nails brittle.

### CAUSES OF HYPOCALCEMIA

#### 1. HYPOPARATHYROIDISM

Hyoparathyroidism may be surgical, autoimmune, familial, or idiopathic. The signs and symptoms are those of chronic hypocalcemia. Biochemically, the hallmarks of hypoparathyroidism are hypocalcemia, hyperphosphatemia (because the phosphaturic effect of PTH is lost), and an inappropriately low or undetectable PTH level.

**Surgical Hypoparathyroidism**

The most common cause of hypoparathyroidism is surgery on the neck, with removal or destruction of the parathyroid glands. The operations most often associated with hypoparathyroidism are cancer surgery, total thyroidectomy, and parathyroidectomy, but the skill and experience of the surgeon are more important predictors than the nature of the operation. Tetany ensues 1 or 2 days postoperatively, but about half of patients with postoperative tetany recover sufficiently so they do not require long-term replacement therapy. In these cases, a devitalized parathyroid remnant has recovered its blood supply and resumes secretion of PTH. In some patients, hypocalcemia may not become evident until years after the procedure. Surgical hypoparathyroidism is the presumptive diagnosis for hypocalcemia in any patient with a surgical scar on the neck.

In patients with severe hyperparathyroid bone disease preoperatively, a syndrome of postoperative hypocalcemia can follow successful parathyroidectomy. This is the **hungry bones syndrome**, which results from avid uptake of calcium and phosphate by the bones. The parathyroids, although intact, cannot compensate. The syndrome is usually seen in patients with an elevated preoperative serum alkaline phosphatase and/or severe uremic secondary hyperparathyroidism. It can usually be distinguished from surgical hypoparathyroidism by the serum phosphorus, which is low in the hungry bones syndrome, because of skeletal avidity for phosphate, and high in hypoparathyroidism, and by the serum PTH, which becomes appropriately elevated in the hungry bones syndrome.

**Idiopathic Hypoparathyroidism**

Acquired hypoparathyroidism is sometimes seen in the setting of polyglandular endocrinopathies. Most commonly, it is associated with primary adrenal insufficiency and mucocutaneous candidiasis in the syndrome of *autoimmune polyglandular syndrome type 1 (APS1)* (see Chapter 3). The typical age at onset of hypoparathyroidism is 5 to 9 years. A similar form of hypoparathyroidism can occur as an isolated finding. The age at onset of idiopathic hypoparathyroidism is 2 to 10 years, and there is a preponderance of female cases. Circulating parathyroid antibodies are common in both APS1 and in isolated hypoparathyroidism. Many patients have antibodies that recognize the CaSR. Many patients with autoimmune hypoparathyroidism have antibodies reactive with NALP5 (NACHT leucine-rich-repeat protein 5), an intracellular signaling molecule expressed in the parathyroid. The pathogenetic role of any of these antibodies is not yet clarified. APS1 is an autosomal recessive disorder in which mutations are found in the *AIRE* (autoimmune regulator) protein. AIRE is a transcription factor involved in negative selection in the thymus and periphery.

Another form of autoimmune hypoparathyroidism has been reported in patients with autoantibodies to the CaSR that functionally activate it and suppress PTH secretion. These rare cases have been detected along with other autoimmune disorders such as Addison disease and Hashimoto thyroiditis.

**Familial Hypoparathyroidism**

Hypoparathyroidism is an uncommon disorder and presents in familial forms transmitted as either autosomal dominant or recessive traits. Autosomal recessive hypoparathyroidism occurs in families with *PTH* gene mutations that interfere with the normal processing of PTH. Another autosomal recessive form of this disease is due to a deletion of the 5' sequence of the gene encoding the transcription factor *glial cell missing 2*, which is necessary for parathyroid gland development. Hypoparathyroidism is evident in the newborn period because of parathyroid gland agenesis.

Autosomal dominant hypoparathyroidism can be due to point mutations in the *CaSR* gene, which render the protein constitutively active. This property enables the receptor to mediate suppression of PTH secretion at normal and even subnormal serum calcium levels. Several families with different mutations have been described; affected individuals typically have mild hypoparathyroidism (mildly reduced serum [Ca\(^{2+}\)] and PTH levels). These patients also demonstrate marked hypercalciuria due to CaSR mutations in their kidneys. The set point for calcium-induced suppression of PTH secretion in these patients is shifted to the left as is the effect of serum [Ca\(^{2+}\)] on renal calcium excretion. Thus, this syndrome is the mirror image of FBHH. Therapy is often not necessary and risks precipitating even greater degrees of hypercalciuria, nephrocalcinosis, and renal stones.

**Other Causes of Hypoparathyroidism**

Neonatal hypoparathyroidism can be part of the DiGeorge syndrome (dysmorphic facies, cardiac defects, immune deficiency, and hypoparathyroidism) due to a microdeletion (or other genetic abnormalities) on chromosome 22q11.2; the HDR syndrome (hypoparathyroidism, sensorineural deafness, and renal anomalies) due to mutations in or deletion of an allele of the GATA3 transcription factor; and other rare conditions. Transfusion-dependent individuals with thalassemia or red cell aplasia who survive into the third decade of life are susceptible to
hypoparathyroidism as the result of iron deposition in the para-
thyroid glands. Copper deposition can cause hypoparathyroidism
in Wilson disease. Infiltration with metastatic carcinoma is a very
rare cause of hypoparathyroidism.

Severe magnesium depletion temporarily paralyzes the parathy-
roid glands, preventing secretion of PTH. Magnesium depletion
also blunts the actions of PTH on target organs (kidney and bone)
to counteract the hypocalcemia. This is seen with magnesium
losses due to gastrointestinal and renal disorders and alcoholism.
The syndrome responds immediately to infusion of magnesium.
As discussed above in the section on regulation of PTH secretion,
magnesium is probably required for effective stimulus-secretion
coupling in the parathyroids.

2. PSEU DOHYPOP ARATHYROIDISM

PHP is a genetic disorder of target-organ unresponsiveness to
PTH. Biochemically, it mimics hormone-deficient forms of
hypoparathyroidism, with hypocalcemia and hyperphosphatemia,
but the PTH level is elevated, and there is a markedly blunted
response to the administration of PTH (see Diagnosis, later).

Clinical Features

Two distinct forms of PHP are recognized. PHP type IB is a dis-
order of isolated resistance to PTH, which presents with the bio-
chemical features of hypocalcemia, hyperphosphatemia, and
secondary hyperparathyroidism. PHP type IA has, in addition to
these biochemical features, a characteristic somatic phenotype

known as Albright hereditary osteodystrophy (AHO). This
consists of short stature, round face, short neck, obesity, brachy-
dactyly (short digits), shortened metatarsals, subcutaneous ossifi-
cations, and often reduced intelligence. Because of shortening of
the metacarpal bones—most often the fourth and fifth
metacarpals—affected digits have a dimple, instead of a knuckle,
when a fist is made (Figure 8–19). Primary hypothyroidism is
frequently seen. Less commonly, these patients have abnormalities
of reproductive function—oligomenorrhea in females and infertil-
ity in males due to primary hypogonadism. Interestingly, certain
individuals in families with PHP inherit the somatic phenotype of
AHO without any disorder of calcium metabolism; this state,
which mimics PHP, is called pseudo-PHP or PPHP.

Pathophysiology

PHP type IA is caused by the loss of function of one allele (haplo-
insufficiency) of the gene encoding the stimulatory G protein
alpha subunit, (G, alpha or GNAS). This abnormality is predicted
to produce only 50% of the normal levels of the alpha subunit of
the heterotrimeric G, which couples the PTH receptor to adeny-
l cyclase. Patients with PHP type IA have a markedly blunted
response of urinary cAMP to administration of PTH. Because G,
also couples many other receptors to adenylyl cyclase, the expec-
ted result of this mutation would be a generalized disorder of hor-
monal unresponsiveness. The presence of primary hypothyroidism
and primary hypogonadism in these patients indicates that resis-
tance to TSH, LH, and FSH occurs fairly commonly. Responsiveness to other hormones (eg, ACTH, glucagon) is fairly

FIGURE 8–19 Hands of a patient with pseudohypoparathyroidism. A: Note the short fourth fingers. B: Note the " absent " fourth knuckle.
C: Film shows the short fourth metacarpal. (Reproduced, with permission, from Potts JT. Pseudohypoparathyroidism: clinical features; signs and
normal. Thus, a 50% loss of the \( G_\alpha \) protein produces resistance to some hormones but not others. \( G_\alpha \) is also deficient in individuals with PPHP, who have AHO but normal responsiveness to PTH. Thus, a mutation in the \( G_\alpha \) gene invariably produces AHO but only sometimes produces resistance to PTH, suggesting that the occurrence of a metabolic phenotype is determined by other factors described below (Table 8-8).

In PHP type IB, there is resistance to PTH but no somatic phenotype (ie, AHO), and levels of \( G_\alpha \) protein in red blood cell or fibroblast membranes are normal. The disorder, however, is also linked to the GNAS locus, but it does not involve mutations in the coding region of GNAS. Instead epigenetic defects in GNAS are present that cause the differentially methylated region at exon A/B to lose its imprinting. Most cases demonstrate a maternally derived 3-kb deletion of DNA sequences located more than 200 kb centromeric of the GNAS locus at the STX16 locus. Other deletions remove this entire differentially methylated region—a key regulator of the levels of GNAS transcription. Transcription directed by this unmethylated promoter does not produce appropriate levels of \( G_\alpha \) protein in the renal cortex where this biallelic promoter activity is important. Thus, abnormal methylation of GNAS regulatory sequences plays a key role in the pathogenesis of PHP1B.

### Genetics

PHP type IA is inherited as an autosomal dominant trait. Individuals who have acquired the trait from their fathers almost always present with PPHP and lack hormone resistance. When the mutant allele is derived from the mother, PHP with hormone resistance is always present. This pattern of inheritance is due to genomic imprinting of the GNAS1 locus. In the kidney cortex, the maternal allele is preferentially expressed and the paternal allele is silenced. Thus, if the mutant GNAS1 allele is maternally derived, the resulting offspring will have PHP; if the mutant GNAS1 allele is paternally derived (and therefore silenced), the resulting offspring will have PPHP. Tissue-specific imprinting of the GNAS1 gene, therefore, determines the expression of hormone resistance in the kidney and thyroid. The expression of AHO does not depend on imprinting mechanisms and occurs in PHP type IA and PPHP.

### Diagnosis

Several disorders present with hypocalcemia and secondary hyperparathyroidism (eg, vitamin D deficiency), but when these features occur together with hyperphosphatemia or AHO, this suggests the diagnosis of PHP. To confirm that resistance to PTH is present, the patient can be challenged with PTH (the Ellsworth-Howard test). For this purpose, synthetic human PTH(1-34) (teriparatide acetate, 3 IU/kg body weight) is infused intravenously over 10 minutes during a water diuresis, and urine is collected during the hour preceding the infusion, during the half-hour following the infusion, 30 to 60 minutes after the infusion, and 1 to 2 hours after the infusion and assayed for cAMP and creatinine. Data are expressed as nanomoles of cAMP per liter of glomerular filtrate, based on creatinine measurements. Normally, there is an increase in urinary cAMP of more than 300 nmol/L glomerular filtrate after administration of PTH. The use of the urinary phosphate response as a gauge of PTH responsiveness is much less reliable. For practical purposes, hypocalcemia, hyperphosphatemia, elevated PTH levels, and normal levels of vitamin D metabolites (with or without AHO) confirm the presence of resistance to PTH.

### 3. VITAMIN D DEFICIENCY

#### Pathogenesis

Vitamin D deficiency results from one or more factors: inadequate sunlight exposure, inadequate nutrition, or malabsorption. In addition, drugs that activate the catabolism of vitamin D and its metabolites, such as phenytoin and phenobarbital, can precipitate vitamin D deficiency in subjects with marginal vitamin D status. Although the human skin is capable of producing sufficient amounts of vitamin D if exposed to sunlight of adequate intensity, institutionalized patients frequently do not get adequate exposure. Furthermore, the fear of skin cancer has led many to avoid sunlight exposure or to apply protective agents that block the ultraviolet portion of sunlight from reaching the lower reaches of the epidermis where most of the vitamin D is produced. Heavily pigmented and elderly individuals have less efficient production of vitamin D for a given exposure to ultraviolet irradiation. Serum levels of 25(OH)D are used to indicate vitamin D status. Although there is no consensus on what level of 25(OH)D constitutes sufficiency, 30 ng/mL has become the preferred target in North America. With that standard, a large portion of the population is vitamin D insufficient. A recent NHANES survey found that in the population over age 60, 67% of Caucasians, 82% of Hispanics, and 88% of African Americans had 25(OH)D levels below 30 ng/mL. Studies of hospitalized patients or those in nursing homes show almost universal vitamin D insufficiency if not frank deficiency. The intensity of sunlight is an important factor that limits effective vitamin D production as a function of season (summer > winter) and latitude (less intense the higher the latitude). The supplementation of milk has reduced the incidence of vitamin D deficiency in the United States, but most countries do not follow this practice. Even in the United States, severe vitamin D deficiency and rickets may occur in children of vegetarian mothers.
who avoid milk products (and presumably have reduced vitamin D stores) and in children who are not weaned to vitamin D-supplemented milk by age 2. Breast milk contains little vitamin D, although vitamin D content can be increased by supplementing the mother. Adults who avoid milk as well as sunlight are likewise at risk. Individuals with a variety of small bowel, pancreatic, and biliary tract disease and those after partial gastrectomy or intestinal bypass surgery have reduced capacity to absorb the vitamin D from the diet.

**Clinical Features**

The clinical features of individuals with severe vitamin D deficiency will be discussed more thoroughly in the section on “Osteomalacia and Rickets.” Severe vitamin D deficiency should be suspected in individuals complaining of lethargy, proximal muscle weakness, and bone pain who have frankly low or low normal serum calcium and phosphate and low urine calcium on routine biochemical evaluation. A low serum 25(OH)D level is diagnostic in this setting. 1,25(OH)₂D levels are often normal and reflect the increased 1-hydroxylase activity in these subjects that is responding appropriately to the increased PTH levels as well as the low serum calcium and phosphate levels. However, it is becoming clear that less severe degrees of vitamin D deficiency may not present with obvious musculoskeletal signs and symptoms. These individuals may be more susceptible to conditions such as hyperparathyroidism, osteoporosis, increased risk of falls and fractures, but also increased infections, hypertension, increased cardiovascular disease, diabetes mellitus, and various malignancies. Solid data from large-scale randomized placebo controlled clinical trials demonstrating cause and effect for vitamin D deficiency and many of these disorders are lacking, although animal studies and a large body of epidemiologic evidence and case control studies point in this direction.

**Treatment**

The goal in treating severe vitamin D deficiency manifesting as rickets or osteomalacia is to normalize the clinical, biochemical, and radiologic abnormalities without producing hypercalcemia, hyperphosphatemia, hypercalciuria, nephrolithiasis, or ectopic calcification. To realize this goal, patients must be followed carefully. As the bone lesions heal or the underlying disease improves, the dosage of vitamin D, calcium, or phosphate needs to be adjusted to avoid such complications. With the appreciation that most individuals have a less severe form of vitamin D deficiency and do not have obvious signs or symptoms associated with rickets or osteomalacia, the goal of treatment is to achieve a level of 25(OH)D that existing data indicate will reduce the predisposition of such individuals to the numerous diseases associated with vitamin D deficiency. Correction of vitamin D deficiency can usually be achieved by the weekly administration of 50,000 IU ergocalciferol for 6 to 8 weeks followed by replacement doses of 800 to 2000 IU/d based on maintenance of adequate serum 25(OH)D levels. Patients with malabsorption may respond to larger amounts of vitamin D (25,000-100,000 IU/d or one to three times per week). 25(OH)D (50-100 μg/d) is better absorbed than vitamin D and may be used if malabsorption of vitamin D is a limiting factor, but is not readily available in the United States. Calcitriol (1,25(OH)₂D₃) and its analogs are not appropriate therapy for patients with vitamin D deficiency because of the likely requirement for vitamin D metabolites other than 1,25(OH)₂D and the advantage of providing adequate substrate (25(OH)D) for tissues capable of producing their own 1,25(OH)₂D as the need arises (eg, as in the immune response). The exception to this rule is in patients with renal failure incapable of producing adequate 1,25(OH)₂D. Vitamin D therapy should be supplemented with 1 to 3 g of elemental calcium per day. Care must be taken in managing patients with vitamin D deficiency who also have elevated PTH levels, because long-standing vitamin D deficiency may produce a degree of autonomy in the parathyroid glands such that rapid replacement with calcium and vitamin D could result in hypercalcemia or hypercalciuria. A listing of available vitamin D metabolites and analogs with their main indications for clinical use is presented in Table 8-2.

4. **PSEUDOVITAMIN D DEFICIENCY**

Pseudovitamin D deficiency is a rare autosomal recessive disease in which rickets is accompanied by low levels of 1,25(OH)₂D but normal levels of 25(OH)D. The disease is due to mutations in the 25(OH)D 1-hydroxylase gene (CYP27B1) that render it nonfunctional. Both alleles need to be defective in order for the disease to be manifest. Although affected patients do not respond to doses of vitamin D that are effective in subjects with vitamin D deficiency, they can respond to pharmacologic doses of vitamin D and to physiologic doses of calcitriol, which is the preferred treatment.

5. **HEREDITARY VITAMIN D-RESISTANT RICKETS**

Hereditary vitamin D-resistant rickets is a rare autosomal recessive disease that presents in childhood with rickets similar to that seen in patients with vitamin D deficiency. Many of these patients also have alopecia, which is not characteristic of vitamin D deficiency or pseudovitamin D deficiency. The biochemical changes are similar to those reported in subjects with vitamin D deficiency except that the 1,25(OH)₂D levels are generally very high. The disease is caused by inactivating mutations in the VDR gene. The location of the mutation can affect the severity of the disease. In particular, mutations in the DNA-binding domain (exons 2, 3) that prevent DNA binding and mutations in the ligand-binding domain (exons 5-7) that prevent 1,25(OH)₂D binding lead to a more severe disease. The latter mutations may alter but not inhibit DNA/ligand binding. These patients are treated with large doses of calcitriol and dietary calcium and may show partial or complete remission as they grow older. An animal model of this disease (inactivation or knockout of both VDR alleles) demonstrates that the bone disease can be corrected with high dietary intake of calcium and phosphate, although the alopecia is not altered. This disease points to a role for the VDR in epithelium and hair development that is independent of its activity in the intestine and bone.
6. OTHER HYPOCALCEMIC DISORDERS

Hypoalbuminemia produces a low total serum [Ca\(^{2+}\)] because of a reduction in the bound fraction of calcium, but the ionized [Ca\(^{2+}\)] is normal. The ionized [Ca\(^{2+}\)] can be determined directly, or the effect of hypoalbuminemia can be roughly corrected for by using the following formula:

\[
\text{Corrected serum calcium} = \frac{\text{Measured serum calcium} + (0.8 \times \text{Measured serum albumin})}{4 - \text{Measured serum albumin}}
\]

Thus, in a patient with a serum [Ca\(^{2+}\)] of 7.8 mg/dL and a serum albumin of 2 g/dL, the corrected serum [Ca\(^{2+}\)] is 7.8 + (0.8) \(4 - 2\) = 9.4 mg/dL.

Several disorders produce acute hypocalcemia even if homeostatic mechanisms are intact, simply because they overwhelm these mechanisms. Acute hyperphosphatemia resulting from rhabdomyolysis or tumor lysis, often in the setting of renal insufficiency, may produce severe symptomatic hypocalcemia. Transfusion of large volumes of citrated blood causes acute hypocalcemia by complexation of calcium as calcium citrate. In this instance, total calcium may be normal, but the ionized fraction is reduced. In acute pancreatitis, hypocalcemia is an ominous prognostic sign. The mechanism of hypocalcemia is sequestration of calcium by saponification with fatty acids, which are produced in the retroperitoneum by the action of pancreatic lipases. Skeletal mineralization, when very rapid, can cause hypocalcemia. This is seen in the hungry bones syndrome, which was discussed above in the section on surgical hypoparathyroidism, and occasionally with widespread osteoblastic metastases from prostatic carcinoma.

TREATMENT OF HYPOCALCEMIA

Acute Hypocalcemia

Patients with tetany should receive intravenous calcium as calcium chloride (272 mg calcium/10 mL), calcium gluconate (90 mg calcium/10 mL), or calcium gluceptate (90 mg calcium/10 mL). Approximately 200 mg of elemental calcium can be given over several minutes. The patient must be observed for stridor and the airway secured if necessary. Oral calcium and a rapidly acting preparation of vitamin D should be started. If necessary, calcium can be infused in doses of 400 to 1000 mg/24 h until oral therapy has taken effect. Intravenous calcium is irritating to the veins and is best infused into a large vein or through a central venous catheter.

Chronic Hypocalcemia

The objective of chronic therapy is to keep the patient free of symptoms and to maintain a serum [Ca\(^{2+}\)] of approximately 8.5 to 9.0 mg/dL. With lower serum [Ca\(^{2+}\)], the patient may not only experience symptoms but may be predisposed over time to cataract formation if the phosphate level is also high. With serum calcium concentrations in the upper normal range, there may be marked hypercalciuria, which occurs because the hypercalcicic effect of PTH has been lost. This may predispose to nephrolithiasis, nephrocalcinosis, and chronic renal insufficiency. In addition, the patient with borderline elevated calcium is at increased risk of overshooting the therapeutic goal and may develop symptomatic hypercalcemia.

The mainstays of treatment are calcium and a form of vitamin D. Oral calcium can be given in a dose of 1.5 to 3 g of elemental calcium or more per day. These large doses of calcium reduce the doses of vitamin D that are needed and allow for rapid normalization of serum calcium if vitamin D intoxication subsequently occurs. Numerous preparations of calcium are available. A short-acting preparation of vitamin D (calcitriol) and the very long-acting preparations such as vitamin D\(_2\) (ergocalciferol) are available (see Table 8–2). By far the most inexpensive regimens are those that use ergocalciferol. In addition to economy, they have the advantage of rather easy maintenance in most patients. The disadvantage is that ergocalciferol can slowly accumulate and produce prolonged vitamin D intoxication. Caution must be exercised in the introduction of other drugs that influence calcium metabolism. For example, thiazide diuretics have a hypocalciuric effect. By reducing urinary calcium excretion in treated patients, whose other adaptive mechanisms such as the modulation of PTH secretion by calcium, are nonoperative and who are thus absolutely dependent on renal excretion of calcium to maintain the serum calcium level, thiazides may produce significant hypercalcemia. In a similar way, intercurrent illnesses that compromise renal function (and therefore calcium excretion) may produce dangerous hypercalcemia in the patient who is maintained on large doses of vitamin D. Short-acting preparations are less prone to some of these effects but may require more frequent titration and are much more expensive than vitamin D\(_2\).

BONE ANATOMY AND REMODELING

FUNCTIONS OF BONE

Bone has four major functions.

1. It provides rigid support to extremities and body cavities containing vital organs. In diseases in which the skeleton is weakened or defective, erect posture may be impossible and vital organ function may be compromised. An example is the cardiopulmonary dysfunction that occurs in patients with severe kyphosis due to vertebral collapse.

2. Bones are crucial to locomotion in that they provide efficient levers and sites of attachment for muscles. With bony deformity, these levers become defective, and severe abnormalities of gait develop.

3. Bone provides a large reservoir of ions, such as calcium, phosphate, magnesium, and sodium that are critical for life and can be mobilized when the external environment fails to provide them.

4. Bone houses the hematopoietic elements. There is increasing evidence of a trophic relationship between the stromal cells in bone and the hematopoietic elements.
STRUCTURE OF BONE

The material properties of normal bone strike an ideal balance between rigidity and elasticity. Bone is rigid enough to provide structural stability and resist applied forces but not overly mineralized and brittle, which would result in an increased tendency to fracture. Bone must also be light enough to be moved by muscle contractions. Cortical bone, composed of densely packed layers of mineralized collagen, provides rigidity and is the major component of tubular bones (Figure 8–20). Trabecular (cancellous) bone is spongy in cross-section, provides strength and elasticity, and constitutes the major portion of the axial skeleton. Disorders in which cortical bone is defective or reduced in mass lead to fractures of the long bones. Disorders in which trabecular bone is defective or scanty, in contrast, lead preferentially to vertebral fractures. Fractures of long bones may also occur because normal trabecular bone reinforcement is lost.

Two-thirds of the weight of bone is due to mineral; the remainder is due to water and type I collagen. Minor organic components such as proteoglycans, lipids, acidic proteins containing gamma-carboxyglutamic acid, osteonectin, osteopontin, and growth factors comprise the remainder.

FIGURE 8-20 Diagram showing features of the microstructure of mature bone seen in both transverse (top) and longitudinal section. Areas of cortical (compact) and trabecular (cancellable) bone are included. (Reproduced, with permission, from Warwick R, Williams PL, eds. Gray’s Anatomy. 35th ed. Longman; 1973.)
Bone Mineral

The mineral of bone is present in two forms. The major form consists of hydroxyapatite in crystals of varying maturity. The remainder is amorphous calcium phosphate, which lacks a coherent x-ray diffraction pattern, has a lower calcium-to-phosphate ratio than pure hydroxyapatite, occurs in regions of active bone formation, and is present in larger quantities in young bone.

Bone Cells

Bone is composed of three types of cells: the osteoblast, the osteocyte, and the osteoclast.

A. Osteoblast  The osteoblast is the principal bone-forming cell. It arises from a pool of mesenchymal stem cells in the bone marrow, which as they differentiate, acquire a set of characteristics, including expression of PTH and vitamin D receptors; surface expression of the ectoenzyme alkaline phosphatase; and expression of bone matrix protein genes—type I collagen, osteocalcin, osteopontin, and others. Differentiated osteoblasts are directed to the bone surface, where they line regions of new bone formation, laying down bone matrix (osteoid) in orderly lamellae and inducing its mineralization (Figure 8-21). In the mineralization process, hydroxyapatite crystals are deposited on the collagen layers to produce lamellar bone. Mineralization requires an adequate supply of extracellular calcium and phosphate as well as alkaline phosphatase, which is secreted in large amounts by active osteoblasts. The fate of senescent osteoblasts is not well defined. Some probably become flattened, inactive lining cells on trabecular bone surfaces, some are buried in cortical bone as osteocytes, and others undergo apoptosis.

B. Osteocyte  Osteoblasts that remain within cortical bone during the remodeling process become osteocytes. Protein synthetic activity decreases markedly, and the cells develop multiple processes (canaliculi) that reach out through lacunae in bone tissue to communicate with nutrient capillaries, with processes of other osteocytes within a unit of bone (osteon), and also with the cell processes of surface osteoblasts (see Figure 8-20). The physiologic functions of osteocytes are poorly understood. They are believed to (1) act as a cellular syncytium that permits the translocation of mineral in and out of regions of bone removed from surfaces, and (2) serve as the sensors of mechanical loading by providing key signals that trigger bone modeling and remodeling.

C. Osteoclast  The osteoclast is a multinucleated giant cell that is specialized for resorption of bone. Osteoclasts are terminally differentiated cells that arise from hematopoietic precursors in the monocyte lineage and do not divide. Osteoblasts stimulate both osteoclast formation and activation via the cell surface molecule RANKL. RANKL stimulates its cognate ligand RANK on the surface of osteoclast precursors and mature osteoclasts (Figure 8-22). Osteoblasts also elaborate macrophage colony stimulating factor-1 (M-CSF), which potentiates the effects of RANKL on osteoclastogenesis. In addition, osteoblasts and other cells produce a decoy receptor, osteoprotegerin (OPG), which binds to RANKL and blocks its actions. PTH and 1,25(OH)2D both increase RANKL expression by osteoblasts, as do cytokines such as
CHAPTER 8 Metabolic Bone Disease

IL-1, IL-6, and IL-11. TNF potentiates the ability of RANKL to stimulate osteoclastogenesis, whereas IFN-gamma blocks this process by direct effects on the osteoclast.

To resorb bone, the motile osteoclast alights on a bone surface and seals off an area by forming an adhesive ring. Having isolated an area of bone surface, the osteoclast develops above the surface an elaborately invaginated plasma membrane structure called the ruffled border (Figure 8–23). The ruffled border is a distinctive organelle, but it acts essentially as a huge lysosome that dissolves bone mineral by secreting acid onto the isolated bone surface and simultaneously breaks down bone matrix by secretion of proteases, in particular cathepsin K. The collagen breakdown products from bone resorption can be assayed in serum and urine as measures of bone resorption rates (N- and C-telopeptides). Bone resorption can be controlled in two ways: by regulating the formation of osteoclasts via changes in cell numbers or by regulating the activity of mature osteoclasts. The mature osteoclast has receptors for CT but does not appear to have PTH or vitamin D receptors.

BONE REMODELING

Bone remodeling is a continuous process of breakdown and renewal that occurs throughout life. During childhood and adolescence, remodeling proceeds at a vigorous rate but is quantitatively overwhelmed by the concomitant occurrence of bone modeling and linear growth. Once peak bone mass has been established, remodeling supervenes as the common mechanism by which bone mass is modified for the remainder of a person's life. Each remodeling event is carried out by individual "bone remodeling units" on bone surfaces throughout the skeleton (see Figure 8–21). Normally, about 90% of these surfaces lie dormant, covered by a thin layer of lining cells. Following physical or biochemical signals, precursor cells from the bone marrow migrate to specific loci on the bone surface, where they fuse into multinucleated bone-resorbing cells known as osteoclasts that then excavate a resorption cavity into the bone.

Cortical bone is remodeled from within by cutting cones, groups of osteoclasts that cut tunnels through the compact bone (Figure 8–24). They are followed by trailing osteoblasts that line the tunnels with a cylinder of new bone, progressively narrowing the tunnels until all that remains are the tiny haversian canals by which the cells left behind as resident osteocytes are fed. The packet of new bone formed by a single cutting cone is called an osteon (see Figure 8–20).

By contrast, trabecular resorption creates scalloped areas of the bone surface called Howship lacunae. Two to three months after initiation, the resorption phase reaches completion, having created
When they do, the coupling mechanism ensures that bone is replaced osteoblast proliferation and differentiation. However, it is also becoming clear that the osteoclast itself can regulate osteoblast differentiation through bidirectional signaling molecules of the ephrin/Eph family.

If the replacement of resorbed bone matched the amount that was removed, remodeling would lead to no net change in bone mass. However, small deficits in bone mass persist on completion of each cycle, reflecting inefficiency in remodeling dynamics. Consequently, lifelong accumulation of remodeling deficits underlies the well-documented phenomenon of age-related bone loss, a process that begins shortly after growth stops. Alterations in remodeling activity represent the final pathway through which diverse stimuli, such as dietary insufficiency, hormones, and drugs affect bone balance. A change in whole body remodeling rate can be brought about through distinct perturbations in remodeling dynamics. Changes in the hormonal milieu often increase the activation of remodeling units. Examples include hyperthyroidism, hyperparathyroidism, and hypervitaminosis D. Other factors may impair osteoblastic functional adequacy, such as high doses of glucocorticoids or ethanol. Yet other perturbations, such as estrogen or androgen deficiency, may augment osteoclastic resorptive capacity. At any given time, a transient deficit in bone exists called the remodeling space representing sites of bone resorption that have not yet filled in. In response to any stimulus that alters the birth rate of new remodeling units, the remodeling space either increases or decreases accordingly until a new steady state is established, and this adjustment is seen as an increase or decrease in bone mass.

**OSTEOPOROSIS**

Osteoporosis is a condition of low bone mass and microarchitectural disruption that results in fractures with minimal trauma. The term primary osteoporosis denotes reduced bone mass and fractures in postmenopausal women (postmenopausal osteoporosis) or in older men and women due to age-related factors. The term secondary osteoporosis refers to bone loss resulting from specific clinical disorders, such as thyrotoxicosis or hyperadrenocorticism (Table 8–9). There is overlap in these designations; for example, many postmenopausal women with low bone mass have vitamin D insufficiency or deficiency which could be considered a secondary cause of osteoporosis.

Osteoporotic fractures are a major public health problem for older women and men in Western society. Half the men and women over age 55 have low bone mass or osteoporosis, placing them at increased risk of fracture. At any age, women experience twice as many osteoporosis-related fractures as men, reflecting gender-related differences in skeletal properties as well as the almost universal loss of bone at menopause. However, the number of osteoporotic fractures in older men is not trivial (Figure 8–25). One white woman in six suffers a hip fracture; mortality after hip fracture is as high as 20% in the first year. One-third of hip fractures occur in men and have been associated with an even higher mortality rate than in women. Billions of dollars are spent annually for acute hospital care of hip fracture alone. The consequences of vertebral deformity are also significant and include chronic pain, inability to conduct daily activities, depression, increased mortality, and high risk of additional vertebral fractures.

Typically, fractures attributed to bone fragility are those due to trauma equal to or less than a fall from a standing position. Common sites of fragility-related fractures include the vertebral bodies, distal forearm, and proximal femur, but because the

Skeletons of patients with osteoporosis are diffusely fragile, other sites, such as ribs and long bones, also fracture with high frequency. Vertebral compression fractures are the most common fragility-related fractures. Pain sufficient to require medical attention occurs in approximately one-third of vertebral fractures, the majority being detected only when height loss or spinal deformity (kyphosis) occurs. However, even asymptomatic vertebral fractures confer an increased risk of future vertebral fractures and mortality. Thus, incidentally detected vertebral fractures have the same clinical significance as a clinical vertebral fracture. Furthermore, even fractures that appear to be due to trauma portend an increased future fracture risk. Both skeletal and extraskeletal factors determine fracture risk (Table 8-10).

Gain, Maintenance, and Loss of Bone

The amount of bone mineral present at any time in adult life represents that which has been gained at skeletal maturity (peak bone mass) minus that which has been subsequently lost. Bone acquisition is completed in the late teenage years and early twenties in girls and by the second decade in boys. Heredity accounts for most of the variance in bone acquisition. African American adolescent girls have greater calcium retention on a fixed calcium intake compared to Caucasian adolescent girls, potentially explaining at least part of the racial differences in bone mass. Specific genes implicated in bone acquisition include those affecting body size, hormone responsiveness, and bone-specific proteins such as type 1 collagen and transforming growth factor beta.

Recent evidence indicates that the Wnt pathway plays a central role in determining bone mass. The low-density lipoprotein (LDL) receptor-like protein 5 (LRP5) along with the frizzled protein serves as coreceptor for members of the Wnt family of ligands. Activation of Wnt and its downstream signaling pathways mediates increased osteoblastic activity (gene expression, cell proliferation). Mutations that render LRP5 constitutively active are associated with high bone mass, and autosomal recessive inactivating mutations in LRP5 play a causative role in the osteoporosis-pseudoglioma syndrome. These mutations lead to accelerated bone loss and fractures as well as blindness. These two disorders of bone mass have firmly established Wnts, LRP5, and frizzled as essential molecules in osteoblast-mediated bone formation.
Other factors contributing to the acquisition of peak bone mass include circulating gonadal steroids, physical activity, and nutrient intake. In adolescents, calcium retention is maximal at a calcium intake of 1300 mg/d; this is the current recommended intake for individuals aged 9 to 18 years. Adolescence is a critical time for the skeleton; bone gained during adolescence accounts for about 60% of final adult bone mass. Assuming adequate exposure to key nutrients, physical activity, and reproductive hormones, adolescent growth supports acquisition of the maximum bone mass permitted by the genetic endowment. Estradiol plays a decisive role in the initiation of adolescent growth and bone acquisition. Rare examples have been reported of young men bearing mutations in the estradiol receptor or in aromatase, the enzyme that converts androgen to estrogen. Although these men had normal or increased circulating concentrations of testosterone, estradiol was either absent or totally ineffective. In all cases, severe deficits in BMD were observed, and these patients had not undergone the anticipated acceleration in linear growth at the time of puberty. In the patients with aromatase deficiency, substantial gains in bone were observed shortly after initiating estrogen therapy.

Adolescent bone acquisition falters in the face of inadequacies in diet, physical activity, or reproductive function, resulting in a lower peak bone mass and less reserve to accommodate future losses. Recent trends in habitual physical activity and calcium intake for North American teenagers, particularly girls, offer little encouragement in this regard. A list of representative conditions often associated with reduced peak bone mass acquisition is presented in Table 8–11.

Once peak bone mass is achieved, bone mass remains fairly stable until the late third or early fourth decades (Figure 8–26). Successful bone maintenance requires continued attention to the same factors that influenced bone acquisition: diet, physical activity, and sex hormone status. Maintenance of bone requires sufficiency in all areas, and deficiency in one is not compensated by the others. For example, amenorrheic athletes lose bone despite frequent high-intensity physical activity and supplemental calcium intake. Successful bone maintenance is also jeopardized by known toxic exposures such as smoking, alcohol excess, and immobility as well as by systemic illnesses and many medications.

Bone mass in healthy children: measurement with quantitative DXA. *Radiology.* 1991;179:735; and from Kelly TL. Bone mineral reference databases for American men and women. *J Bone Miner Res.* 1990;5(suppl 2):702. Courtesy of Hologic, Inc.)
Bone Loss Associated with Estrogen Deficiency

Estrogen deprivation promotes bone remodeling by releasing constraints on the production and activity of cytokines, particularly IL-6, which stimulates the proliferation of osteoclast precursors. Estradiol suppresses IL-6 secretion by marrow stromal osteoblastic cells, and treatment of mice with neutralizing IL-6 antibodies suppresses osteoclast production after oophorectomy. Estradiol directly suppresses IL-6 production in human osteoblasts, and IL-6 gene knockout prevents bone loss in oophorectomized mice. Thus, a strong case implicates IL-6 as a critical molecule by which osteoblasts signal increased bone remodeling and suggests that this link is a major site for estrogen action in bone. Subsidiary roles for IL-1 and IL-11 have also been described. As discussed above, the RANK-RANKL-OPG system acts as a bone regulatory system through which osteoblast signals stimulate the production of osteoclasts. With estrogen deficiency, OPG secretion is low, permitting a robust response of osteoclast precursors to RANKL. With estrogen sufficiency, increased local concentrations of OPG bind to RANKL, reduce osteoclast production, and thereby decrease bone turnover.

With accelerated bone turnover, delivery of calcium from bone to the circulation increases, and the resultant subtle increase in plasma calcium concentration suppresses the secretion of PTH, thereby enhancing calcium, suppressing renal production of 1,25(OH)2D, and reducing intestinal calcium absorption efficiency. At menopause, loss of endogenous estrogen promotes an increase in daily calcium loss from 20 mg to about 60 mg, reflecting a relative increase in bone resorption over formation activity. Although small, this magnitude of change in mineral balance accounts, after a decade, for about 13% of an original whole body calcium mass of 1000 g, equivalent to a standard deviation in BMD, and leads to a two- to threefold increase in the risk of fracture (see Figure 8–26). In the 5 years after menopause, women not on estrogen can lose as much as 5% to 8% of bone mass. To accommodate menopausal changes in calcium economy by dietary means alone, a rise in daily calcium intake from 1000 mg to about 1500 mg would be necessary. Increased calcium intake can slow but usually does not entirely prevent the bone loss that occurs with menopause.

Bone Loss in Later Life

Progressive deficits in renal and intestinal function impair whole body calcium economy during normal human aging. These deficits include progressive inefficiency of vitamin D production by the skin as well as declining ability to convert 25(OH)D to 1,25(OH)2D in the kidney. Consequently, intestinal calcium absorption becomes less efficient, leading to modest reductions in plasma ionized calcium activity and compensatory hypersecretion of PTH. PTH maintains blood calcium concentrations by activating new bone remodeling units, although as a result of its inherent inefficiency, increased bone remodeling leads to accelerated bone loss. Little can be done to counteract remodeling inefficiency, but the impact of these physiologic deficits can be minimized by suppressing the stimulus for PTH secretion by consuming adequate amounts of dietary calcium (about 1500 mg/d) and vitamin D (at least 800-1200 units/d).

Diagnosis of Osteoporosis

The diagnosis of osteoporosis may be obvious in patients who have sustained fragility fractures (Figure 8–27), but noninvasive
methods to estimate BMD are required to identify high-risk patients who have not yet sustained a fracture. Due to the significant consequences of fractures, diagnosis prior to fracture is essential. Several techniques have been developed for this purpose, but DXA offers the most precise measurements at multiple skeletal sites for the least amount of radiation exposure. Current guidelines recommend that all women over the age of 65 years be screened for osteoporosis using bone densitometry. Under age 65, the National Osteoporosis Foundation (NOF) guidelines recommend that screening start after menopause in women with risk factors for fracture. NOF recommends screening men over 70 and targeted screening of men between age 50 and 70 if there is a risk factor for bone loss and or fracture. There are no routine screening recommendations for younger individuals. Younger men and women should have bone density testing as clinically indicated (eg, clinical evidence of bone fragility). Assessment of skeletal health should be based on age-matched normative data (Z-scores). Although there are no formal guidelines and a paucity of long-term data, most experts consider a BMD more than two standard deviations below the age-matched normal reference population (a Z score of –2 or lower) to indicate low BMD in a young person. However, BMD in younger individuals must be interpreted in light of the clinical situation and other risk factors for fracture.

BMD is a highly significant predictor of fracture risk. For each standard deviation BMD below the average BMD of individuals at the age of peak bone mass, fracture risk approximately doubles. Site-specific measurements best predict fracture risk at that site (ie, hip BMD best predicts hip fracture), but a measurement at any site predicts overall fracture risk. Based on data from Caucasian postmenopausal women and originally intended to be used as an epidemiologic tool, a World Health Organization (WHO) panel in 1994 offered an absolute standard for categorization of BMD. By this criterion, BMD values ≤2.5 or more SD below the average value for a person at the age of peak bone mass (a T-score of –2.5 or below) are categorized as osteoporosis. BMD values between –1.0 and –2.5 SD below the standard (T-score between –1 and –2.5) are categorized as low bone density or osteopenia.

While not their original intended purpose, these T-score cut points became integrated into clinical practice and have been used to place individuals with low BMD into diagnostic categories. Problematically, there are no risk thresholds at these values and an individual with a T-score of –2.4 and an individual with a T-score of –2.5 have nearly identical fracture risk, but one is considered to have osteoporosis and one is not. Additionally, two individuals with the same T-score value can have very different fracture risk. A woman in her fifties with no personal or family history of fracture but a femoral neck T-score of –2.5 has a 10-year risk of fracture of less than 10%. However, an 80-year-old woman whose mother had a hip fracture and who has a personal history of fracture but the same femoral neck T-score of –2.5 has a 10-year risk of fracture of more than 50%. It has long been recognized that the combination of risk factors for fracture and BMD can improve fracture risk prediction. An approach to formally estimating individual fracture risk from femoral neck bone density and risk factors for fracture was developed by the WHO and became available in 2008 at the website http://www.shef.ac.uk/FRAX/index.htm. While still undergoing revisions and improvements, the FRAX tool has greatly improved the clinician’s ability to estimate fracture risk for an individual patient. The levels of risk at which treatment should be initiated are country specific and being revised, but a cost-effectiveness analysis in the United States suggests that individuals with a 10-year probability of major osteoporotic fracture of 20% or of hip fracture of 3% should be considered for treatment. Limitations of this fracture prediction model include that it only incorporates BMD by DXA at the hip, many risk factors are not available in the model, and there is no way to incorporate the effect of prior treatment on fracture risk.

### TREATMENT OF OSTEOPOROSIS

Drugs used for prevention and treatment of osteoporosis act either by decreasing the rate of bone resorption, thereby slowing the rate of bone loss, or by increasing bone formation (Table 8–12). Because of the coupled nature of bone resorption and formation, agents that decrease bone resorption ultimately decrease the rate of bone formation. Thus, increases in BMD, representing a reduction of the remodeling space to a new steady-state level, are commonly observed during the first year or two of therapy, after which BMD increases slowly and may even reach a plateau. It is not uncommon for there to be minimal changes in BMD observed with treatment in clinical practice. Analysis of data from the Fracture Intervention Trial demonstrated that women in the alendronate treatment group whose bone density did not increase during treatment still benefited with rates of fracture reduction similar to the women whose BMD measurably increased. Thus, women on treatment with stable BMD should not be considered treatment failures based on a perceived lack of response.

Speciﬁc Antiresorptive Agents

A. Calcium In the seventh decade and beyond, supplemental calcium and vitamin D therapy suppresses bone turnover, increases bone mass, and has been shown in clinical trials to decrease fracture incidence. Studies conﬁrming the clinical efﬁcacy of various pharmacologic agents to increase BMD or decrease fracture have been performed in the setting of calcium and vitamin D suﬃciency. Thus, adequate intake of calcium and vitamin D should be considered a basic approach for prevention and treatment of osteoporosis in all patients (Table 8–13).

The current recommended intake of calcium is 1300 mg/d for adolescents, 1000 mg/d for adults up to age 50, and 1200 mg/d for adults over age 50 years. Intakes of 1500 mg/d for individuals with or at risk of developing osteoporosis are recommended by some authors. A dairy-free diet contains approximately 250 mg/d of calcium. Achieving the recommended calcium intake goals by food alone typically requires consumption of three to four servings per day of dairy foods or calcium-fortiﬁed foods. Patients who are unable to increase dietary calcium by diet alone may choose from many palatable, low-cost calcium preparations, the most frequently prescribed being the carbonate salt. Others include the lactate, gluconate, and citrate salts and hydroxyapatite. Absorption of most commonly prescribed calcium products is similar. For many patients, cost and palatability outweigh modest differences in absorption. Calcium carbonate requires an acid environment for optimal absorption. For older individuals who may have hypo- or achlorhydria, taking calcium carbonate tablets with meals generally provides adequate acidity for this requirement. To maximize absorption, calcium should be taken in doses of 500 mg or less at a time and spread throughout the day. Calcium can interfere with the absorption of iron and L-thyroxine and should be ingested separately from these medications.

B. Vitamin D and calcitriol In recent years, it has become necessary to reassess our concepts of vitamin D suﬃciency (see also Vitamin D earlier). Although circulating 25(OH)D concentrations above 10 ng/mL appear adequate for preventing histologic evidence of osteomalacia, a strong case can now be made that values below 25 to 30 ng/mL are associated with hypersecretion of PTH, proximal muscle weakness predisposing to falls, and increased bone turnover. In some regions of the United States, healthy adults show average 25(OH)D concentrations of 30 ng/mL or above, but in others, such as New England or in states farther north than Missouri, the ultraviolet component of sunlight fails to contain suﬃcient amounts, at the critical region of approximately 270 to 310 nm, to support cutaneous vitamin D synthesis. In those areas, vitamin D insuﬃciency is very common, particularly in frail, homebound, or hospitalized patients. Vitamin D supplementation in individuals with marginal or deﬁcient vitamin D status improves intestinal calcium absorption, suppresses PTH and bone remodeling, increases bone mass, and, in doses of 800 IU/d or greater, reduces fracture risk.

The use of potent vitamin D analogs or metabolites—such as calcitriol—to treat osteoporosis is an intervention distinct from ensuring vitamin D nutritional adequacy. In the treatment of osteoporosis, the rationale is to exploit the ability of these compounds to interact with the VDR in parathyroid cells to suppress PTH secretion directly and reduce bone turnover. Clinical experience with calcitriol remains mixed. Higher doses impose an added risk of hypercalcemia and hypercalciuria.

C. Estrogen Conjugated equine estrogens at a dose of 0.625 mg/d increase BMD about 5% and 2.5% at the lumbar spine and proximal femur respectively, and reduce the risk of hip and vertebral fractures by 35% to 40%. Both oral and transdermal estrogen offers protection against bone loss. Cessation of estrogen administration leads to rapid bone loss, and protection against fracture dissipates within a few years of stopping even after prolonged treatment.

Data from the Women’s Health Initiative (WHI) released since 2002 underscore the lack of cardiovascular disease prevention in estrogen-treated postmenopausal women and the small but statistically signiﬁcant increases in breast cancer and venous thromboembolic phenomena that occur with estrogen and progesterone therapy (hormone therapy; HT) in postmenopausal women. The WHI has led to a marked change in prescribing of HT for postmenopausal women such that only patients suffering from signiﬁcant vasomotor effects of estrogen deﬁciency and early in menopause are currently prescribed HT and for the shortest possible time. Reduced BMD is not considered an indication for HT, because effective alternative therapies for skeletal preservation exist. In older women who also receive adequate calcium supplementation, 0.3 mg of conjugated estrogens produces similar gains in bone density, but this dose has not been tested for antifracture effects. In the relatively small randomized trials in which lower doses of estrogen have been studied, increases in vascular events or breast cancer have not been seen. Interest remains in whether there might be a low dose of estrogen at which the skeletal beneﬁts could be achieved without incurring the adverse vascular and malignant consequences. It is unclear
whether a trial of sufficient size to address this question is feasible at the present time.

D. Selective estrogen response modulators  The past decade has witnessed the design and development of several molecules that act as estrogens on some tissues but antiestrogens on others. The only currently approved SERM, raloxifene, is an estrogen agonist at bone and liver, that promotes conservation of BMD and lowering of LDL cholesterol concentrations, but it is inert at the endometrium and a potent antiestrogen at the breast. Raloxifene has been shown to decrease the vertebral fracture incidence in older osteoporotic women and has received FDA approval for both prevention and treatment of osteoporosis in postmenopausal women.

E. Calcitonin  The role of endogenous calcitonin in calcium metabolism is unclear. However, given as a pharmacologic agent, calcitonin inhibits osteoclastic bone resorption. Originally available only as an injectable form, calcitonin is now also available as a nasal spray, and both formulations are approved for postmenopausal osteoporosis treatment. CT nasal spray (200 IU/d) increases BMD by 2% to 3% and reduces vertebral fractures by about 35%. Calcitonin has not been shown to reduce hip or nonspine fractures in randomized trials; however, a meta-analysis of 14 CT trials suggested a significant reduction in both vertebral and nonvertebral fractures with CT therapy. CT may provide some analgesic benefit in women with acute or painful vertebral fractures, possibly through central nervous system effects. Side-effects of nasal spray CT appear mild and include rhinitis. The nasal spray daily dose should be alternated between nostrils. Injectable CT has additional side-effects of flushing, nausea, and local injection reactions, making the nasal option the preferred form of administration.

F. Bisphosphonates  Bisphosphonates bind avidly to the hydroxyapatite crystals in bone, particularly at sites of active remodeling. The currently approved amino bisphosphonates interfere with protein prenylation in the osteoclast, impairing osteoclast-mediated bone resorption as well as enhancing osteoclast apoptosis. Four bisphosphonates, alendronate, risedronate, ibandronate, and zoledronic acid are FDA-approved for prevention and treatment of osteoporosis. Three of them, alendronate, risedronate, and zoledronic acid are approved for treatment of glucocorticoid-induced osteoporosis in men and women and for the treatment of osteoporosis in men.

All the approved bisphosphonates have been shown to reduce vertebral fractures by approximately 50% to 60%. Alendronate, risedronate, and zoledronic acid have also been shown to reduce the risk of nonvertebral fractures. In clinical trials, hip fractures were reduced by 51% after treatment with alendronate, 30% after treatment with risedronate, and 41% after annual infusions of zoledronic acid for 3 years. Head-to-head comparisons, however, have not been performed. Treatment of individuals (men and women) who have had a hip fracture with zoledronic acid has also been shown to reduce subsequent fractures and decrease mortality in individuals. Ibandronate has not been shown to reduce the risk of nonvertebral fractures except in the post hoc analysis of women with T-scores less than -3. The fracture trials for all the bisphosphonates were conducted using daily dosing, except for zoledronic acid which was given as a 5 mg annual intravenous dose. Based on equivalent effects on BMD to daily dosing, alendronate and risedronate are approved for weekly dosing, and risedronate and ibandronate are approved for monthly dosing. Ibandronate is also approved for quarterly intravenous dosing.

Oral bisphosphonate absorption is very low, less than 1% of the administered dose. Consequently, patients must take these medications on first arising in the morning, on an empty stomach, with at least 8 oz of water, remain upright to ensure passage of the pill into the stomach, and ingest nothing else for 30 minutes for alendronate and risedronate, and 60 minutes for ibandronate. Side-effects from the oral bisphosphonates are primarily gastrointestinal, most notably esophageal irritation if the pill does not clear the esophagus. Hence the requirement to administer with sufficient water and remain upright after dosing. None of the bisphosphonates are recommended for use in patients with significant renal impairment (creatinine clearance <35 mL/min).

Intravenous therapy can be given conveniently for zoledronic acid (5 mg annually) and ibandronate (3 mg quarterly).

Osteonecrosis of the jaw has been reported in patients taking bisphosphonates, and a warning regarding this possible adverse effect was recently added to all bisphosphonate labeling. The vast majority of cases have occurred after dental work in patients with malignancies on intravenous bisphosphonates at more frequent intervals and at much higher doses of drug than the annual infusions for patients with osteoporosis. Several cases, however, have been reported in patients with osteoporosis. Estimates of the incidence of this complication related to bisphosphonate treatment in benign conditions vary widely, but appear to be approximately 1/50,000 patient years. Rates are significantly higher in malignant conditions such as multiple myeloma or breast cancer. Osteonecrosis of the jaw is a difficult disorder to treat, and additional oral procedures including biopsy of the affected site may worsen the condition. Suspected cases should be referred to an experienced dental professional.

Other bisphosphonate related side-effects include bone pain and, for the intravenous agents, an acute phase reaction temporally related to dosing and typically limited to the patient's first dose.

G. Rank-L inhibition  Denosumab, a human monoclonal IgG2 antibody to RANK-L, has been shown to reduce spine fractures by 68%, hip fractures by 40%, and nonvertebral fractures by 20% in postmenopausal women with low bone density (T-score <-2.5 and >-4.0) aged 60 to 90 years. In the pivotal trial establishing this antifracture efficacy, 60 mg denosumab was administered subcutaneously every 6 months for 3 years. Denosumab has been approved by the FDA for the treatment of patients with severe osteoporosis at high risk for fracture. Adverse events include eczema and cellulitis. Another clinical trial in men with prostate cancer undergoing androgen deprivation therapy has shown substantial increases in BMD and reduced risk of vertebral fractures.
in these men. At present, the FDA has not given formal approval to the use of denosumab in these high-risk men.

Bone-Forming Agents

A. Parathyroid hormone  Fractures, skeletal deformity, and bone pain are well-described manifestations of bone disease associated with severe primary hyperparathyroidism. It may seem counterintuitive, therefore, to suggest that administration of PTH to individuals with low BMD may not only improve BMD but also reduce the risk of fractures. Yet, that is what experience over the past two decades indicates. The decisive element apparently that determines the effects of PTH to be destructive or therapeutic is whether PTH concentrations in blood are elevated constantly or only intermittently. In severe hyperparathyroidism, PTH concentrations remain high, varying little throughout the day. In most cases of mild hyperparathyroidism seen today, PTH concentrations are lower, sometimes even within the normal range. In such patients, normal and even increased lumbar spine BMD measurements are commonly observed. Administration of PTH as daily pulse injections has been shown to increase BMD in both animals and humans. Abundant evidence now indicates that PTH is truly an osteotropic agent, and several groups have shown increases in vertebral BMD of patients with osteoporosis. In a large clinical trial conducted in postmenopausal women with osteoporosis, recombinant human PTH(1-34)(rhPTH[1-34]), given in daily subcutaneous doses for approximately 21 months, reduced the incidence of vertebral fractures by more than 60% and that of nonvertebral fractures by 50%. During the course of this trial, a long-term carcinogenicity study showed that rats given near-lifet ime daily injections of rhPTH(1-34) showed a dose-related incidence of osteosarcoma. Clinical studies with this agent were immediately suspended, pending a thorough review of all relevant information by an independent group of cancer biologists, who concluded that the rat osteosarcoma finding was not likely to predict a relationship to osteosarcoma in humans. Consequently, human trials with rhPTH(1-34) were resumed. rhPTH(1-34) or teriparatide was approved by the FDA for use in both men and postmenopausal women with osteoporosis who are at high risk for fractures as well as in glucocorticoid-induced osteoporosis. Therapeutic use is limited to 2 years and is recommended for individuals who have had a fracture related to osteoporosis, who have multiple risk factors for fracture, or who cannot use other osteoporosis treatments. Side-effects include hypercalcemia, hypercalciuria, and bone pain. Teriparatide is contraindicated for patients with conditions placing them at increased risk for osteosarcoma such as Paget disease of bone, unexplained elevations of alkaline phosphatase, open epiphyses, or patients who have received radiation therapy involving the skeleton. Over 430,000 patients have received teriparatide therapy, and there have been two reported cases of possible osteosarcoma; this approximates the background risk of osteosarcoma in the general population. After cessation of PTH therapy, bone loss resumes, and all bone gained may be lost over 1 to 2 years. It is strongly recommended that PTH therapy be followed with a bisphosphonate, thus maintaining the gain in BMD achieved with PTH administration. Given the potency of bisphosphonates like alendronate and zoledronic acid, it is not recommended that patients treated with these agents receive teriparatide therapy concomitantly.

B. Androgen  Testosterone increases bone mass in hypogonadal men. Androgens also improve bone mass in osteoporotic women, but therapy is frequently limited by virilizing side-effects. Nandrolone decanoate, 50 mg intramuscularly every 3 weeks, and the androgenic progestin norethisterone acetate increased BMD in osteoporotic women without bothersome side-effects. Fracture data do not yet permit a conclusion about the clinical utility of these agents.

Nonpharmacologic Aspects of Osteoporosis Management

Much of the day-to-day management of osteoporotic patients involves issues that are not specific for bone. These include depression, therapy as appropriate, pain control, maintaining nutritional status, exercise, fall prevention, and assisting the patient to organize activities of daily living.

Minimal attention has been devoted to the role of exercise for patients with established osteoporosis. Patients and physicians often show reluctance to participate in exercise because of concerns for additional injury. However, activity avoidance aggravates bone loss and places the skeleton in even greater jeopardy, whereas improving muscle strength, particularly of the back extensor groups, constitutes a powerful means for reducing pain and increasing functional capacity. Even the most frail individuals can successfully implement exercise regimens with the assistance of a trained physical therapist.

Exercise regimens that include a component of weight bearing and/or resistance exercise have been shown to increase BMD approximately 1% per year in randomized trials. If exercise is discontinued, these gains in BMD are lost.

Because the great majority of hip fractures are the immediate result of a fall, strategies aimed at reduction of falls are of critical importance. Muscle weakness is an important predictor of fall risk, and decreased muscle mass and strength are consequences of normal human aging. Resistance exercise (ie, weight training) promotes muscle strength even in very old men and women, and evidence suggests that increased lower extremity strength may reduce falls risk by improving postural stability. Thus, a widely disseminated program of leg-strengthening exercise could lower the risk of falling and reduce hip fracture incidence even if no changes in BMD are achieved.

Several additional measures may lower the risk of fracture for osteoporotic patients. Proper footwear and installation of safety features around the home may minimize the risk of falling. Such features include bathroom safety rails and night lights, rails and lighting for stairways, and elimination of floor clutter. Canes and other walking aids should be recommended to patients with an unsteady gait. Physicians may need to overcome substantial patient resistance, but these aids can be lifesaving. Visual acuity should be maximized and visual impairments corrected to the
extent possible. Corsets and other support garments stabilize posture and relieve strain on paraspinal muscles. Metal braces may be indicated at times, but they are expensive, poorly accepted by most patients, and frequently end up unused. Attention should be given to other comorbid conditions that may affect fracture risk such as pain and depression and the effects of medications that may cause diminished alertness and responsiveness by causing sedation or orthostatic hypotension.

**GLUCOCORTICOID-INDUCED OSTEOPOROSIS**

In children, chronic exposure to glucocorticoids impairs skeletal growth. Glucocorticoid-induced deficits in childhood bone mass reflect failure of normal skeletal acquisition occasionally compounded by bone loss. In adults, initiation of glucocorticoid therapy leads to rapid bone loss, resulting in significant BMD deficits within even a few months with a greater impact on trabecular than cortical bone. The magnitude of bone loss can be large, typically approaching 40% reduction of the initial BMD. Approximately half of long-term glucocorticoid-treated patients suffer a fracture. Skeletal fragility is not the only risk factor for fracture in steroid-treated patients, because glucocorticoids (and the illnesses for which they are prescribed) are also associated with muscle weakness, which itself creates instability and increases the risk of falling.

Glucocorticoid-induced bone loss generally follows sustained administration of systemic doses greater than 5 mg/d of prednisone or its equivalent. Short, infrequent courses of glucocorticoids, such as for poison oak dermatitis, do not appear to have long-term skeletal consequences. Used according to manufacturer recommendations, most steroid inhalers available in the United States also appear to be without skeletal consequence, because systemic absorption of glucocorticoids is minimal. However, excessive use of standard preparations may achieve systemic concentrations, adequate to suppress the hypothalamic-pituitary axis and predictably lead to loss of bone mass. Patients receiving maintenance hydrocortisone dosages (eg, 20 mg/d) for adrenocortical insufficiency do not generally have an increased skeletal risk. However, based on accurate measurements of steroid production rates in normal humans, maintenance doses of hydrocortisone are now estimated to be lower (ie, 15 mg/d) than have traditionally been recommended (about 30 mg/d). Patients who continue to be treated according to older recommendations may be at risk of excessive bone loss.

**Pathophysiology**

Glucocorticoids affect mineral balance through alterations in renal, intestinal, and skeletal function.

**A. Renal calcium losses** Within a few days after initiating therapy, direct inhibition of renal tubular calcium reabsorption leads to hypercalciuria, which is magnified by excessive dietary sodium intake and attenuated by thiazide diuretics.

**B. Intestinal calcium losses** Glucocorticoids, given in high doses for several weeks, inhibit intestinal calcium absorption, lowering plasma ionized [Ca\(^{2+}\)]. This is thought to stimulate compensatory hypersecretion of PTH, which restores ionized [Ca\(^{2+}\)] by increasing the efficiency of renal calcium reabsorption and by activating bone turnover to increase delivery of calcium to the circulation from bone. However, it has never been shown consistently that plasma PTH concentrations are actually elevated in steroid-treated patients. Evidence suggests that PTH action in bone and kidney may be enhanced even if there are minimal or no increases in detectable PTH. PTH may contribute to the pathophysiology of bone loss in glucocorticoid-treated patients. Consistent effects of glucocorticoids on the production, clearance, and circulating concentrations of vitamin D metabolites have not been demonstrable, so it appears that the intestinal actions of glucocorticoids are independent of the vitamin D system.

**C. Skeletal losses** Glucocorticoids affect the skeleton by multiple mechanisms. There is evidence for direct stimulation of bone resorption via increased RANK-L expression and decreased OPG production. Glucocorticoids also inhibit osteoblastic maturation and activity. Recent information indicates that glucocorticoids shift multipotent stem cell maturation away from osteoblastic lineage toward other cell lines, particularly adipocytes. Glucocorticoids also promote apoptosis in osteoblasts and osteocytes. In patients chronically treated with glucocorticoids, bone formation is suppressed. High-dose glucocorticoid administration also suppresses gonadotropin secretion and creates a hypogonadal state in both men and women. Thus, a component of the bone loss in some steroid-treated patients is likely to be related to loss of gonadal function.

**Prevention and Treatment of Glucocorticoid-Related Osteoporosis**

**A. Reduction of steroid dose** Prevention of bone loss remains the approach most likely to give a favorable outcome. The most important aspect of a preventive strategy is to limit exposure to glucocorticoids and to find alternative treatments if possible. Opportunities should be sought for initiating dose reduction or switching to non systemic forms of steroid administration. Unfortunately, the use of alternate-day steroids, which is known to protect growth in steroid-treated children, appears not to offer skeletal protection to adults. The possibility that a bone-sparing glucocorticoid might be developed has been under consideration for many years, but no such agent is currently available. In patients who require immunosuppression following organ transplantation, the use of cyclosporine and tacrolimus has permitted reductions in glucocorticoid use. However, these newer drugs also have been associated with lower BMD; whether long-term therapy will have less negative skeletal effects than glucocorticoids is not established.

**B. Calcium and vitamin D** Providing supplemental calcium and vitamin D to glucocorticoid-treated patients normalizes
plasma-ionized [Ca\textsuperscript{2+}], suppresses PTH secretion, and reduces bone remodeling, thereby reducing the number of active remodeling units at a given time. So long as the patient continues to take glucocorticoids, however, suppression of osteoblast function does not reverse. Patients should receive 1200 mg/d of supplemental calcium on the condition that such supplementation does not result in hypercalciuria. Vitamin D dosing should be targeted to maintain values at or above the current target of 30 ng/mL. However, periodic surveillance of glucocorticoid-treated patients for urinary calcium excretion is warranted, because they are at higher risk of developing kidney stones as a consequence of hypercalciuria.

**C. Physical activity** Skeletal immobilization precipitates bone loss, so inactivity must be avoided in steroid-treated patients. Some conditions such as polymyalgia rheumatica respond exuberantly to steroid therapy, giving patients a rapid and complete recovery of function. These patients may have little difficulty maintaining a vigorous schedule of weight-bearing activities during treatment. Patients with other conditions may not regain full mobility and may have residual functional disabilities. It is particularly important that such patients receive physical therapy or other appropriate support for maintaining and restoring functional capacity.

**D. Hormone therapy** In some rheumatologic conditions (e.g., systemic lupus erythematosus), estrogens have traditionally been avoided. If there are no contraindications to estrogen administration, HT will counteract the negative skeletal consequences of pituitary-gonadal suppression. Evaluation of gonadal hormone status should be considered in all glucocorticoid-treated patients and estrogen or testosterone therapy utilized where appropriate.

**Pharmacologic Therapy of Glucocorticoid-Related Osteoporosis**

Alendronate, risedronate, zoledronic acid, and teriparatide have been shown to increase BMD and decrease the risk of new vertebral fractures by up to 70% in patients on glucocorticoid therapy.

Because the bone loss associated with glucocorticoid therapy has a very rapid onset and occurs in approximately 50% of treated patients, it is prudent to assess BMD prior to initiating therapy and consider starting a bisphosphonate along with the glucocorticoids in patients whose BMD is already low. Patients with normal BMD may be followed by repeating the BMD at a shorter interval than is typically done with osteoporosis, namely, in 6 to 9 months. If significant bone loss is evident, a bisphosphonate or teriparatide may then be started. All patients should receive appropriate calcium and vitamin D and other risk factors for fracture addressed.

**OSTEOMALACIA AND RICKETS**

Osteomalacia and rickets are caused by the abnormal mineralization of bone and cartilage. Osteomalacia is a bone defect occurring after the epiphyseal plates have closed (i.e., in adults). Rickets occur in growing bone (i.e., in children). Abnormal mineralization in growing bone affects the transformation of cartilage into bone at the zone of provisional calcification. As a result, an enormous profusion of disorganized, nonmineralized, degenerating cartilage appears in this region, leading to widening of the epiphyseal plate (observed radiologically as a widened radiolucent zone) with flaring or cupping and irregularity of the epiphyseal-metaphyseal junctions. This latter problem gives rise to the clinically obvious beaded swellings along the costochondral junctions known as the rachitic rosely and the swelling at the ends of the long bones. Growth is retarded by the failure to make new bone. Once bone growth has ceased (i.e., after closure of the epiphyseal plates), the clinical evidence for defective mineralization becomes more subtle, and special diagnostic procedures may be required for its detection.

**Pathogenesis**

The best-known cause of abnormal bone mineralization is vitamin D deficiency (see discussed earlier). Vitamin D, through its biologically active metabolites, ensures that the calcium and phosphate concentrations in the extracellular milieu are adequate for mineralization. Vitamin D may also permit osteoblasts to produce a bone matrix that can be mineralized and then allows them to mineralize that matrix normally. Phosphate deficiency can also cause defective mineralization, as in diseases in which phosphate is lost in the urine or poorly absorbed in the intestine. Phosphate deficiency may act independently or in conjunction with other predisposing abnormalities, because most hypophosphatemic disorders associated with osteomalacia or rickets also affect the vitamin D endocrine system. Dietary calcium deficiency has been shown to lead to rickets in children in the absence of vitamin D deficiency and may contribute to the osteomalacia of elderly adults who are also susceptible to vitamin D deficiency.

Osteomalacia or rickets may develop despite adequate levels of calcium, phosphate, and vitamin D if the bone matrix cannot undergo normal mineralization as a result of enzyme deficiencies, such as decreased alkaline phosphatase in patients with hypophosphatasia, or in the presence of inhibitors of mineralization, such as aluminum, fluoride, or etidronate. Table 8-14 lists diseases associated with osteomalacia or rickets according to their presumed mechanism. Several diseases appear under several headings, indicating that they contribute to bone disease by several mechanisms.

**Diagnosis**

The following discussion refers primarily to vitamin D deficiency. In children, the presentation of rickets is generally obvious from a combination of clinical and radiologic evidence. The diagnostic challenge is to determine the cause. In adults, the clinical, radiologic, and biochemical evidence of osteomalacia is often subtle. In situations in which osteomalacia should be suspected such as malnutrition or malabsorption, BMD is strikingly low, and the clinician must decide whether to obtain a bone biopsy for histomorphometric examination. This decision rests on the

availability of resources to obtain and examine the biopsy specimen, the index of suspicion coupled with the lack of certainty from other diagnostic procedures, and the degree to which the therapeutic approach will be altered by the additional information. In many cases, a therapeutic trial of vitamin D supplements suffices to establish the diagnosis without the need for bone biopsy.

Clinical Features

A. Symptoms and signs  The clinical presentation of rickets depends on the age of the patient and, to some extent, the cause of the syndrome. The affected infant or young child may be apathetic, listless, weak, hypotonic, and growing poorly. A soft, somewhat misshapen head, with widened sutures and frontal bossing, may be observed. Eruption of teeth may be delayed, and teeth that do appear may be pitted and poorly mineralized. The enlargement and cupping of the costochondral junctions produce the *rachitic rosary* on the thorax. The tug of the diaphragm against the softened lower ribs may produce an indentation at the point of insertion of the diaphragm (Harrison groove). Muscle hypotonia can result in a pronounced potbelly and a waddling gait. The limbs may become bowed, and joints may swell because of flaring at the ends of the long bones (including phalanges and metacarpals) (Figure 8–28). Pathologic fractures may occur in patients with florid rickets. After the epiphyses have closed, the clinical signs of rickets or osteomalacia are subtle and cannot be relied on to make the diagnosis. Patients with severe osteomalacia complain of bone pain and proximal muscle weakness. Difficulty climbing stairs or rising from chairs may be reported and should be looked for. Such individuals may have a history of fractures and be diagnosed as having osteoporosis.

B. Laboratory findings

1. Biochemistry—Vitamin D deficiency results in decreased intestinal absorption of calcium and phosphate. In conjunction with the resulting secondary hyperparathyroidism, vitamin D deficiency leads to an increase in bone resorption, increased excretion of urinary phosphate, and increased renal tubular reabsorption of calcium. The net result tends to be low-normal...

FIGURE 8–28 The clinical appearance of a young child with rickets. The most striking abnormalities are the bowing of the legs and protuberant abdomen. Flaring of the ends of the long bones can also be appreciated. (Photograph courtesy of Dr. Sara Arnaud.)
serum calcium, low serum phosphate, elevated serum alkaline phosphatase, increased PTH, decreased urinary calcium, and increased urinary phosphate levels. Finding a low 25(OH)D level, in combination with these other biochemical alterations, strengthens the diagnosis of vitamin D deficiency. The 1,25(OH)2D level may be normal, making this determination less useful for the diagnosis of osteomalacia. Both 25(OH)D and 1,25(OH)2D levels may be reduced in patients with liver disease or nephrotic syndrome because the binding proteins for the vitamin D metabolites are low secondary to decreased production (liver disease) or increased renal losses (nephrotic syndrome; see later). Such individuals may have normal free concentrations of these metabolites and so are not vitamin D deficient. Other factors, such as age and diet, must be considered. For example, serum phosphate values are normally lower in adults than in children. Dietary history is important, because urinary phosphate excretion and, to a lesser extent, urinary calcium excretion reflect dietary phosphate and calcium content. Because phosphate excretion depends on the filtered load (the product of the glomerular filtration rate and plasma phosphate concentration), urinary phosphate levels may be reduced despite the presence of hyperparathyroidism, when serum phosphate levels are particularly low. Expressions of renal phosphate clearance that account for these variables (eg, renal threshold for phosphate, or \( T_{\text{n}}P/GFR \)) are a better indicator of renal phosphate handling than is total phosphate excretion. The \( T_{\text{n}}P/GFR \) can be calculated from a nomogram using measurements of a fasting serum and urine phosphate concentration.

2. Histologic examination—Transcortical bone biopsy is the definitive means of making the diagnosis of osteomalacia. A rib or the iliac crest is the site at which biopsy is usually performed. To assess osteoid content and mineral appositional rate, the bone biopsy specimen is processed without decalcification. This requires special equipment. In osteomalacia, bone is mineralized poorly and slowly, resulting in wide osteoid seams (>12 μm) and a large fraction of bone covered by unmineralized osteoid. States of high bone turnover (increased bone formation and resorption), such as hyperparathyroidism, can also cause wide osteoid seams and an increased osteoid surface, producing a superficial resemblance to osteomalacia. Therefore, the rate of bone turnover should be determined by labeling bone with tetracycline, which provides a fluorescent marker of the calcification front. When two doses of tetracycline are given at different times, the distance between the two labels divided by the time interval between the two doses equals the mineral appositional rate. The normal appositional rate is approximately 0.74 μm/d. Mineralization lag time—the time required for newly formed osteoid to be mineralized—can be calculated by dividing osteoid seam width by the appositional rate corrected by the linear extent of mineralization of the calcification front (a measure of the bone surface that is undergoing active mineralization as measured by tetracycline incorporation). Mineralization lag time is normally about 20 to 25 days. Bone formation rate is calculated as the product of the appositional rate times the linear extent of mineralization of the calcification front. Depressed appositional rate, increased mineralization lag time, and reduced bone formation rate clearly distinguish osteomalacia from high-turnover states such as hyperparathyroidism. Low-turnover states, as can be seen in various forms of osteoporosis, also have low appositional and bone formation rates, but these conditions are distinguished from osteomalacia by normal or reduced osteoid surface and volume.

C. Imaging studies The radiologic features of rickets can be quite striking, especially in the young child. In growing bone, the radiolucent epiphyses are wide and flared, with irregular epiphyseal-metaphyseal junctions. Long bones may be bowed. The cortices of the long bones are often indistinct. Occasionally, evidence of secondary hyperparathyroidism—subperiosteal resorption in the phalanges and metacarpals and erosion of the distal ends of the clavicles—is observed. Pseudofractures (also known as looser zones or milkman fractures) are an uncommon but nearly pathognomonic feature of rickets and osteomalacia (Figure 8–29). These radiolucent lines are most often found along the concave side of the femoral neck, pubic rami, ribs, clavicles, and lateral aspects of the scapulae. Pseudofractures may result from unhealed microfractures at points of stress or at the entry point of blood vessels into bone. They may progress to complete fractures that go unrecognized and thus lead to substantial deformity and disability. BMD is not a reliable indicator of osteomalacia, because BMD can be decreased in patients with vitamin D deficiency or increased in patients with chronic renal failure. In adults with normal renal function, radiologic evidence of a mineralization defect is often subtle and not readily distinguished from osteoporosis, with which it often coexists.

Treatment

The treatment of vitamin D deficiency is covered under that heading. The treatment of other diseases causing rickets or osteomalacia is found below under the specific disease headings.

NPHROTIC SYNDROME

Nephrotic syndrome may lead to osteomalacia because of losses of vitamin D metabolites in the urine. Vitamin D metabolites are tightly bound to DBP, an α-globulin, and less tightly bound to
albumin as described earlier. Patients with the nephrotic syndrome may lose large amounts of DBP and albumin in their urine and so deplete their vitamin D stores. Such patients can have very low levels of vitamin D metabolites in their serum, although the free concentrations are less affected. Thus, the measurement of total 25(OH)D or 1,25(OH)2D may be misleading with respect to the severity of the vitamin D deficiency. Although bone disease has been recognized as a complication of the nephrotic syndrome, the prevalence of osteomalacia in this population is unknown. If vitamin D deficiency is suspected, treatment with vitamin D is indicated with the proviso that normal total levels of 25(OH)D and 1,25(OH)2D are not the goal. Blood levels of calcium, phosphate, and PTH are a more reliable guide to treatment.

HEPATIC OSTEODYSTROPHY

Hepatic osteodystrophy is the bone disease associated with liver disease. In the United States, patients with severe liver disease generally have osteoporosis, not osteomalacia. Both osteomalacia and osteoporosis are found in patients with liver disease in Great Britain, where vitamin D deficiency is more common. Although the liver is the site of the first step in the bioactivation of vitamin D—the conversion of vitamin D to 25(OH)D—this process is not tightly controlled, and until the liver disease is severe it is not rate limiting. Neither cholestatic nor parenchymal liver disease has much effect on 25(OH)D production until the late stages of liver failure. The low levels of 25(OH)D and 1,25(OH)2D associated with liver disease can usually be attributed to the reduced production of DBP and albumin, poor nutrition, or malabsorption rather than a deficiency in the vitamin D 25-hydroxylase. As in patients with the nephrotic syndrome, the low total levels of the vitamin D metabolites may be misleading, as they reflect a reduction in DBP and albumin rather than a reduction in the free concentrations of these metabolites.

DRUG-INDUCED OSTEOMALACIA

Phenytoin and phenobarbital are anticonvulsants that induce drug-metabolizing enzymes in the liver that alter the hepatic metabolism of vitamin D and its metabolites. This action is not limited to anticonvulsants; the antituberculosis drug rifampin has been reported to do likewise. This effect may account for the lower circulating levels of 25(OH)D found in patients treated with such drugs. Levels of 1,25(OH)2D are less affected. Chronic anticonvulsant or antituberculosis therapy does not appear to lead to clinically significant bone disease except in subjects with other predisposing factors such as inadequate sunlight exposure (institutionalized patients) and poor nutrition. Children may be more vulnerable than adults. In animal studies, phenytoin has been noted to exert a direct inhibitory effect on bone mineralization, but the relevance of this observation to the human use of this drug is uncertain. The decrease in 25(OH)D levels in patients taking these drugs can be readily reversed with supplemental vitamin D administration.

HYPOPHOSPHATEMIC DISORDERS

Chronic hypophosphatemia may lead to rickets or osteomalacia independently of other predisposing abnormalities. The principal diseases in which hypophosphatemia is associated with osteomalacia or rickets, however, also include other abnormalities that can interfere with bone mineralization. Chronic phosphate depletion is caused by dietary deficiency (as in strict vegetarians), decreased intestinal absorption, or increased renal clearance (renal wasting). Acute hypophosphatemia can result from movement of phosphate into cells (eg, after infusion of insulin and glucose), but this condition is transient and does not result in bone disease.

Seventy to ninety percent of dietary phosphate is absorbed under normal conditions in the jejunum. This process is not tightly regulated, although 1,25(OH)2D stimulates phosphate absorption, a factor that needs to be considered when calcitriol is being used to treat other conditions. Meat and dairy products are the principal dietary sources of phosphate. The incidence of osteomalacia in vegetarians who avoid all meat and dairy products is unknown, but its occurrence has been reported. Intrinsic small bowel disease and small bowel surgery interfere with phosphate absorption and, if coupled with diarrhea or steatorrhea, can result in phosphate depletion. A number of antacids (eg, Mylanta, Maalox, Basaljel, and Amphojel) contain aluminum hydroxide, which binds phosphate and prevents its absorption. Patients who ingest large amounts of these antacids may become phosphate depleted. When this occurs in the setting of renal failure, reductions in serum phosphate plus aluminum intoxication in these individuals, who also have reduced 1,25(OH)2D production, can produce profound osteomalacia. Eighty-five to ninety percent of the phosphate filtered by the glomerulus is reabsorbed, primarily in the proximal tubule. This process is regulated by PTH which reduces renal tubular phosphate reabsorption. It is also probably regulated by various vitamin D metabolites that appear to increase renal tubular phosphate reabsorption, and importantly by FGF23, which blocks the insertion of sodium phosphate cotransporters into and increases their internalization from the luminal membrane of renal proximal tubular cells. Many diseases that affect renal handling of phosphate are associated with osteomalacia—especially those also associated with abnormalities in vitamin D metabolism and in FGF23 production and or clearance, as discussed later (see also Chapter 21).

Treatment of phosphate deficiency is generally geared to correction of the primary problem. Oral preparations of phosphate (and the amounts required to provide 1 g of elemental phosphorus) include Fleet Phospho-soda (6.12 mL) and Neutra-Phos (300 mL). These preparations are usually given in amounts that provide 1 to 3 g of phosphorus daily in divided doses, although diarrhea may limit the dose. Careful attention to both serum calcium and serum phosphate concentrations is required to avoid hypocalcemia, ectopic calcification, or secondary hyperparathyroidism.
**X-Linked and Autosomal Dominant Hypophosphatemia**

X-linked hypophosphatemia (XLH), formerly called vitamin D-resistant rickets, is characterized by renal phosphate wasting, hypophosphatemia, and decreased 1,25(OH)_{2}D production relative to the degree of hypophosphatemia. Clinical presentation is variable, but children often present with florid rickets. This X-linked dominant disorder generally affects males more severely than females. A similar but genetically distinct syndrome, autosomal dominant hypophosphatemic rickets (ADHR), is less common, affects females to the same extent as males, and may present later in life (second to fourth decades). Animal studies have indicated that the cause of the renal phosphate wasting in XLH is humoral rather than a structural defect in the phosphate transporter itself. Recent evidence strongly suggests that this humoral factor is FGF23, although other candidates have been proposed. Circulating FGF23 appears to be responsible for both the reduction in phosphate reabsorption in the renal proximal tubule and the blunted response of the proximal tubule to the ensuing hypophosphatemia with respect to 1,25(OH)_{2}D production. The gene responsible for XLH has been identified and is called PHEX. It shares structural homology with a number of endopeptidase genes and is located on the X chromosome. As is implicit in this ambiguous name, the role of PHEX in renal phosphate transport is not clear. The prevailing hypothesis is that PHEX indirectly leads to the cleavage and subsequent inactivation of FGF23, thus relieving the inhibition of phosphate reabsorption and 1,25(OH)_{2}D production.

ADHR is due to a mutation in FGF23 that renders it resistant to cleavage. Recent evidence suggests that the defects in XLH and ADHR may not be restricted to the proximal renal tubule but may affect osteoblast function as well, a cell in which PHEX is expressed. With the recent cloning of PHEX and FGF23, our understanding of these diseases should rapidly increase.

Treatment of XLH and ADHR generally requires a combination of phosphate (1-4 g/d in divided doses) combined with calcitriol (1-3 μg/d) as tolerated. Vitamin D is less effective than calcitriol and should not be used for this condition. Appropriate therapy heals the rachitic lesions and increases growth velocity. A frequent complication of these diseases, however, is the development of hyperparathyroidism, which may become autonomous and require parathyroidectomy. It is unclear whether the hyperparathyroidism is a complication of therapy or intrinsic to the disease process itself. Treatment with phosphate and calcitriol may also lead to ectopic calcification, including nephrocalcinosis. Thus, these patients need to be followed closely.

**Tumor-Induced Osteomalacia**

The association of osteomalacia and hypophosphatemia with tumors, primarily of mesenchymal origin, has been recognized for half a century (see Chapter 21). The cause of this syndrome has until recently remained obscure. Removal of the tumors, which are often small and difficult to find, cures the disease. Although most implicated tumors are mesenchymal, including fibromas and osteoblastomas, other tumors, including breast, prostate, and lung carcinomas; multiple myeloma; and chronic lymphocytic leukemia have been associated with this syndrome. The patient generally presents with bone pain, muscle weakness, and osteomalacia. Symptoms may occur for years before the diagnosis is made. Renal phosphate wasting, hypophosphatemia, and normal serum calcium and 25(OH)D levels but inappropriately low 1,25(OH)_{2}D levels characterize the disease. Thus, it resembles XLH or ADHR. Tumor extracts contain molecules that inhibit renal phosphate transport and 1,25(OH)_{2}D production, suggesting that a phosphate-regulating substance or phosphatonin is involved. Thus, it was of great interest to observe that many of these tumors overproduce FGF23 and that production by the tumor of FGF23 can explain the metabolic abnormalities associated with the hypophosphatemic syndrome (see Figure 8–10). Other tumor products such as MEPE (matrix extracellular phosphoglycoprotein) and sFRP4 (secreted frizzled related protein 4) have also been implicated. The best treatment is removal of the tumor, but this is not always possible. Phosphate and calcitriol have been the mainstays of treatment but with limited success. Patients should be dosed to tolerance as in XLH and ADHR.

**Fibrous Dysplasia**

Fibrous dysplasia results from activating mutations in the GNAS gene, which encodes Gs alpha. Fibrous dysplasia of bone is a component of the McCune-Albright syndrome. The bony lesions in this disorder overproduce FGF23 which like tumor-induced osteomalacia, described above, leads to hypophosphatemia, osteomalacia, and inappropriately normal 1,25(OH)_{2}D. These lesions can be mono-ostotic or polyostotic, with the extent of bone involved correlating with the degree of FGF23 hypersecretion, and hence the hypophosphatemia observed.

**De Toni-Debré-Fanconi Syndrome and Hereditary Hypophosphatemic Rickets with Hypercalciuria**

The De Toni-Debré-Fanconi syndrome includes a heterogeneous group of disorders affecting the proximal tubule and leading to phosphaturia and hypophosphatemia, aminoaciduria, glycosuria, bicarbonaturia, and proximal renal tubular acidosis. Not all features must be present to make the diagnosis. Damage to the renal proximal tubule secondary to genetic or environmental causes is the underlying cause. This syndrome may be divided into two types depending on whether vitamin D metabolism is also abnormal. In the more common type I, 1,25(OH)_{2}D production is reduced relative to the degree of hypophosphatemia. In type II, 1,25(OH)_{2}D production is appropriately elevated in response to the hypophosphatemia, and this leads to hypercalciuria. The reason that 1,25(OH)_{2}D production is reduced in type I, despite the hypophosphatemia, is unclear but may suggest damage to the mitochondria where the 1-hydroxylase is located.

The type II Fanconi syndrome shares the principal features of hereditary hypophosphatemic rickets with hypercalciuria (HHRH).
This rare disorder results from mutations in SLC34A3, the gene that encodes the type IIc sodium phosphate cotransporter (NaPillc), leading to loss of function of this transporter. Mutations in NaPilla, the other major renal sodium phosphate cotransporter, produces a similar picture. The key difference between HHRH and ADHR or XLH is that FGF23 is not elevated—so 1-hydroxylase activity is not suppressed. Thus, the hypophosphatemia leads to increased 1,25(OH)2D production, increased intestinal calcium absorption, and hypercalcemia. HHRH is heterogeneous in clinical presentation, but in severely affected individuals, it begins in childhood with bone pain and skeletal deformities. The syndrome is characterized by renal phosphate wasting and hypophosphatemia, hypercalcemia and normal serum calcium, and elevated 1,25(OH)2D levels. The osteomalacia associated with these renal phosphate-wasting syndromes is probably the result of the hypophosphatemia, with contributions from the acidosis and decreased 1,25(OH)2D levels in the type I syndrome.

The ideal treatment is correction of the underlying defect, which may or may not be identified and/or reversible. Otherwise, treatment includes phosphate supplementation in all cases, correction of the acidosis, and 1,25(OH)2D replacement in the type I syndrome, but not in HHRH as this will aggravate the hypercalcemia.

CALCIUM DEFICIENCY

Calcium deficiency may contribute to the mineralization defect that complicates gastrointestinal disease and proximal tubular disorders, but it is less well established as a cause of osteomalacia than is vitamin D or phosphate deficiency. In carefully performed studies of children who ingested a very low-calcium diet in Africa, there was clinical, biochemical, and histologic evidence of osteomalacia. The serum phosphate and 25(OH)D and 1,25(OH)2D levels were normal; serum alkaline phosphatase levels were elevated; and serum and urine calcium levels were low. Because intestinal absorption of calcium decreases with age, the daily requirement for calcium increases from approximately 800 mg in young adults to 1400 mg in the elderly. Calcium deficiency can result not only from inadequate dietary intake but also from excessive fecal and urinary losses. Except in cases in which a renal leak of calcium plays an important role in the etiology of calcium deficiency (certain forms of idiopathic hypercalcemia or following glucocorticoid therapy for inflammatory diseases), urinary calcium excretion provides a useful means to determine the appropriate level of oral calcium replacement. Because of its low cost and high percentage of elemental calcium, calcium carbonate is the treatment of choice.

PRIMARY DISORDERS OF THE BONE MATRIX

Several diseases lead to abnormalities in bone mineralization because of intrinsic defects in the matrix or in the osteoblast producing that matrix. With the exception of osteogenesis imperfecta, these tend to be rare. Examples are listed below.

OSTEOGENESIS IMPERFECTA

Osteogenesis imperfecta is a heritable disorder of connective tissue due to a qualitative or quantitative abnormality in type I collagen, the most abundant collagen in bone. The disease is typically transmitted in an autosomal dominant mode, although autosomal recessive inheritance has also been described. Clinical expression is highly variable, depending on the location and type of mutation observed. Although skeletal deformity and fracture are the hallmarks of this disease, other tissues are often affected, including the teeth, skin, ligaments, and scleras. Routine biochemical studies of bone and mineral metabolism are generally normal; however, elevated serum alkaline phosphatase and increased excretion of biochemical markers of bone turnover and calcium are often found. Bone histology shows abundant disorganized, poorly mineralized matrix but with a high rate of bone turnover as reflected by increased tetracycline labeling.

Treatment is supportive and includes orthopedic, rehabilitative, and dental intervention as appropriate. Bisphosphonates have recently been shown to be of value in children to prevent fractures and reduce bone pain and skeletal morbidity.

Hypophosphatasia

Hypophosphatasia, transmitted in an autosomal recessive or dominant pattern, has considerable variability in clinical expression ranging from a severe form of rickets in children to a predisposition to fractures in adults. The biochemical hallmarks are low serum and tissue levels of alkaline phosphatase (liver-bone-kidney but not intestine-placenta) and increased urinary levels of phosphoethanolamine. Serum calcium and phosphate levels may be high, and many patients have hypercalcemia. Levels of vitamin D metabolites and PTH are generally normal. In some families, a mutation in the alkaline phosphatase gene has been identified. Radiologic examination shows osteopenia, with the frequent occurrence of stress fractures and chondrocalcinosis. Bone biopsy specimens show osteomalacia. It is not clear why these patients develop osteomalacia or rickets. Skeletal alkaline phosphatase cleaves pyrophosphate, an inhibitor of bone mineralization. Thus, patients deficient in alkaline phosphatase may be unable to hydrolyze this inhibitor and so develop a mineralization defect.

There is no established medical therapy. Use of vitamin D or its metabolites may further increase the already elevated serum calcium and phosphate and should not be used.

Fibrogenesis Imperfecta Ossium

Fibrogenesis imperfecta ossium is a rare, painful disorder that affects middle-aged subjects in what appears to be a sporadic fashion. Serum alkaline phosphatase activity is increased. The bones have a dense, amorphous mottled appearance radiologically and a disorganized arrangement of collagen with decreased birefringence histologically when viewed with polarized light microscopy. Presumably, the disorganized collagen matrix retards normal bone mineralization. There is no specific therapy.
Axial Osteomalacia
This rare disease involves only the axial skeleton and affects mostly middle-aged or elderly males. Most cases are sporadic. It is not particularly painful. Alkaline phosphatase activity may be increased, but calcium, phosphate, and vitamin D metabolite levels are normal. Histologically, the bone shows increased osteoid and reduced tetracycline incorporation. The reason for the mineralization disorder is uncertain. No effective medical therapy has been established.

INHIBITORS OF MINERALIZATION
Several drugs are known to cause osteomalacia or rickets by inhibiting mineralization. However, the mechanisms by which this occurs are not fully understood.

Aluminum
Aluminum-induced bone disease is found primarily in patients with renal failure on chronic hemodialysis and in patients being treated with total parenteral nutrition (TPN). With the recognition of this complication and the switch to deionized water for dialysis, decreased use of aluminum-containing antacids, and the use of purified amino acids rather than casein hydrolysates (which contained large amounts of aluminum) for TPN, the incidence and prevalence of this complication have been markedly reduced. The problem, however, still exists. As described under renal osteodystrophy, the bone disease is osteomalacia and can be severe and painful. Aluminum deposits in the mineralization front and appears to inhibit the mineralization process. Removal of the aluminum with deferoxamine chelation therapy is the treatment of choice.

Fluoride
Fluoride is a potent stimulator of bone formation. If administered at high doses with inadequate calcium supplementation, the bone formed as a result is poorly mineralized. The mechanisms underlying the effects of fluoride on osteoblast function and bone mineralization remain unclear.

PAGET DISEASE OF BONE (OSTEITIS DEFORMANS)
Paget disease is a focal disorder of bone remodeling that leads to greatly accelerated rates of bone turnover, disruption of the normal architecture of bone, and sometimes to gross deformities of bone. As a focal disorder it is not, strictly speaking, a metabolic bone disease. Paget disease is prevalent in northern Europe, particularly in England and Germany. It is also common in the United States but is unusual in Africa and Asia.

Etiology
It has long been thought that Paget disease, with its late onset and spotty involvement of the skeleton, might be due to a chronic slow virus infection of bone. Inclusion bodies that resemble paramyxovirus inclusions have been identified in pagetic osteoclasts, and the presence of measles virus transcripts has been detected by molecular techniques. However, considerably more work would be required to prove the infectious etiology of Paget disease. There are also familial clusters of the disease, with up to 20% of patients in some studies having afflicted first-degree relatives so a heterogeneity of pathogenetic mechanisms is likely (see later).

Pathology
At the microscopic level, the disorder is characterized by highly vascular and cellular bone, consistent with its high metabolic activity. The osteoclasts are sometimes huge and bizarre, with up to 100 nuclei per cell. Because pagetic osteoclasts initiate the bone remodeling cycle in a chaotic fashion, the end result of remodeling is a mosaic pattern of lamellar bone. Paget disease (and other high turnover states) can also produce woven bone—bone that is laid down rapidly and in a disorganized fashion, without the normal lamellar architecture.

Pathogenesis
Abnormal osteoclastic bone resorption is the probable initiating event in Paget disease. Not only are the osteoclasts very abnormal histologically and prone to unruly behavior, but some forms of the disease are marked by an early resorptive phase in which pure osteolysis occurs without an osteoblastic response. Additionally, Paget disease responds dramatically to inhibitors of osteoclastic bone resorption.

The rate of bone resorption is often increased by as much as 10- to 20-fold, and this is reflected in biochemical indices of bone resorption. Over the skeleton as a whole, osteoblastic new bone formation responds appropriately to this challenge. Even though local disparities in remodeling may result in areas with the radiographic appearance of osteolysis or dense new bone, there is a close relationship between biochemical markers of bone resorption (eg, N-telopeptide, C-telopeptide, deoxypyridinoline) and formation (eg, alkaline phosphatase, osteocalcin). Because this tight coupling is maintained in Paget disease, in the face of enormously increased skeletal turnover rates, systemic mineral homeostasis is usually unperturbed.

Genetic Forms
Approximately 20% of patients with Paget disease have a positive family history. This interesting observation plus the uncertain viral etiology has led several groups to determine the genetic loci responsible for the disease. These studies plus work done to unravel the molecular defects in patients with rare but clear disorders of accelerated and unregulated bone remodeling have shed light on molecular pathways that may be important in sporadic Paget disease.

Mutations in RANK and OPG are important in the pathogenesis of high bone remodeling states. Whyte and colleagues investigated two unrelated Navajo patients with autosomal recessive juvenile Paget disease in whom they found approximately 100-kb
deletions of the gene encoding TNFRSF11B or OPG on chromosome 8q24.2. In two other clinical disorders of high bone remodeling designated as familial expansile osteolysis and expansile skeletal hyperphosphatasia, tandem duplications are present within the signal peptide of RANK, leading to a gain-of-function in the activity of RANK. This is predicted to enhance osteoclastogenesis.

Familial Paget disease is not, however, generally explained by abnormalities in RANK or OPG genes. In contrast, several groups have uncovered mutations in SQSTM1 or sequestosome 1 (also known as p62) in multiple kindreds with Paget disease. SQSTM1 is a ubiquitin-binding protein involved in signaling pathways for IL-1, TNF, and RANKL—all molecules important in the production and function of osteoclasts. A variety of different SQSTM1 mutations are thought to explain approximately 30% of cases of familial Paget disease. The identification of additional candidate genes is in progress.

**Clinical Features**

**A. Symptoms and signs** Typical Paget disease may affect any of the bones, but the most common sites are the sacrum and spine (50% of patients), femur (46%), skull (28%), and pelvis (22%). The clinical features of Paget disease are pain, fractures, deformity, and manifestations of the neurologic, rheumatologic, or metabolic complications of the disease. However, at least two-thirds of patients are asymptomatic. Thus, Paget disease is often discovered as an incidental radiologic finding or during the investigation of an elevated alkaline phosphatase level. On physical examination, enlargement of the skull, frontal bossing, or deafness may be evident. Involvement of the weight-bearing long bones of the lower extremity often results in bowing. The femur and tibia bow anteriorly and laterally, but the fibula is almost never affected. Cutaneous erythema and warmth, as well as bone tenderness, may be evident over affected areas of the skeleton, reflecting greatly increased blood flow through pagetic bone. The findings of pain, warmth, and erythema led to the appellation osteitis deformans, although Paget disease is not truly an inflammatory disorder. The most common fractures in Paget disease are vertebral crush fractures and incomplete fissure fractures through the cortex, usually on the convex surface of the tibia or femur. Affected bones may fracture completely; when they do, healing is usually rapid and complete—the increased metabolic activity of pagetic bone seems to favor fracture healing.

**B. Laboratory findings** The serum alkaline phosphatase activity is usually increased, sometimes to very high levels. Levels of biochemical markers of bone turnover are often high, but it is not clear that their determination offers any special advantage over that of serum alkaline phosphatase activity. The serum calcium and phosphate concentrations and the urinary calcium excretion are normal, although if a patient sustains a fracture and becomes immobilized, hypercalciuria and hypercalcemia may occur.

**C. Imaging studies** The early stages of Paget disease are often osteolytic. Examples are erosion of the temporal bone of the skull, osteoporosis circumscripta, and pagetic lesions in the extremities, which begin in the metaphysis and migrate down the shaft as a V-shaped resorptive front (Figure 8–30). Over years or even decades, the typical mixed picture of late Paget disease evolves. Trabeculae are thickened and coarse. The bone may be enlarged or bowed. In the pelvis, the iliopectineal line or pelvic brim is often thickened (Figure 8–31). In the spine, osteoblastic lesions of the vertebral bodies may present a picture-frame appearance or a homogeneously increased density, the ivory vertebra. Associated osteoarthritis may present with narrowing of the joint space (see Figure 8–31). Osteosarcoma may present with cortical destruction or a soft tissue mass (see Figure 8–31). Radionuclide bone scanning with technetium-labeled bisphosphonates or other bone-seeking agents is uniformly positive in active Paget disease and is useful for surveying the skeleton when a focus of Paget disease has been found radiographically (Figure 8–32) or the disease is suspected.

**Complications**

Complications of Paget disease may be neurologic, otologic, rheumatologic, neoplastic, or cardiac (Table 8–15).
FIGURE 8–31  Paget disease of the right femur and pelvis. The right femur displays cortical thickening and coarse trabeculation. The right ischium is enlarged, with sclerosis of ischial and pubic rami and the right ilium. Two complications of Paget disease are present. There is concentric bilateral narrowing of the hip joint space, signifying osteoarthritis. The destructive lesion interrupting the cortex of the right ilium is an osteosarcoma. (Reproduced, with permission, from Strewler GJ. Paget disease of bone. West J Med. 1984;140:763.)

FIGURE 8–32  Bone scan of a patient with Paget disease of the pelvis, right femur, and acetabulum. Note localization of bone-seeking isotope (⁹⁹ᵐTc-labeled bisphosphonate) in these areas.

A. Neurologic/Otologic  The brain, spinal cord, and peripheral nerves are all at risk. Sensorineural deafness occurs in up to 50% of patients in whom the skull is involved, and compression of the other cranial nerves can also occur. At the base of the skull, Paget disease can produce platybasia and basilar impression of the brain stem, with symptoms of brain stem compression, obstructive hydrocephalus, or verteobasilar insufficiency. Spinal stenosis is common in vertebral Paget disease, in part because the pagetic vertebra can be enlarged, and may extend posteriorly when collapse occurs, but spinal stenosis responds well to medical treatment of the disease.

B. Rheumatologic  Osteoarthritis is common in Paget disease. It may be an unrelated finding in elderly patients with the disorder, or it may result directly from pagetic deformities and their effects on wear and tear in the joints. Arthritis presents a conundrum to the clinician attempting to relieve pain, as it may be difficult to determine whether the pain originates in pagetic bone or in the nearby joint. An association of osteitis deformans and gout was first noted by James Paget himself, and asymptomatic hyperuricemia is also common.

C. Neoplastic  The most dreaded complication of Paget disease is development of a sarcoma. The tumor arises in pagetic bone, typically in individuals with polyostotic involvement, and may present with soft tissue swelling, increased pain, or a rapidly increasing alkaline phosphatase. Osteosarcoma, chondrosarcoma, and giant cell tumors all occur in Paget disease, with a combined incidence of about 1%. Because osteosarcoma is otherwise uncommon in the elderly, fully 30% of elderly patients with osteosarcoma have underlying Paget disease.

D. Cardiac  High-output congestive heart failure occurs rarely and is due to markedly increased blood flow to bone, usually in patients with more than 50% involvement of the skeleton.

Treatment  In a patient known to have Paget disease, bone pain that is unresponsive to nonsteroidal anti-inflammatory agents deserves a trial of specific therapy. As noted earlier, it may not be easy to
differentiate pagetic bone pain from that due to osteoarthritis. The other indications for treatment of Paget disease are controversial. Treatment has been advocated for neurologic compression syndromes, as preparation for surgery, and to prevent deformities. Neurologic deficits often respond to medical treatment, and a trial of treatment is often warranted. Pretreatment for 2 to 3 months before orthopedic surgery prevents excessive bleeding and postoperative hypercalcemia, but satisfactory bone healing usually occurs without medical treatment. Paget disease is sometimes treated in the hope of arresting the progress of deformities (eg, bowing of the extremities and resultant osteoarthritis), but it is not certain whether medical treatment can achieve this aim or whether it will arrest the progression of deafness in patients with skull involvement.

Two classes of agents are used in the treatment of Paget disease: bisphosphonates and CT. Both inhibit osteoclastic bone resorption.

A. Bisphosphonates The oral bisphosphonates (alendronate and risedronate) are commonly used in the treatment of Paget disease. Alendronate is administered at a dose of 40 mg daily for 6 months. On average, alkaline phosphatase activity is suppressed by about 80% using such treatment. Biochemical remissions are often prolonged for more than 1 year, after the drug is stopped. The main side-effect is gastrointestinal upset, requiring discontinuation of therapy in about 6% of patients. Risedronate, given at a dosage of 30 mg/d for 2 months, is also highly efficacious in lowering and even normalizing alkaline phosphatase activity and reducing bone pain. For patients with gastrointestinal intolerance to oral bisphosphonates or more severe bony involvement, it may be more convenient or appropriate to administer intravenous bisphosphonates. If the disease is highly active and surgery is planned in the immediate future, intravenous therapy is generally preferred. Pamidronate, an amino-bisphosphonate closely related to alendronate, has been used for this purpose. Intravenous infusions of pamidronate (60 or 90 mg) produce a high remission rate and a durable response. More recently, intravenous zoledronic acid (5 mg) has been shown to be efficacious, in terms of both the strength and duration of alkaline phosphatase suppression, in patients with Paget disease. The principal side-effect observed with intravenous aminobisphosphonate administration is an acute-phase response, including fever and myalgias, that occurs in about 10% of patients and may last for several days after a dose. A very small percentage of patients receiving multiple and typically high doses of intravenous bisphosphonates can develop osteonecrosis of the jaw.

B. Calcitonin Salmon CT is administered initially at a dosage of 50 to 100 IU daily until symptoms are improved; thereafter, many patients can be maintained on 50 units three times a week. Improvement in pain is usually evident within 2 to 6 weeks. On average, the alkaline phosphatase falls by 50% within 3 to 6 months. Many patients have a sustained response to treatment extending over years, and biochemical parameters are often suppressed for 6 months to 1 year after treatment is discontinued. Up to 20% of patients receiving chronic CT treatment develop late resistance to CT, which may be antibody-mediated. Data on the use of nasal spray CT's efficacy in Paget disease are limited.

**RENAL OSTEODYSTROPHY**

**Pathogenesis**

Metabolism of 25(OH)D to 1,25(OH)₂D and 24,25(OH)₂D in the kidney is tightly regulated. Renal disease results in reduced circulating levels of both of these metabolites. With the reduction in 1,25(OH)₂D levels, intestinal calcium absorption falls, and bone resorption appears to become less sensitive to PTH—a result that leads to hypocalcemia. Phosphate excretion by the diseased kidney is decreased, resulting in hyperphosphatemia, which amplifies the fall in serum calcium and independently increases PTH secretion. The fall in serum calcium combined with the low levels of 1,25(OH)₂D, which is an inhibitor of PTH secretion, and the hyperphosphatemia result in hyperparathyroidism (Figure 8-33). The parathyroid glands, under chronic proliferative stimulation in uremic individuals, can develop clonal expansion of cells that harbor mutations in known parathyroid growth-promoting genes. This can result in nodular hyperplasia. In addition, the expression of both VDRs and CaSRs is often depressed in tissues from individuals with chronic secondary hyperparathyroidism. Both calcium, likely acting via CaSRs, and 1,25(OH)₂D, acting via VDRs, exert inhibitory effects on parathyroid cell growth. Furthermore, the hyperphosphatemia of uremia stimulates FGF23 production by bone, and this can further inhibit 1,25(OH)₂D production.

![Figure 8-33 Pathogenesis of renal secondary hyperparathyroidism.](image-url)
The net effect of deficient 1,25(OH)₂D and 24,25(OH)₂D and excess PTH and FGF23 on bone in uremia is complex. Patients may have osteitis fibrosa (reflecting excessive PTH), osteomalacia (in part reflecting decreased vitamin D metabolites and high FGF23 which have complex effects on bone mineralization), or a combination of the two. One particularly debilitating form of renal osteodystrophy is now found in an increasing percentage of patients on hemodialysis in whom only osteomalacia occurs. Rarely now, some patients have increased aluminum content in their bones, particularly in the region where mineralization is occurring (calcification front), and this appears to inhibit mineralization. More commonly, however, these patients do not have aluminum excess or increased osteoid but have low bone turnover, a state termed adynamic bone disease. These patients are particularly prone to develop symptoms of bone pain, fractures, and muscle weakness, and are particularly sensitive to developing hypercalcemia when treated with calcitriol despite the relatively low levels of PTH.

**Clinical Features**

Most patients with renal osteodystrophy have osteitis fibrosa alone or in combination with osteomalacia. If not well controlled, these patients will have a low serum level of calcium and high serum levels of phosphorus, alkaline phosphatase, and PTH. A few patients develop severe secondary hyperparathyroidism in which the PTH level increases dramatically and stays elevated even with restoration of the serum calcium to normal. Such patients are prone to developing hypercalcemia with the usual replacement doses of calcium (sometimes referred to as tertiary hyperparathyroidism). Another subset of patients with renal osteodystrophy present with relatively normal levels of PTH and alkaline phosphatase. Their serum calcium levels are often elevated after treatment with small doses of calcitriol. These patients generally have adynamic bone disease on bone biopsy and may suffer from aluminum intoxication (see discussed earlier).

**Treatment**

Patients with renal osteodystrophy generally respond to calcitriol (0.5-1 μg/d) or one of the vitamin D analogs paricalcitol (19-nor-1-alpha, 25(OH)₂D₃) or doxercalciferol (1α(OH)D₃), calcium supplementation (1-3 g/d), and phosphate restriction. Vitamin D supplementation is also recommended to ensure adequate 25(OH)D levels (30 ng/mL). Because of the concern about aluminum intoxication, sevelamer (Renagel) and other nonaluminum phosphate binders have replaced aluminum hydroxide to reduce intestinal phosphate absorption. To minimize the calcium-phosphate product, absorbable calcium-containing salts are used only at low doses to maintain sufficient calcium intake and not to act as a phosphate binder. The goal is to maintain normal serum levels of calcium, phosphate, and alkaline phosphatase. This regimen treats osteitis fibrosa more effectively than osteomalacia.

To prevent the development of adynamic bone disease, intact PTH levels higher than the upper limit of normal in standard intact PTH assays are allowed. The optimal intact PTH level for preserving skeletal integrity in end-stage renal disease and in patients on dialysis is uncertain. Newer or so-called biointact or whole PTH assays give a better reflection of the levels of the full-length PTH(1-84) molecule in these settings (described earlier). As previously noted, aluminum toxicity is associated with low-turnover bone disease rarely now. In the absence of aluminum toxicity, the etiology of uremic adynamic bone disease is unknown.

Patients with aluminum intoxication are very sensitive to and respond poorly to calcitriol and calcium, with rapid onset of hypercalcemia and little improvement in their bone disease. These patients may respond to chelation therapy with deferoxamine, a drug also used for iron chelation.

Severe secondary hyperparathyroidism is difficult to manage. These patients are prone to the development of hypercalcemia with calcium supplementation. Intravenous doses of calcitriol with hemodialysis may preferentially inhibit PTH secretion with less effect on raising serum calcium. Several analogs of calcitriol with less hypercalcemic potential than calcitriol itself have recently been approved for the management of such patients, as has the calcimimetic cinacalcet. Cinacalcet inhibits PTH secretion by activating the CaSR on parathyroid cells. Calcimimetic therapy has the distinct advantage of lowering PTH and presumably bone turnover, and thereby serum phosphate, calcium, and their product unlike the vitamin D analogs which tend to raise serum calcium and phosphate. Cinacalcet has contributed substantially to the management of uremic secondary hyperparathyroidism, although its major side effect, nausea and vomiting, limits its use in some patients.

**HEREDITARY FORMS OF HYPERPHOSPHATEMIA**

**Tumoral Calcinosi**

Mutations in genes leading to reduced FGF23 production, secretion, or action have recently been described which result in hyperphosphatemia and increased 1,25(OH)₂D₂ production. FGF23 requires glycosylation for its export from the cell where it is produced. Although FGF23 utilizes FGF receptors in common with many other members of the FGF family (FGFR 1 and 3), it also requires a coreceptor alpha klotho, to activate FGF23-mediated signaling in target cells. Inactivating mutations in FGF23 itself, the enzyme that glycosylates FGF23 which is necessary for secretion, GALNT3 (UDP-N-acetyl-α-D-galactosamine transferase), and alpha klotho all lead to hyperphosphatemia and increased 1,25(OH)₂D₂ levels, although serum calcium levels are generally normal. Urinary phosphate reabsorption is increased. These findings are the opposite of those of familial hypophosphatemic disorders described earlier. As a result of the increased calcium-phosphate product, ectopic calcification occurs, generally around joints.
and soft tissues. Dentition may be affected in some individuals. Treatment involves the use of phosphate binders in an effort to reduce the serum phosphate levels and reduce the painful and sometimes disfiguring ectopic calcifications which can become very large.

Paget Disease

Renal Osteodystrophy

The adrenal cortex produces many steroid hormones of which the most important are cortisol, aldosterone, and the adrenal androgens. Disorders of the adrenal glands lead to classic endocrinopathies such as Cushing syndrome, Addison disease, hyperaldosteronism, and the syndromes of congenital adrenal hyperplasia. This chapter describes the physiology and disorders of the glucocorticoids and the adrenal androgens. Disorders of aldosterone secretion are discussed in Chapter 10 and congenital defects in adrenal hormone biosynthesis in Chapters 10 and 14. Hirsutism and virilization (which reflect excess androgen action) are discussed in Chapter 13.

Advances in diagnostic procedures have simplified the evaluation of adrenocortical disorders; in particular, the assay of plasma glucocorticoids, androgens, and adrenocorticotropic (ACTH) has allowed more rapid and precise diagnosis. In addition, advances in surgical and medical treatment have improved the outlook for patients with these disorders.

**EMBRYOLOGY AND ANATOMY**

**Embryology**

The adrenal cortex is of mesodermal origin and derives from a single cell lineage characterized by expression of certain transcription factors such as steroidogenic factor-1 (SF-1). At 2 months' gestation, the cortex, already identifiable as a separate organ, is composed of a fetal zone and a definitive zone similar to the adult adrenal cortex. The adrenal cortex then increases rapidly in size; at mid gestation, it is considerably larger than the kidney and much larger than the adult gland in relation to total body mass. The fetal
Anatomy

The anatomic relationship of the fetal and definitive zones is maintained until birth, at which time the fetal zone gradually disappears, with a consequent decrease in adrenocortical weight in the 3 months following delivery. During the next 3 years, the adult adrenal cortex develops from cells of the outer layer of the cortex and differentiates into the three adult zones: glomerulosa, fasciculata, and reticularis—adrenal zonation.

The adult adrenal glands, with a combined weight of 8 to 10 g, lie in the retroperitoneum above or medial to the upper poles of the kidneys (Figure 9-1). A fibrous capsule surrounds the gland; the cortex comprises 90% of the adrenal weight, the inner medulla is about 10%.

The adrenal cortex is richly vascularized and receives its main arterial supply from branches of the inferior phrenic artery, the renal arteries, and the aorta. These small arteries form an arterial plexus beneath the capsule and then enter a sinusoidal system that penetrates the cortex and medulla, draining into a single central vein in each gland. The right adrenal vein drains directly into the posterior aspect of the vena cava; the left adrenal vein enters the left renal vein. These anatomic features account for the fact that it is relatively easier to catheterize the left adrenal vein than it is to catheterize the right adrenal vein.

Microscopic Anatomy

Histologically, the adult cortex is composed of three zones: an outer zona glomerulosa, a zona fasciculata, and an inner zona reticularis (Figure 9-2). However, the inner two zones appear to function as a unit (see later). The zona glomerulosa, which produces aldosterone and constitutes about 15% of adult cortical volume, is deficient in 17α-hydroxylase activity and thus cannot produce cortisol or androgens (see later and Chapter 10). The zona glomerulosa lacks a well-defined structure, and the small lipid-poor cells are scattered beneath the adrenal capsule. The zona fasciculata is the thickest layer of the adrenal cortex, making up about 75% of the cortex, and produces cortisol and androgens. The cells of the zona fasciculata are larger and contain more lipid and thus are termed clear cells. These cells extend in columns from the narrow zona reticularis to either the zona glomerulosa or to the capsule. The inner zona reticularis surrounds the medulla and also produces cortisol and androgens. The compact cells of this narrow zone lack significant lipid content but do contain lipofuscin granules. The zonae fasciculata and reticularis are regulated by ACTH; excess or deficiency of this hormone alters their

structure and function. Thus, both zones atrophy when ACTH is deficient; when ACTH is present in excess, hyperplasia and hypertrophy of these zones occur. In addition, chronic stimulation with ACTH leads to a gradual depletion of the lipid from the clear cells of the zona fasciculata at the junction of the two zones; these cells thus attain the characteristic appearance of the compact reticularis cells. With chronic excessive stimulation, the compact reticularis cells extend outward and may reach the outer capsule. It is postulated that the zona fasciculata cells can respond acutely to ACTH stimulation with increased cortisol production, whereas the reticularis cells maintain basal glucocorticoid secretion and that induced by prolonged ACTH stimulation.

**BIOSYNTHESIS OF CORTISOL AND ADRENAL ANDROGENS**

**Steroidogenesis**

The major hormones secreted by the adrenal cortex are cortisol, the androgens, and aldosterone. The carbon atoms in the steroid molecule are numbered as shown in Figure 9-3, and the major biosynthetic pathways and hormonal intermediates are illustrated in Figures 9-4 and 9-5.

The scheme of adrenal steroidogenic synthesis has been clarified by analysis of the steroidogenic enzymes. Most of these enzymes belong to the family of cytochrome P450 oxygenases (see Table 9-1 for current and historical nomenclature conventions). In mitochondria, the CYP11A gene, located on chromosome 15, encodes

**FIGURE 9-3** Structure of adrenocortical steroids. The letters in the formula for progesterone identify the A, B, C, and D rings; the numbers show the positions in the basic C21 steroid structure. The angular methyl groups (positions 18 and 19) are usually indicated simply by straight lines, as in the lower formula. Dehydroepiandrosterone is a 17-ketosteroid formed by cleavage of the side chain of the C21 steroid 17-hydroxypregnenolone and its replacement by an O atom. (Reproduced, with permission, from Ganong WF. *Review of Medical Physiology*. 14th ed. McGraw-Hill; 1989.)
P450scc, the enzyme responsible for cholesterol side chain cleavage, CYP11B1, a gene located on chromosome 8, encodes P450c11, another mitochondrial enzyme, which mediates 11β-hydroxylase in the zona reticularis and zona fasciculata. This reaction converts 11-deoxycortisol to cortisol and 11-deoxycorticosterone (11-DOC) to corticosterone. In the zona glomerulosa, CYP11B2, also located on chromosome 8, encodes the enzyme P450aldo, also known as aldosterone synthase. P450aldo mediates 11β-hydroxylase, 18-hydroxylase, and 18-oxidation to convert 11-DOC to corticosterone, 18-hydroxycorticosterone, and aldosterone, respectively. In the endoplasmic reticulum, gene CYP17, located on chromosome 10, encodes a single enzyme, P450c17, which mediates both 17α-hydroxylase activity and 17,20-lyase activity, and the gene CYP21A2 encodes the enzyme P450c21, which mediates 21-hydroxylation of both progesterone and 17-hydroxyprogesterone. The 3β-hydroxysteroid dehydrogenase: Δ⁴-isomerase activities are mediated by a single non-P450 microsomal enzyme (see Figure 9–4).

A. Zones and steroidogenesis Because of enzymatic differences between the zona glomerulosa and the inner two zones, the adrenal cortex functions as two separate units, with differing regulation and secretory products. Thus, the zona glomerulosa, which produces aldosterone, lacks 17α-hydroxylase activity and cannot synthesize 17α-hydroxyprogrenolone and 17α-hydroxyprogesterone, which are the precursors of cortisol and the adrenal androgens. The synthesis of aldosterone by this zone is primarily regulated by the renin-angiotensin system and by potassium (see Chapter 10).

The zona fasciculata and zona reticularis (see Figure 9–4) produce cortisol, androgens, and small amounts of estrogens. These zones, primarily regulated by ACTH, do not express the gene CYP11B2 (encoding P450aldo) and therefore cannot convert 11-DOC to aldosterone (see Chapter 10).

B. Cholesterol uptake and synthesis Synthesis of cortisol and the androgens by the zonae fasciculata and reticularis begins with cholesterol, as does the synthesis of all steroid hormones. Plasma lipoproteins are the major source of adrenal cholesterol, although synthesis within the gland from acetate also occurs. Low-density lipoprotein accounts for about 80% of cholesterol delivered to the adrenal gland. A small pool of free cholesterol within the adrenal is available for rapid synthesis of steroids when the adrenal is stimulated. When stimulation occurs, there is also increased hydrolysis of stored cholesteryl esters to free cholesterol, increased uptake from plasma lipoproteins, and increased cholesterol synthesis within the gland. The acute response to a steroidogenic stimulus is mediated by the steroidogenic acute regulatory protein (StAR). This mitochondrial phosphoprotein enhances cholesterol transport from the outer to the inner mitochondrial membrane. Mutations in the StAR gene result in congenital lipid adrenal hyperplasia with severe cortisol and aldosterone deficiencies at birth.
C. Cholesterol metabolism The conversion of cholesterol to pregnenolone is the rate-limiting step in adrenal steroidogenesis and the major site of ACTH action in the adrenal. This step occurs in the mitochondria and involves two hydroxylations and then the side chain cleavage of cholesterol. A single enzyme, CYP11A, mediates this process; each step requires molecular oxygen and a pair of electrons. The latter are donated by NADPH to adrenodoxin reductase (ferredoxin reductase), a flavoprotein, and then to adrenodoxin, an iron-sulfur protein, and finally to CYP11A. Both adrenodoxin reductase and adrenodoxin are also involved in the action of CYP11B1 (see earlier). Electron transport to microsomal cytochrome P450 involves P450 reductase, a flavoprotein distinct from adrenodoxin reductase. Pregnenolone is then transported outside the mitochondria before further steroid synthesis occurs.

D. Synthesis of cortisol Cortisol synthesis proceeds by 17α-hydroxylation of pregnenolone by CYP17 within the smooth endoplasmic reticulum to form 17α-hydroxyprogrenolon. This steroid is then converted to 17α-hydroxyprogesterone after conversion of its 5,6 double bond to a 4,5 double bond by the 3β-hydroxysteroid dehydrogenase: Δ⁵⁴-oxosteroid isomerase enzyme complex, which is also located within the smooth endoplasmic reticulum. An alternative but apparently less important pathway in the zona fasciculata and reticularis is from pregnenolone to progesterone to 17α-hydroxyprogesterone (see Figure 9–4).

The next step, which is again microsomal, involves the 21-hydroxylation by CYP21A2 of 17α-hydroxyprogesterone to form 11-deoxycortisol; this compound is further hydroxylated within mitochondria by 11β-hydroxylation (CYP11B1) to form cortisol. The zona fasciculata and zona reticularis also produce 11-DOC, 18-hydroxydeoxycorticosterone, and corticosterone. However, as noted above, the absence of the mitochondrial enzyme CYP11B2 prevents production of aldosterone by these zones of the adrenal cortex (Figure 9–5). Cortisol secretion under basal (ie, non-stressed) conditions ranges from 8 to 25 mg/d (22-69 μmol/d), with a mean of about 9.2 mg/d (25 μmol/d)—rates lower than most previous calculations.

E. Synthesis of androgens The production of adrenal androgens from pregnenolone and progesterone requires prior 17α-hydroxylation (CYP17) and thus does not occur in the zona glomerulosa. The major quantitative production of androgens is by conversion of 17α-hydroxyprogrenolon to the 19-carbon compounds (C-19 steroids) DHEA and its sulfate conjugate DHEA sulfate. Thus, 17α-hydroxyprogrenolon undergoes removal of its two-carbon side chain at the C17 position by microsomal 17,20-desmolase (CYP17), yielding DHEA with a keto group at C17. DHEA is then converted to DHEA sulfate by a reversible adrenal sulfokinase. The other major adrenal androgen, androstenedione, is produced mostly from DHEA, mediated by CYP17, and possibly from 17α-hydroxyprogesterone, also by CYP17. Androstenedione can be converted to testosterone, although adrenal secretions of this hormone is minimal. The adrenal androgens, DHEA, DHEA sulfate, and androstenedione, have minimal intrinsic androgenic activity, and they contribute to androgenicity by their peripheral conversion to the more potent androgens testosterone and dihydrotestosterone. Although DHEA and DHEA sulfate are secreted in greater quantities, androstenedione is qualitatively more important, because it is more readily converted peripherally to testosterone (see Chapter 12). Of note, recent studies have identified de novo synthesis of some steroid hormones in nerve and cardiac tissues, where they appear to act as paracrine or autocrine factors. Steroidogenic enzymes (eg, 3β-hydroxysteroid dehydrogenase and aromatase) are expressed in many tissues.

Regulation of Secretion

A. Secretion of CRH and ACTH ACTH is the trophic hormone of the zona fasciculata and reticularis and the major regulator of cortisol and adrenal androgen production, although other factors produced within the adrenal, including neurotransmitters, neuropeptides, and nitric oxide also play a role. ACTH in turn is regulated by the hypothalamus and central nervous system via neurotransmitters and corticotropin-releasing hormone (CRH)

and arginine vasopressin (AVP). The neuroendocrine control of CRH and ACTH secretion involves three mechanisms (see later and Chapter 4).

**B. ACTH effects on the adrenal cortex** ACTH administration leads to the rapid synthesis and secretion of steroids; plasma levels of these hormones rise within minutes. ACTH increases RNA, DNA, and protein synthesis. Chronic stimulation leads to adrenocortical hyperplasia and hypertrophy; conversely, ACTH deficiency results in decreased steroidogenesis and is accompanied by adrenocortical atrophy, decreased gland weight, and decreased protein and nucleic acid content.
C. ACTH and steroidogenesis  ACTH binds to high-affinity plasma membrane receptors, thereby activating adenyl cyclase and increasing cyclic adenosine monophosphate, which in turn activates intracellular phosphoprotein kinases (Figure 9-6), including StAR. ACTH action results in increased free cholesterol formation as a consequence of increased cholesterol esterase activity and decreased cholesterol esterase synthetase as well as increased lipoprotein uptake by the adrenal cortex. This process stimulates the rate-limiting step—cholesterol delivery to the side chain cleavage enzyme (P450scc or CYP11A1) for conversion to Δ5-pregnenolone, thereby initiating steroidogenesis.

D. Neuroendocrine control  Cortisol secretion is closely regulated by ACTH, and plasma cortisol levels parallel those of ACTH (Figure 9-7). There are three mechanisms of neuroendocrine control: (1) episodic secretion and the circadian rhythm of ACTH, (2) stress responsiveness of the hypothalamic-pituitary-adrenal (HPA) axis, and (3) feedback inhibition by cortisol of ACTH secretion.

1. Circadian rhythm—Circadian rhythm is superimposed on episodic secretion; it is the result of central nervous system events that regulate both the number and magnitude of CRH and ACTH secretory episodes. Cortisol secretion is low in the late evening and continues to decline in the first several hours of sleep, at which time plasma cortisol levels may be undetectable. During the third and fifth hours of sleep there is an increase in secretion; but the major secretory episodes begin in the sixth to eighth hours of sleep (see Figure 9-7) and then begin to decline as wakefulness occurs. About half of the total daily cortisol output is secreted during this period. Cortisol secretion then gradually declines during the day, with fewer secretory episodes of decreased magnitude; however, there is increased cortisol secretion in response to eating and exercise.

Although this general pattern is consistent, there is considerable intra- and interindividual variability, and the circadian rhythm may be altered by changes in sleep pattern, light-dark exposure, and feeding times. The rhythm is also changed by (1) physical stresses such as major illness, surgery, trauma, or starvation; (2) psychologic stress, including severe anxiety, endogenous depression, and the manic phase of manic-depressive psychosis; (3) central nervous system and pituitary disorders; (4) Cushing syndrome; (5) liver disease and other conditions that affect cortisol metabolism; (6) chronic renal failure; and (7) alcoholism. Cyproheptadine inhibits the circadian rhythm, possibly by its antiserosotonic effects, whereas other drugs usually have no effect.

2. Stress responsiveness—Plasma ACTH and cortisol secretion are also characteristically responsive to physical stress. Thus, plasma ACTH and cortisol are secreted within minutes following the onset of stresses such as surgery and hypoglycemia, and these responses abolish circadian periodicity if the stress is prolonged. Stress responses originate in the central nervous system and increase hypothalamic CRH and thus pituitary ACTH secretion. Stress responsiveness of plasma ACTH and cortisol is abolished by prior high-dose glucocorticoid administration and in spontaneous Cushing syndrome; conversely, the responsiveness of ACTH secretion is enhanced following adrenalectomy. Regulation of the HPA axis is linked to that of the immune system. For example, interleukin-1 (IL-1) stimulates ACTH secretion, and cortisol inhibits IL-1 synthesis.

3. Feedback inhibition—the third major regulator of ACTH and cortisol secretion is that of feedback inhibition by glucocorticoids of CRH, ACTH, and cortisol secretion. Glucocorticoid feedback inhibition occurs at both the pituitary and hypothalamus and involves two distinct mechanisms—fast and delayed feedback inhibition.
Fast feedback inhibition of ACTH secretion is rate-dependent; that is, it depends on the rate of increase of the glucocorticoid but not the dose administered. This phase is rapid (within minutes) and transient (lasting <10 minutes), suggesting mediation by a noncytosolic glucocorticoid receptor mechanism. Delayed feedback inhibition is both time- and dose-dependent. With continued glucocorticoid administration, ACTH levels continue to decrease and become unresponsive to stimulation, ultimately resulting in suppression of CRH and ACTH release and atrophy of the zonae fasciculata and reticularis. The suppressed HPA axis fails to respond to stress and stimulation. Delayed feedback appears to act via the classic glucocorticoid receptor mechanism (see later).

E. ACTH effects on regulation of androgen production

Adrenal androgen production in adults is also regulated by ACTH; both DHEA and androstenedione exhibit circadian plasma concentrations of DHEA and androstenedione increase logically inactive; the unbound or free fraction is active. The existence of a separate anterior pituitary hormone that regulates adrenal androgen secretion has long been postulated and it is this bio logically active cortisol that is regulated by ACTH.

CIRCULATION OF CORTISOL AND ADRENAL ANDROGENS

Cortisol and the adrenal androgens circulate bound to plasma proteins. The plasma half-life of cortisol (60-90 minutes) is determined by the extent of plasma binding and by the rate of metabolic inactivation.

Plasma-Binding Proteins

Cortisol and adrenal androgens are secreted in an unbound state; however, these hormones bind to plasma proteins on entering the circulation. Cortisol binds mainly to corticosteroid-binding globulin (CBG, transcortin) and to a lesser extent to albumin, whereas the androgens bind chiefly to albumin. Bound steroids are biologically inactive; the unbound or free fraction is active. The plasma proteins may provide a pool of circulating cortisol by delaying metabolic clearance, thus preventing more marked fluctuations of plasma-free cortisol levels during episodic secretion by the gland. Because there are no binding proteins in saliva, salivary cortisol reflects free cortisol.

Free and Bound Cortisol

Under basal conditions, about 10% of the circulating cortisol is free, about 75% is bound to CBG, and the remainder is bound to albumin. The plasma free cortisol level is approximately 1 μg/dL, and it is this biologically active cortisol that is regulated by ACTH.

A. Corticosteroid-binding globulin

Corticosteroid-binding globulin (CBG) has a molecular weight of about 50,000, is produced by the liver, and binds cortisol with high affinity. The CBG in plasma has a cortisol-binding capacity of about 25 μg/dL. When total plasma cortisol concentrations rise above this level, the free concentration rapidly increases and exceeds its usual fraction of 10% of the total cortisol. Other endogenous steroids usually do not appreciably affect cortisol binding to CBG; an exception is in late pregnancy, when progesterone may occupy about 25% of the binding sites on CBG. Synthetic steroids do not bind significantly to CBG—with the exception of prednisolone. CBG levels are increased in high-estrogen states (pregnancy; estrogen or oral contraceptive use), hyperthyroidism, diabetes, certain hematologic disorders, and on a genetic basis. CBG concentrations are decreased in familial CBG deficiency, hypothyroidism, and protein deficiency states such as severe liver disease or nephrotic syndrome.

B. Albumin

Albumin has a much greater capacity for cortisol binding but a lower affinity. It normally binds about 15% of the circulating cortisol, and this proportion increases when the total cortisol concentration exceeds the CBG-binding capacity. Synthetic glucocorticoids are extensively bound to albumin (eg, about 75% of dexamethasone in plasma is bound to albumin).

C. Androgen binding

Androstenedione, DHEA, and DHEA sulfate circulate weakly bound to albumin. However, testosterone is bound extensively to a specific globulin, sex hormone-binding globulin (SHBG) (see Chapter 12).

METABOLISM OF CORTISOL AND ADRENAL ANDROGENS

The metabolism of these steroids renders them inactive and increases their water solubility, as does their subsequent conjugation with glucuronide or sulfate groups. These inactive conjugated metabolites are more readily excreted by the kidney. The liver is the major site of steroid catabolism and conjugation, and 90% of these metabolized steroids are excreted by the kidney.

Conversion and Excretion of Cortisol

Cortisol is modified extensively before excretion in urine; less than 1% of secreted cortisol appears in the urine unchanged.

A. Hepatic conversion

Hepatic metabolism of cortisol involves a number of metabolic conversions of which the most important (quantitatively) is the irreversible inactivation of the steroid by Δ^4-reductases, which reduce the 4,5 double bond of the A ring. Dihydrocortisol, the product of this reaction, is then converted to tetrahydrocortisol by a 3-hydroxysteroid dehydrogenase. Cortisol is also converted extensively by 11β-hydroxysteroid dehydrogenase to the biologically inactive cortisone, which is then metabolized by the enzymes described above to yield tetrahydrocortisone. Tetrahydrocortisol and tetrahydrocortisone can be further altered to form the cortico acids. These conversions result
in the excretion of approximately equal amounts of cortisol and cortisone metabolites. Cortisol and cortisone are also metabolized to the cortols and cortolones and to a lesser extent by other pathways (eg, to 6β-hydroxycortisol).

B. Hepatic conjugation  More than 95% of cortisol and cortisone metabolites are conjugated by the liver and then reenter the circulation to be excreted in the urine. Conjugation is mainly with glucuronic acid at the 3α-hydroxyl position.

C. Variations in clearance and metabolism  The metabolism of cortisol is altered by a number of circumstances. It is decreased in infants and in the elderly. It is impaired in chronic liver disease, leading to decreased renal excretion of cortisol metabolites; however, the plasma cortisol level remains normal. Hypothyroidism decreases both metabolism and excretion; conversely, hyperthyroidism accelerates these processes. Cortisol clearance may be reduced in starvation and anorexia nervosa and is also decreased in pregnancy because of the elevated CBG levels. The metabolism of cortisol to 6β-hydroxycortisol is increased in the neonate, in pregnancy, with estrogen therapy, and in patients with liver disease or severe chronic illness. Cortisol metabolism by this pathway is also increased by drugs that induce hepatic microsomal enzymes, including barbiturates, phenytoin, mitotane, aminoglutethimide, and rifampin. These alterations generally are of minor physiologic importance as the free cortisol levels remain relatively stable in these conditions. However, they result in decreased excretion of the urinary metabolites of cortisol measured as 17-hydroxycorticosteroids. These conditions and drugs have a greater influence on the metabolism of synthetic glucocorticoids and may result in inadequate plasma levels of the administered glucocorticoid because of rapid clearance and metabolism.

D. Cortisol-cortisone shunt  Aldosterone is the principal mineralocorticoid controlling sodium and potassium exchange in the distal nephron. Mineralocorticoid receptors in the kidney are responsible for this effect, and the sensitivities of both the glucocorticoid receptor and the mineralocorticoid receptor for cortisol in vitro are similar. Small changes in aldosterone affect sodium and potassium exchange in the kidney, whereas free and biologically active cortisol does not, yet cortisol circulates in much higher concentrations. This apparent paradox is explained by an intracellular enzyme—11β-hydroxysteroid dehydrogenase type 2 (11βHSD2)—that metabolizes cortisol to the inactive cortisone and protects the mineralocorticoid receptor from cortisol binding (Figure 9–8). However, when circulating cortisol is extremely high

![Figure 9-8](image-url)  
**Figure 9-8**  Cortisol-cortisone shunt. Contrasting functions of the isozymes of 11β-HSD. 11β-HSD2 is an exclusive 11β-dehydrogenase that acts in classical aldosterone target tissues to exclude cortisol from otherwise nonselective mineralocorticoid receptors. Inactivation of cortisol also occurs in placenta. 11β-HSD1 is a predominant 11β-reductase in vivo that acts in many tissues to increase local intracellular glucocorticoid concentrations and thereby maintain adequate exposure of relatively low affinity glucocorticoid receptors to their ligand.
Cortisol is overwhelmed and the mineralocorticoid receptor is activated by cortisol, resulting in volume expansion, hypertension, and hypokalemia. The skin expresses this enzyme, explaining why cortisone cream can be effective. More importantly, the liver expresses 11β-HSD1 and can activate cortisone to cortisol, thereby completing the cortisol-cortisone shunt such that the kidney inactivates cortisol to cortisone and the liver can reactivate cortisone to cortisol. The expression of 11β-HSD1 in adipose tissue may contribute to abdominal obesity seen in metabolic syndrome without biochemical hypercortisolism.

**Conversion and Excretion of Adrenal Androgens**

Adrenal androgen metabolism results either in degradation and inactivation or the peripheral conversion of these weak androgens to their more potent derivatives testosterone and dehydrotestosterone. DHEA is readily converted within the adrenal to DHEA sulfate, the adrenal androgen secreted in greatest amount. DHEA secreted by the gland is also converted to DHEA sulfate by the liver and kidney, or it may be converted to Δ4-androstenedione. DHEA sulfate may be excreted without further metabolism; however, both it and DHEA are also metabolized to 7α- and 16α-hydroxylated derivatives and by 17β-reduction to Δ5-androstenediol and its sulfate. Androstenedione is converted either to testosterone or by reduction of its 4,5 double bond to etiocholanolone or androsterone, which may be further converted by 17α reduction to etiocholanediol and androstanediol, respectively. Testosterone is converted to dihydrotestosterone in androgen-sensitive tissues by 5α reduction, and it, in turn, is mainly metabolized by 3α reduction to androstanediol. The metabolites of these androgens are conjugated either as glucuronides or sulfates and excreted in the urine.

**BIOLOGIC EFFECTS OF ADRENAL STEROIDS**

**Glucocorticoids**

Although glucocorticoids were originally so called because of their influence on glucose metabolism, they are currently defined as steroids that exert their effects by binding to specific cytosolic receptors that mediate the actions of these hormones. These glucocorticoid receptors are present in virtually all tissues, and glucocorticoid-receptor interaction is responsible for most of the known effects of these steroids. Alterations in the structure of the glucocorticoids have led to the development of synthetic compounds with greater glucocorticoid activity. The increased activity of these compounds is due to increased affinity for the glucocorticoid receptors and delayed plasma clearance, which increases tissue exposure. In addition, many of these synthetic glucocorticoids have negligible mineralocorticoid effects and thus do not result in sodium retention, hypertension, and hypokalemia. This section describes the molecular mechanisms of glucocorticoid action and the effects on individual metabolic functions and tissues (Table 9-2).

**Molecular Mechanisms**

Glucocorticoid action is initiated by entry of the steroid into the cell and binding to the cytosolic glucocorticoid–receptor proteins (see Figures 1-13, 1-14, and 1-15). The most abundant cytoplasmic glucocorticoid–receptor complex includes two subunits of the 90-kDa heat shock protein (hsp) 90. After binding, the hsp90 subunits dissociate and activated hormone–receptor complexes enter the nucleus and interact with nuclear chromatin acceptor sites. The DNA-binding domain of the receptor is a cysteine-rich region which, when it chelates zinc, assumes a conformation called a zinc finger. The receptor–glucocorticoid complex acts via two mechanisms: (1) binding to specific sites in nuclear DNA, the glucocorticoid regulatory elements; and (2) interactions with other transcription factors such as nuclear factor KB, an important regulator of cytokine genes. These result in altered expression of specific genes and the transcription of specific mRNAs. The resulting proteins elicit the glucocorticoid response, which may be inhibitory or stimulatory depending on the specific gene and tissue affected. Although glucocorticoid receptors are similar in many tissues, the proteins synthesized in response to glucocorticoids vary widely and are the result of expression of specific genes in different cell types. The mechanisms underlying this specific regulation are unknown. Analyses of cloned complementary DNAs for human glucocorticoid receptors have revealed marked structural and amino acid sequence homology between glucocorticoid receptors and receptors for other steroid hormones (e.g., mineralocorticoids, estrogen, progesterone) as well as for thyroid hormone and the oncogene v-erb-A. Although the steroid-binding domain of the glucocorticoid receptor confers specificity for glucocorticoid binding, glucocorticoids such as cortisol and corticosterone bind to the mineralocorticoid receptor with an affinity equal to that of aldosterone. Mineralocorticoid receptor specificity is maintained by the expression of 11β-HSD in classic mineralocorticoid-sensitive tissues—the cortisol-cortisone shunt (see earlier).

Although glucocorticoid–receptor complexes and their subsequent regulation of gene expression are responsible for most glucocorticoid effects, other effects may occur through plasma membrane receptors.

**Glucocorticoid Agonists and Antagonists**

The study of glucocorticoid receptors has led to the definition of glucocorticoid agonists and antagonists. These studies have also identified a number of steroids with mixed effects termed partial agonists, partial antagonists, or partial agonist–partial antagonists. In addition, novel glucocorticoid receptor ligands are being

developed that have more selectivity in terms of receptor binding or transcription of specific genes.

A. Agonists In humans, cortisol, synthetic glucocorticoids (eg, prednisolone, dexamethasone), corticosterone, and aldosterone are glucocorticoid agonists. The synthetic glucocorticoids have substantially higher affinity for the glucocorticoid receptor, and these have greater glucocorticoid activity than cortisol when present in equimolar concentrations. Corticosterone and aldosterone have substantial affinity for the glucocorticoid receptor; however, their plasma concentrations are normally much lower than that of cortisol, and thus these steroids do not have significant physiologic glucocorticoid effects.

B. Antagonists Glucocorticoid antagonists bind to the glucocorticoid receptors but do not elicit the nuclear events required to cause a glucocorticoid response. These steroids compete with agonist steroids such as cortisol for the receptors and thus inhibit agonist responses. Other steroids have partial agonist activity when present alone (ie, they elicit a partial glucocorticoid response). However, in sufficient concentration, they compete with agonist steroids for the receptors and thus competitively inhibit agonist responses; that is, these partial agonists may function as partial antagonists in the presence of more active glucocorticoids. Steroids such as progesterone, 11-deoxycorticisol, DOC, testosterone, and 17β-estradiol have antagonist or partial agonist-partial antagonist effects; however, the physiologic role of these hormones in glucocorticoid action is probably negligible, because they circulate in low concentrations. The antiprogestational agent mifepristone has substantial glucocorticoid antagonist properties and has been used to block glucocorticoid action in patients with Cushing syndrome.

Intermediary Metabolism (Table 9–2)
Glucocorticoids in general inhibit DNA synthesis. In addition, in most tissues they inhibit RNA and protein synthesis and accelerate protein catabolism. These actions provide substrate for intermediary metabolism; however, accelerated catabolism also accounts for the deleterious effects of glucocorticoids on muscle, bone, connective tissue, and lymphatic tissues. In contrast, RNA and protein synthesis in liver is stimulated.

A. Hepatic glucose metabolism Glucocorticoids increase hepatic gluconeogenesis by stimulating the gluconeogenic enzymes phosphoenolpyruvate carboxykinase and glucose-6-phosphatase. They have a permissive effect in that they increase hepatic responsiveness to the gluconeogenic hormone glucagon, and they also increase the release of substrates for gluconeogenesis from peripheral tissues, particularly muscle. This latter effect may be enhanced by the glucocorticoid-induced reduction in peripheral amino acid uptake and protein synthesis. Glucocorticoids also increase glycerol and free fatty acid release by lipolysis and increase muscle lactate release. They enhance hepatic glycogen synthesis and storage by stimulating glycogen synthetase activity and to a lesser extent by inhibiting glycogen breakdown. These effects are insulin dependent.

B. Peripheral glucose metabolism Glucocorticoids also alter carbohydrate metabolism by inhibiting peripheral glucose uptake in muscle and adipose tissue. This effect and the others described earlier may result in increased insulin secretion in states of chronic glucocorticoid excess.

C. Effects on adipose tissue In adipose tissue, the predominant effect is increased lipolysis with release of glycerol and free fatty acids. This is partially due to direct stimulation of lipolysis by glucocorticoids, but it is also contributed to by decreased glucose uptake and enhancement by glucocorticoids of the effects of lipolytic hormones. Although glucocorticoids are lipolytic, increased fat deposition is a classic manifestation of glucocorticoid excess. This paradox may be explained by the increased appetite caused by high levels of these steroids and by the lipogenic effects of the hyperinsulinemia that occurs in this state. The reason for abnormal fat deposition and distribution in states of cortisol excess is unknown. In these instances, fat is classically deposited centrally in the face, cervical area, trunk, and abdomen; the extremities are usually spared.

D. Summary The effects of the glucocorticoids on intermediary metabolism can be summarized as follows:

1. Effects are minimal in the fed state. However, during fasting, glucocorticoids contribute to the maintenance of plasma glucose levels by increasing gluconeogenesis and decreasing uptake of glucose by adipose tissue.
2. Hepatic glucose production is enhanced, as is hepatic RNA and protein synthesis.
3. The effects on muscle are catabolic (ie, decreased glucose uptake and metabolism, decreased protein synthesis, and increased release of amino acids). This provides amino acid substrates for gluconeogenesis in the liver.
4. In adipose tissue, lipolysis is stimulated. This increases fatty acid delivery to the liver where their metabolism provides energy to support gluconeogenesis.
5. In glucocorticoid deficiency, hypoglycemia may result, whereas in states of glucocorticoid excess there may be hyperglycemia, hyperinsulinemia, muscle wasting, and weight gain with abnormal fat distribution.

Effects on Other Tissues and Functions (Table 9–2)

A. Connective tissue Glucocorticoids in excess inhibit fibroblasts, lead to loss of collagen and connective tissue, and thus result in thinning of the skin, easy bruising, stria formation, and poor wound healing.

B. Bone The physiologic role of glucocorticoids in bone metabolism and calcium homeostasis is unknown; however, in excess, they have major deleterious effects. Glucocorticoids directly inhibit bone formation by decreasing cell proliferation and the synthesis of RNA, protein, collagen, and hyaluronate. Initially, supraphysiologic doses of glucocorticoids also stimulate bone resorption, at least in part via interference of the receptor
activator of nuclear factor kappa B (RANK)-ligand/RANK/osteoprotegerin pathway. This leads to osteolysis and increased biochemical markers of bone turnover. In addition, glucocorticoids may potentiate the proresorptive actions of parathyroid hormone (PTH) and 1,25-dihydroxycholecalciferol (1,25(OH)₂D₃) on bone, and this may further contribute to net bone resorption. Chronically, however, the key effect to promote bone loss is due to the detrimental impact on bone formation (see Chapter 8).

C. Calcium metabolism Glucocorticoids also have other major effects on mineral homeostasis. They markedly reduce intestinal calcium absorption, which tends to lower serum calcium. This theoretically promotes a state of secondary hyperparathyroidism to maintain the serum calcium within the normal range. In reality, however, chronic elevations in intact PTH levels have been difficult to demonstrate consistently in patients on glucocorticoid therapy. The mechanism of decreased intestinal calcium absorption is thought to result from antagonism of 1,25(OH)₂D action in the intestine. It is not due to decreased synthesis or decreased serum levels of the active vitamin D metabolites; in fact, 1,25(OH)₂D levels are normal or even increased in the presence of glucocorticoid excess. Increased 1,25(OH)₂D synthesis in this setting may result from decreased serum phosphorus levels (see later), increased PTH secretion, direct stimulation by glucocorticoids of renal 1α-hydroxylase, and or reduced target cell (intestine) responsiveness. Glucocorticoids increase urinary calcium excretion, and hypercalcuria is a frequent feature of cortisol excess. They also reduce the tubular reabsorption of phosphate, leading to phosphaturia and decreased serum phosphorus concentrations.

Thus, glucocorticoids in excess result in negative calcium balance, with decreased calcium absorption and increased urinary calcium excretion. Serum calcium levels are maintained, but at the expense of net bone resorption. Decreased bone formation and increased resorption ultimately result in the disabling osteoporosis that is often a major complication of spontaneous and iatrogenic glucocorticoid excess (see Chapter 8).

D. Growth and development Glucocorticoids accelerate the development of a number of systems and organs in fetal and differentiating tissues, although the mechanisms are unclear. As discussed above, glucocorticoids are generally inhibitory, and these stimulatory effects may be due to glucocorticoid interactions with other growth factors. Examples of these development-promoting effects are increased surfactant production in the fetal lung and the accelerated development of hepatic and gastrointestinal enzyme systems.

Glucocorticoids in excess inhibit growth in children, and this adverse effect is a major complication of therapy. This may be a direct effect on bone cells, although decreased growth hormone (GH) secretion and insulin-like growth factor I generation also contribute (see Chapter 6).

E. Blood cells and immunologic function
1. Erythrocytes—Glucocorticoids have little effect on erythropoiesis and hemoglobin concentration. Although mild polycythemia and anemia may be seen in Cushing syndrome and Addison disease, respectively, these alterations are more likely to be secondary to altered androgen metabolism.

2. Leukocytes—Glucocorticoids influence both leukocyte movement and function. Thus, glucocorticoid administration increases the number of intravascular polymorphonuclear neutrophils/leukocytes (PMNs) by increasing PMN release from bone marrow, by increasing the circulating half-life of PMNs, and by decreasing PMN movement out of the vascular compartment. Glucocorticoid administration reduces the number of circulating lymphocytes, monocytes, and eosinophils, mainly by increasing their movement out of the circulation. The converse (ie, neutropenia, lymphocytosis, monocytosis, and eosinophilia) is seen in adrenal insufficiency. Glucocorticoids also decrease the migration of inflammatory cells (PMNs, monocytes, and lymphocytes) to sites of injury, and this is probably a major mechanism of the anti-inflammatory actions and increased susceptibility to infection that occur following chronic administration. Glucocorticoids also decrease lymphocyte production and the mediator and effector functions of these cells.

3. Immunologic effects—Glucocorticoids influence multiple aspects of immunologic and inflammatory responsiveness, including the mobilization and function of leukocytes, as discussed earlier. They inhibit phospholipase A₂, a key enzyme in the synthesis of prostaglandins. This inhibition is mediated by a class of peptides called lipocortins or annexins. They also impair the release of effector substances such as the lymphokine IL-1, antigen processing, antibody production and clearance, and other specific bone marrow-derived and thymus-derived lymphocyte functions. The immune system, in turn, affects the HPA axis; IL-1 stimulates the secretion of CRH and ACTH.

Although traditionally used as anti-inflammatory and/or immunosuppressive agents, glucocorticoids, especially at lower doses, also have stimulatory and permissive effects on the inflammatory response to injury.

F. Cardiovascular function Glucocorticoids may increase cardiac output, and they also increase peripheral vascular tone, possibly by augmenting the effects of other vasoconstrictors (eg, the catecholamines). Glucocorticoids also regulate expression of adrenergic receptors. Thus, refractory shock may occur when the glucocorticoid-deficient individual is subjected to stress. Glucocorticoids in excess may cause hypertension independently of their mineralocorticoid effects. Although the incidence and the precise cause of this problem are unclear, it is likely that the mechanism involves the renin-angiotensin system; glucocorticoids regulate renin substrate, angiotensinogen, the precursor of angiotensin I.

G. Renal function These steroids affect water and electrolyte balance by actions mediated either by mineralocorticoid receptors (sodium retention, hypokalemia, and hypertension) or via glucocorticoid receptors (increased glomerular filtration rate due to increased cardiac output or due to direct renal effects on salt and water retention). Thus, corticosteroids such as betamethasone or dexamethasone, which have little mineralocorticoid activity, increase sodium and water excretion. Glucocorticoid-deficient subjects have decreased glomerular filtration rates and are unable to excrete a water load. This may be further aggravated by
increased ADH secretion, which may occur in glucocorticoid deficiency.

**H. Central nervous system function** Glucocorticoids readily enter the brain, and although their physiologic role in central nervous system function is unknown, their excess or deficiency may profoundly alter behavior and cognitive function.

1. **Excessive glucocorticoids**—In excess, the glucocorticoids initially cause euphoria; however, with prolonged exposure, a variety of psychologic abnormalities occur, including irritability, emotional lability, and depression. Hyperkinetic or manic behavior is less common; overt psychoses occur in a small number of patients, particularly those with underlying bipolar disorder. Many patients also note impairment in cognitive functions, most commonly memory and concentration. Other central effects include increased appetite, decreased libido, and insomnia, with decreased rapid eye movement sleep and increased stage II sleep.

2. **Decreased glucocorticoids**—Patients with Addison disease are apathetic and depressed and tend to be irritable, negativistic, and reclusive. They have decreased appetite but increased sensitivity of taste and smell mechanisms.

**I. Effects on other hormones**

1. **Thyroid function**—Glucocorticoids in excess affect thyroid function. Thyroid-stimulating hormone (TSH) synthesis and release are inhibited by glucocorticoids, and TSH responsiveness to thyrotropin-releasing hormone (TRH) is frequently subnormal. Although basal levels are usually normal, the TSH concentration may be acutely low in patients treated with moderate- to high-dose glucocorticoids. Serum total thyroxine (T₄) concentrations are usually low normal because of a decrease in thyroxine-binding globulin, but free T₄ levels are normal. Total and free T₃ (triiodothyronine) concentrations may be low, because glucocorticoid excess decreases the conversion of T₄ to T₃ and increases conversion to reverse T₃. Despite these alterations, manifestations of hypothyroidism are not apparent.

2. **Gonadal function**—Glucocorticoids also affect gonadotropin and gonadal function. In males, they inhibit gonadotropin secretion, as evidenced by decreased responsiveness to administered gonadotropin-releasing hormone (GnRH) and subnormal plasma testosterone concentrations. In females, glucocorticoids also suppress luteinizing hormone (LH) responsiveness to GnRH, resulting in suppression of estrogens and progestins with inhibition of ovulation and amenorrhea.

**J. Miscellaneous effects**

1. **Peptic ulcer**—The role of steroid excess in the production or reactivation of peptic ulcer disease is controversial. However, there appears to be a modest independent effect of glucocorticoids to promote peptic ulcer disease (relative risk about 1.4), and when this effect is combined with that of nonsteroidal anti-inflammatory drugs there is a synergistic interaction that considerably increases the risk.

2. **Ophthalmologic effects**—Intraocular pressure varies with the level of circulating glucocorticoids and parallels the circadian variation of plasma cortisol levels. In addition, glucocorticoids in excess increase intraocular pressure in patients with open-angle glaucoma. Glucocorticoid therapy may also cause cataract formation. Central serous chorioretinopathy, an accumulation of subretinal detachment, may also complicate endogenous or exogenous glucocorticoid excess.

**ADRENAL ANDROGENS**

The direct biologic activity of the adrenal androgens (androstenedione, DHEA, and DHEA sulfate) is minimal, and they function primarily as precursors for peripheral conversion to the active androgenic hormones, testosterone and dihydrotestosterone. Thus, DHEA sulfate secreted by the adrenal androgens undergoes limited conversion to DHEA; this peripherally converted DHEA and that secreted by the adrenal cortex can be further converted in peripheral tissues to androstenedione, the immediate precursor of the active androgens.

The actions of testosterone and dihydrotestosterone are described in Chapter 12. This section will deal only with the adrenal contribution to androgenicity.

**Effects in Males**

In males with normal gonadal function, the conversion of adrenal androstenedione to testosterone accounts for less than 5% of the production rate of this hormone, and thus the physiologic effect is negligible. In adult males, excessive adrenal androgen secretion has no clinical consequences; however, in boys, it causes premature penile enlargement and early development of secondary sexual characteristics.

**Effects in Females**

In females, the adrenal substantially contributes to total androgen production by the peripheral conversion of androstenedione to testosterone. In the follicular phase of the menstrual cycle, adrenal precursors account for two-thirds of testosterone production and one-half of dihydrotestosterone production. During midcycle, the ovarian contribution increases, and the adrenal precursors account for only 40% of testosterone production.

In females, abnormal adrenal function as seen in Cushing syndrome, adrenal carcinoma, and congenital adrenal hyperplasia results in excessive secretion of adrenal androgens, and their peripheral conversion to testosterone results in androgen excess, manifested by acne, hirsutism, and virilization.

**LABORATORY EVALUATION**

Cortisol and the adrenal androgens are measured by specific plasma assays. Certain urinary assays, particularly measurement of 24-hour urine free cortisol, are also useful. In addition, plasma concentrations of ACTH can be determined. The assays for plasma steroids commonly use measured the total hormone concentrations and are therefore influenced by alterations in plasma-binding proteins. Furthermore, because ACTH and the plasma concentrations of the adrenal hormones fluctuate markedly (see Figure 9-7), single plasma measurements are frequently unreliable.
Thus, plasma levels must be interpreted cautiously, and more specific diagnostic information is usually obtained by performing appropriate dynamic tests (stimulation and suppression) or other tests that reflect cortisol secretory rate.

**Plasma ACTH**

**A. Methods of measurement** Plasma ACTH measurements are extremely useful in the diagnosis of pituitary-adrenal dysfunction. The normal range for a plasma ACTH, using a sensitive immunoradiometric assay (IRMA) or immunochemiluminometric assay (ICMA), is 9 to 52 pg/mL (2-11.1 pmol/L).

**B. Interpretation** Plasma ACTH levels are most useful in differentiating pituitary causes from adrenal causes of adrenal dysfunction as follows:

1. In adrenal insufficiency due to primary adrenal disease, plasma ACTH levels are elevated. Conversely, in pituitary ACTH deficiency and secondary hypoadrenalism, plasma ACTH levels are inappropriately normal or less than 10 pg/mL (2.2 pmol/L).
2. In Cushing syndrome due to primary glucocorticoid-secreting adrenal tumors, plasma ACTH is suppressed, and a level less than 5 pg/mL (1.1 pmol/L) is diagnostic. In patients with Cushing disease (pituitary ACTH hypersecretion), plasma ACTH levels are inappropriately normal or elevated.
3. Plasma ACTH levels are usually markedly elevated in the ectopic ACTH syndrome, but there is a considerable amount of overlap with levels seen in Cushing disease. In addition, values lower than expected may be observed rarely in ectopic ACTH syndrome when the two-site immunoradiometric assay (IRMA) is used; this assay may not detect high-molecular-weight precursors of ACTH that can be produced in ectopic ACTH syndrome.
4. Plasma ACTH levels are also elevated in patients with the common forms of congenital adrenal hyperplasia and are useful in the diagnosis and management of these disorders (see Chapters 10 and 14).

**Plasma Cortisol**

**A. Methods of measurement** The most common methods of measurement of plasma cortisol are radioimmunoassay, enzyme-linked immunosorbent assay (ELISA), high-performance liquid chromatography (HPLC), and liquid chromatography tandem mass spectroscopy (LC/MS/MS). These methods measure total cortisol (both bound and free) in plasma. Most commonly used drugs and medications do not interfere with this assay. In contrast to radioimmunoassays, HPLC and LC/MS/MS do not demonstrate cross-reactivity with synthetic glucocorticoids.

**B. Interpretation** The diagnostic utility of single plasma cortisol concentrations is limited by the episodic nature of cortisol secretion and its appropriate elevations during stress. As explained below, more information is obtained by dynamic testing of the HPA axis.

1. **Normal values**—Normal plasma cortisol levels vary with the method used and time of day the sample is obtained. With radioimmunoassay, levels at 8 AM range from 3 to 20 µg/dL (80-550 nmol/L) and average 10 to 12 µg/dL (275.9-331.1 nmol/L). Values obtained later in the day are lower and at 4 PM are approximately half of morning values. At 10 PM to 2 AM, the plasma cortisol concentrations by these methods are usually less than 3 µg/dL (80 nmol/L).

2. **Levels during stress**—Cortisol secretion increases in patients who are acutely ill, during surgery, and following trauma. Plasma concentrations may reach greater than 40 to 60 µg/dL (1100-1655 nmol/L).

3. **High-estrogen states**—The total plasma cortisol concentration is also elevated with increased CBG-binding capacity, which occurs most commonly when circulating estrogen levels are high (eg, during pregnancy and when exogenous estrogens or oral contraceptives are being used). In these situations, plasma cortisol may reach levels two to three times normal.

4. **Other conditions**—CBG levels may be increased or decreased in other situations, as discussed above in the sections on circulation and metabolism. Total plasma cortisol concentrations may also be increased in severe anxiety, endogenous depression, starvation, anorexia nervosa, alcoholism, and chronic kidney disease.

**Salivary Cortisol**

Cortisol in the saliva is in equilibrium with the free and biologically active cortisol in the blood. Salivary cortisol concentrations are not affected by changes in serum cortisol-binding proteins, by salivary flow or composition, and they are stable at room temperature for many days. Measurements of salivary cortisol can be obtained from late-night, ambulatory saliva samples, which are used as a means of establishing the presence or absence of Cushing syndrome. Salivary cortisol may also be used to obtain accurate free cortisol levels in patients with abnormal serum-binding proteins.

**A. Methods of measurement** Saliva can easily be sampled at home by the patient using a variety of techniques, including the use of a commercially available sampling device or by passive drooling. The same methods that are employed to measure plasma cortisol, radioimmunoassay, ELISA, HPLC, and LC/MS/MS, are used to measure salivary cortisol concentrations.

**B. Interpretation**

1. **Normal values**—Reference ranges for late-night salivary cortisol concentrations are dependent on the assays employed, but with radioimmunoassay and ELISA, the normal salivary cortisol level at midnight is generally less than 0.15 µg/dL (4 nmol/L).

2. **Diagnostic utility**—As with single plasma cortisol measurements, randomly obtained salivary cortisol concentrations are of limited use. However, plasma and salivary cortisol in normal individuals reach a nadir from 10 PM to 2 AM. Patients with Cushing syndrome do not reach a normal nadir at this time, and several studies have shown that elevated late-night time salivary cortisol is a sensitive and specific diagnostic test for Cushing syndrome.

**Plasma Free Cortisol**

This assay measures the free or biologically active fraction of plasma cortisol and, thus, is not influenced by alterations in
corticosteroid-binding globulin and serum albumin. The best current method involves equilibrium dialysis to separate bound and free hormone followed by measurement of the free fraction by radioimmunoassay. In patients with normal serum albumin and CBG, the free cortisol correlates well with total cortisol levels; however, in patients with disturbances in plasma-binding proteins this correlation is lost.

Although this assay is not in common use, it is of importance in the assessment of adrenal function in patients with critical illness. In these patients the measurement of total plasma cortisol and its response to ACTH has overestimated the number of patients with adrenal insufficiency especially in the most severely ill patients who frequently have hypoalbuminemia and subnormal corticosteroid-binding globulin levels.

**Urinary Corticosteroids**

**A. Free cortisol**

1. **Methods of measurement**—The assay of unbound cortisol excreted in the urine is an excellent method for the diagnosis of Cushing syndrome. Normally, less than 1% of the secreted cortisol is excreted unchanged in the urine. However, in states of excess secretion, the binding capacity of CBG is exceeded, and plasma free cortisol therefore increases, as does its urinary excretion. Urine free cortisol is measured in a 24-hour urine collection by HPLC, radioimmunoassay, and by LC/MS/MS.

2. **Normal values**—HPLC and LC/MS/MS provide the most specific measurement of cortisol and are the current procedures of choice. The normal range for urine free cortisol assayed by HPLC or LC/MS/MS is 5 to 50 μg/24 h (14-135 nmol/24 h).

3. **Diagnostic utility**—This method is particularly useful in differentiating simple obesity from Cushing syndrome, because urine free cortisol levels are not elevated in obesity, as are the urinary 17-hydroxycorticosteroids (see later). The levels may be elevated in the same conditions that increase plasma cortisol (see earlier), including a slight elevation during pregnancy. This test is not useful in adrenal insufficiency, because it lacks sensitivity at low levels and because low cortisol excretion is often found in normal persons.

**B. 17-Hydroxycorticosteroids** These urinary steroids are largely of historical interest and should not be measured at present because of the greater utility of plasma cortisol and urine free cortisol measurements.

**Dexamethasone Suppression Tests**

**A. Low-Dose test**—This procedure is used to establish the presence of Cushing syndrome regardless of its cause. Dexamethasone, a potent glucocorticoid, normally suppresses pituitary ACTH release with a resulting fall in plasma and urine cortisol, thus assessing feedback inhibition of the HPA axis. In Cushing syndrome, this mechanism is abnormal, and steroid secretion fails to be suppressed in the normal way. Dexamethasone in the doses used does not interfere with the measurement of plasma and urinary cortisol.

The overnight 1-mg dexamethasone suppression test is commonly used as a screening test for Cushing syndrome. Dexamethasone, 1 mg orally, is given as a single dose at 11:00 PM, and the following morning a plasma sample is obtained for cortisol determination. Cushing syndrome is probably excluded if the serum or plasma cortisol level is less than 1.8 μg/dL (50 nmol/L). Utilizing this criterion leads to very high sensitivity but also has an increased false-positive rate and results in a specificity of 80% to 90%.

Eighty to ninety-nine percent of patients with Cushing syndrome have abnormal responses. False-negative results are more common in mild hypercortisolism and may also occur in patients in whom dexamethasone metabolism is abnormally slow, because plasma levels of dexamethasone in these patients are higher than normally achieved and result in apparently normal suppression of cortisol. Simultaneous measurement of plasma dexamethasone and cortisol levels identifies these patients.

False-positive results occur in hospitalized and chronically ill patients. Acute illness, depression, anxiety, alcoholism, high-oestrogen states, and uremia may also cause false-positive results. Patients taking phenytoin, barbiturates, and other inducers of hepatic microsomal enzymes may have accelerated metabolism of dexamethasone and thus fail to achieve adequate plasma levels to suppress ACTH.

**B. High-dose tests**—High-dose dexamethasone suppression testing has historically been used to differentiate Cushing disease (pituitary ACTH hypersecretion) from ectopic ACTH and adrenal tumors. This rationale has been based on the fact that in some patients with Cushing disease, the HPA axis is suppressible with supraphysiological doses of glucocorticoids, whereas cortisol secretion is autonomous in patients with adrenal tumors and in most patients with the ectopic ACTH syndrome. Unfortunately, exceptions to these rules are so common that high-dose dexamethasone suppression testing must be interpreted with extreme caution.

1. **Overnight high-dose dexamethasone suppression test**—After a baseline morning cortisol specimen is obtained, a single dose of dexamethasone, 8 mg orally, is administered at 11:00 PM and plasma cortisol is measured at 8:00 AM the following morning. Generally, patients with Cushing disease suppress plasma cortisol level to less than 50% of baseline values—in contrast to patients with the ectopic ACTH syndrome, who fail to suppress to this level. Patients with cortisol-producing adrenal tumors also fail to suppress: their cortisol secretion is autonomous, and ACTH secretion is already suppressed by the high endogenous levels of cortisol.

2. **Two-day high-dose dexamethasone suppression test**—This test is performed by administering dexamethasone, 2 mg orally every 6 hours for 2 days. Twenty-four-hour urine samples are collected before and on the second day of dexamethasone administration. Patients with Cushing disease have a reduction of urine cortisol excretion to less than 50% of baseline values, whereas those with adrenal tumors or the ectopic ACTH syndrome usually have little or no reduction in urinary cortisol excretion. However, some patients with an ectopic ACTH-secreting neoplasm suppress steroid secretion with high doses of dexamethasone, and some patients with pituitary
ACTH-dependent Cushing syndrome fail to suppress to these levels. The diagnostic sensitivity, specificity, and accuracy of the high-dose dexamethasone suppression test are only about 80%. Better specificity and accuracy can be achieved by utilizing different criteria. However, it has been increasingly clear that high-dose dexamethasone suppression testing, regardless of the criteria employed, cannot distinguish pituitary from nonpituitary ACTH hypersecretion with certainty. Currently, the only biochemical test with a high enough diagnostic accuracy to distinguish between these causes is inferior petrosal sinus ACTH sampling.

**Pituitary-Adrenal Reserve**

These tests are used to evaluate the ability of the HPA axis to respond to stress. ACTH administration directly stimulates adrenal secretion; metyrapone inhibits cortisol synthesis, thereby stimulating pituitary ACTH secretion; and insulin-induced hypoglycemia stimulates ACTH release by increasing CRH secretion. More recently, CRH has been utilized to directly stimulate pituitary corticotrophs to release ACTH. The relative utility of these procedures is discussed below in the section on adrenocortical insufficiency and also in Chapter 4.

**A. ACTH stimulation testing**

1. **Procedure and normal values—High-dose ACTH stimulation test.** The rapid ACTH stimulation test measures the acute adrenal response to ACTH and is used to diagnose both primary and secondary adrenal insufficiency. A synthetic human α-24- ACTH called tetracosactrin or cosyntropin is used. Fasting is not required, and the test may be performed at any time of the day. A baseline cortisol sample is obtained; cosyntropin is administered in a dose of 250 μg intramuscularly or intravenously; and additional samples for plasma cortisol are obtained at 30 or 60 minutes following the injection. Because the peak concentration of ACTH with this test achieves a pharmacologic level exceeding 10,000 pg/mL, this study assesses maximal adrenocortical capacity. The peak cortisol response, 30 to 60 minutes later, should exceed 18 to 20 μg/dL (497-552 nmol/L). The 30-minute peak cortisol response to ACTH is constant and is unrelated to the basal cortisol level. In fact, there is no difference in the peak cortisol level at 30 minutes regardless of whether 250 μg, 5 μg, or even 1 μg of ACTH is administered. Early studies of the salivary or plasma free cortisol response to ACTH suggest that this method may be useful in patients with abnormal levels of cortisol-binding proteins.

   **Low-dose ACTH stimulation test.** Since the standard or high-dose test may be normal in patients with partial secondary adrenal insufficiency, a low-dose (1 μg) ACTH stimulation test was developed. Although some studies reported increased sensitivity and specificity, two meta-analyses did not establish a distinct advantage for the low-dose test.

   To perform the low-dose test appropriately it must be undertaken in the morning and the ACTH must be given intravenously. In addition, technical limitations are significant (i.e., ACTH is available only in 250-μg vials, it is unstable in solution, and adheres to glass and plastic syringes and IV tubing). Thus, there are serious issues as to the accuracy of the dose of ACTH during reconstitution, dilution, and IV injection. For these reasons, the low-dose ACTH stimulation test is not practical for routine clinical practice.

2. **Subnormal responses**—If the cortisol response to the rapid ACTH stimulation test is inadequate, adrenal insufficiency is present. In primary adrenal insufficiency, destruction of cortical cells reduces cortisol secretion and increases pituitary ACTH secretion. Therefore, the adrenal is already maximally stimulated, and there is no further increase in cortisol secretion when exogenous ACTH is given; that is, there is decreased adrenal reserve. In secondary adrenal insufficiency due to ACTH deficiency, there is atrophy of the zona fasciculata and reticularis, and the adrenal thus is either hyporesponsive or unresponsive to acute stimulation with exogenous ACTH. In either primary or secondary types, a subnormal response to the rapid ACTH stimulation test accurately predicts deficient responsiveness of the axis to insulin hypoglycemia, metyrapone, and surgical stress.

3. **Normal responses**—A normal response to the rapid ACTH stimulation test excludes both primary adrenal insufficiency (by directly assessing adrenal reserve) and overt secondary adrenal insufficiency with adrenal atrophy. However, a normal response does not rule out partial ACTH deficiency (decreased pituitary reserve) in patients whose basal ACTH secretion is sufficient to prevent adrenocortical atrophy and patients with recently developed secondary adrenal insufficiency who have not yet undergone adrenal atrophy. These patients may be unable to further increase ACTH secretion and thus may have subnormal pituitary ACTH responsiveness to stress or hypoglycemia. In such patients, further testing with metyrapone, hypoglycemia, or CRH may be indicated. For further discussion, see the section on diagnosis of adrenocortical insufficiency.

**B. Metyrapone testing** Metyrapone testing has been used to diagnose adrenal insufficiency and to assess pituitary-adrenal reserve. The test procedures are detailed in Chapter 4. Metyrapone blocks cortisol synthesis by inhibiting the 11β-hydroxylase enzyme that converts 11-deoxycortisol to cortisol. This stimulates ACTH secretion, which in turn increases the secretion and plasma levels of 11-deoxycortisol. The overnight metyrapone test is most commonly used and is best suited to patients with suspected pituitary ACTH deficiency; patients with suspected primary adrenal failure are usually evaluated with the rapid ACTH stimulation test as described earlier and discussed in the section on diagnosis of adrenocortical insufficiency. The normal response to the overnight metyrapone test is a plasma 11-deoxycortisol level greater than 7 ng/dL (0.2 nmol/L) and a plasma ACTH level greater than 100 pg/mL (22 pmol/L) and indicates both normal ACTH secretion and adrenal function. A subnormal response establishes adrenocortical insufficiency. A normal response to metyrapone accurately predicts normal stress responsiveness of the hypothalamic-pituitary axis and correlates well with responsiveness to insulin-induced hypoglycemia. Metyrapone is only available directly from the manufacturer.

**C. Insulin-induced hypoglycemia testing** The details of this procedure are described in Chapter 4. Hypoglycemia induces a central nervous system stress response, increases CRH release, and in this way increases ACTH and cortisol secretion. It therefore measures the integrity of the axis and its ability to respond to stress. The normal plasma cortisol response is an increment greater
disorders. CRH testing has also been used to differentiate among
assays are available for total plasma levels of DHEA, DHEA sui-
tative ACTH secretion (secondary adrenocortical insufficiency).
Androgens excess is usually evaluated by measurement of basal
levels of these hormones, because suppression and stimulation
tests are not as useful as in disorders affecting glucocorticoids.
Assays are available for total plasma levels of DHEA, DHEA sul-
fate, androstenedione, testosterone, and dihydrotestosterone.
Plasma-free testosterone (ie, testosterone not bound to SHBG)
can be measured and is a more direct measure of circulating bi-
ologically active testosterone than the total plasma level, but com-
mercially available methods vary widely in their accuracy
(see Chapter 12).

**DISORDERS OF ADRENOCORTICAL INSUFFICIENCY**

Deficient adrenal production of glucocorticoids or mineralocorti-
coids results in adrenocortical insufficiency, which is either the
consequence of destruction or dysfunction of the cortex (primary
adrenocortical insufficiency, or Addison disease) or secondary to
deficient pituitary ACTH secretion (secondary adrenocortical
insufficiency). Glucocorticoid therapy is the most common cause
of secondary adrenocortical insufficiency.

**PRIMARY ADRENOCORTICAL INSUFFICIENCY (ADDISON DISEASE)**

**Etiology and Pathology (Figure 9-9)**

The etiology of primary adrenocortical insufficiency has changed
time. Prior to 1920, tuberculosis was the major cause of ade-
nocortical insufficiency. Since 1950, autoimmune adrenalitis with
adrenal atrophy has accounted for about 80% of cases. It is associ-
ated with a high incidence of other immunologic and autoim-
mune endocrine disorders (see later). Causes of primary adrenal
insufficiency are listed in Table 9–3. Primary adrenocortical insuf-
ciency, or Addison disease, is rare, with a reported prevalence of
35 to 140 per million population. When part of the polyglan-
dular system, it is more common in females, with a female-male ratio of
approximately 2:1. Addison disease is usually diagnosed in the
third to fifth decades.

**A. Autoimmune adrenocortical insufficiency** Pathologi-
cally, the adrenals are small and atrophic, and the capsule is
thickened. The adrenal medulla is preserved, although cortical
cells are largely absent, show degenerative changes, and are sur-
rounded by a fibrous stroma and the characteristic lymphocytic
infiltrates.

Autoimmune Addison disease is frequently accompanied by
other immune disorders. There are two different syndromes in
which autoimmune adrenal insufficiency may occur. The best
characterized one is known as autoimmune polyendocrinopathy-
candidiasis-ectodermal dystrophy syndrome (APCED), or auto-
immune polyglandular syndrome type 1 (APS-1). This is an
autosomal recessive disorder that usually presents in childhood
and is accompanied by hypoparathyroidism, adrenal failure, and
mucocutaneous candidiasis. APS-1 results in most cases from a
mutation of the autoimmune regulator gene (AIRE), which is
located on chromosome 21q22.3. These patients have a defect in
T-cell-mediated immunity, especially toward the candidal anti-
gens. APS-1 has no relationship to human leukocyte antigen
(HLA) and is often associated with hepatitis, dystrophy of dental
enamel and nails, alopecia, vitiligo, and keratopathy and may be
accompanied by hypofunction of the gonads, thyroid, pancreatic
B cell, and gastric parietal cells. Autoantibodies against the choles-
terol side chain cleavage enzyme (P450scc, CYP11A1) and others
have been described in patients with this disorder.

The more common presentation of autoimmune adrenocorti-
cal insufficiency is associated with HLA-related disorders includ-
ing type 1 diabetes mellitus and autoimmune thyroid disease.
Other less common related disorders include alopecia areata, viti-
ligo, primary hypogonadism, pernicious anemia, and celiac dis-
 ease. This disorder is often referred to as APS type 2. The genetic
susceptibility to this disorder is linked to HLA-DR3 or DR4 (or
both). These patients have antiadrenal cytoplasmic antibodies that
may be important in the pathogenesis of this disorder, and autoan-
tibodies directed against 21α-hydroxylase (P450c21, CYP21A2)
have been identified (see Chapter 2).

**B. Adrenal hemorrhage** Bilateral adrenal hemorrhage is a
rare cause of adrenal insufficiency. The diagnosis is usually made
in critically ill patients in whom a computed tomography (CT)
scan of the abdomen is performed. Bilateral adrenal enlargement
is found, leading to an assessment of adrenocortical function.
Anatomic factors predispose the adrenal glands to hemorrhage.
The adrenal glands have a rich arterial blood supply, but they are
drained by a single vein. Adrenal vein thrombosis may occur dur-
ing periods of stasis or turbulence, thereby increasing adrenal vein
pressure and resulting in a vascular dam. This causes hemorrhage
into the gland and is followed by adrenocortical insufficiency.

Most patients with adrenal hemorrhage have been taking anti-
coagulant therapy for an underlying coagulopathy or are predis-
posed to thrombosis. Heparin-induced thrombocytopenia
syndrome may be accompanied by adrenal vein thrombosis and
FIGURE 9-9 Hypothalamic-pituitary axis in adrenal insufficiency of different causes. These panels illustrate hormone secretion in the normal state (upper left), primary adrenal insufficiency (upper right), secondary adrenal insufficiency—ACTH deficiency (lower left), and tertiary adrenal insufficiency—CRH deficiency (lower right). Renin-angiotensin system is also illustrated. In contrast to normal secretion and hormone levels, decreased hormonal secretion is indicated by a dotted line and increased secretion by a dark solid line.
Adrenoleukodystrophy has an incidence of approximately one in 25,000 and is an X-linked disorder (chromosome Xq28) with incomplete penetrance. Molecular analysis is available clinically and can be used both in family screening and in prenatal evaluation. Two clinical phenotypes have been described. Cerebral adrenoleukodystrophy usually presents in childhood, and its neurologic symptoms include cognitive dysfunction, behavioral problems, emotional lability, and visual and gait disturbances. It may progress to dementia. Because 30% of these patients develop adrenal insufficiency before the onset of neurologic symptoms, a young man with primary adrenal insufficiency should always be screened for adrenoleukodystrophy. A clinically milder phenotype, adrenomyeloneuropathy, usually presents in the second to fourth decades of life. Spinal cord and peripheral nerve demyelination occur over years and may result in loss of ambulation, cognitive dysfunction, urinary retention, and impotence. Once again, adrenal insufficiency may occur before the onset of neurologic symptoms.

The diagnosis of adrenoleukodystrophy can be confirmed by demonstration of the defect in fatty acid metabolism with the abnormal accumulation of saturated VLCFAs, especially C26:0 fatty acid.

E. Metastatic adrenal disease The adrenal glands are common sites of metastasis for lung, gastrointestinal, breast, and renal neoplasia. Bilateral adrenal involvement is present in approximately 50% of patients; however, adrenal insufficiency does not occur with unilateral metastatic disease. Even with bilateral involvement adrenal insufficiency appears to be uncommon. Despite being uncommon, patients with bilateral disease should be evaluated for adrenal insufficiency and then followed as adrenal insufficiency is a potentially life threatening condition. In addition, non-Hodgkin and Hodgkin lymphoma may present with involvement of the adrenal glands with bilateral adrenal enlargement and primary adrenal insufficiency.

F. Familial glucocorticoid deficiency and congenital adrenal hypoplasia Familial glucocorticoid deficiency is a rare disorder in which there is hereditary adrenocortical unresponsiveness to ACTH. This leads to adrenal insufficiency with subnormal glucocorticoid and adrenal androgen secretion as well as elevated plasma ACTH levels. As a rule, aldosterone secretion is preserved. At least two distinct types of this disorder have been described. One type is associated with mutations in the ACTH receptor on the cells of the adrenal cortex. Another type is often associated with achalasia and alacrima (Allgrove syndrome; triple A syndrome) and progressive neurologic impairment, but no mutations in the ACTH receptor have been seen in these patients. The responsible gene is on chromosome 12 (12q13) and encodes a protein belonging to the WD repeat proteins. Its function remains unknown. Congenital adrenal hypoplasia is a developmental abnormality usually presenting in the neonatal period. X-linked forms associated with mutations of DAX1 and autosomal recessive forms have been reported.

G. Cortisol resistance Primary cortisol resistance is an unusual disorder representing target cell resistance to cortisol due to either qualitative or quantitative abnormalities of the glucocorticoid receptor. This disorder is characterized by hypercortisolism.

Hemorrhage. The primary antiphospholipid antibody syndrome (lupus anticoagulant) has emerged as one of the more common causes of adrenal hemorrhage.

C. Infections Although tuberculosis is a common cause of primary adrenal insufficiency in the rest of the world, it is a rare cause of this problem in the United States. Clinically significant adrenal insufficiency appears to occur in only about 5% of patients with disseminated tuberculosis. With the use of anti-tuberculous chemotherapy, it may even be reversible if detected in early stages. It is important to recognize that rifampin may accelerate the metabolic clearance of cortisol, thereby increasing the replacement dose needed in these patients. Most if not all systemic fungal infections can involve and destroy the adrenal cortex. Tuberculosis and fungal infections are associated with enlarged adrenals that may show calcifications. Of note, theazole antifungal agents, such as ketoconazole, inhibit adrenal cytochrome P450 steroidogenic enzymes that are essential for cortisol biosynthesis. Thus, azole antifungal treatment, especially with ketoconazole, in patients with marginal adrenocortical reserve due to fungal disease may precipitate adrenal crisis.

HIV/AIDS has been associated with pathologic involvement of the adrenal gland. Although adrenal necrosis is commonly seen in postmortem examination of patients with AIDS, primary adrenal insufficiency appears to complicate only a few patients with this disorder. Primary adrenal insufficiency in AIDS is usually caused by opportunistic infections such as fungal infection, cytomegalovirus, and mycobacterium avium complex. Adrenocortical insufficiency usually occurs as a late manifestation in AIDS patients with very low CD4 counts (see Chapter 25).

D. Adrenoleukodystrophy X-linked adrenoleukodystrophy is an important cause of adrenal insufficiency in men. This disorder represents two distinct entities that may cause malfunction of the adrenal cortex and demyelination in the central nervous system. These disorders are characterized by abnormally high levels of very long chain fatty acids (VLCFAs) due to their defective beta oxidation within peroxisomes. The abnormal accumulation of VLCFAs in the brain, adrenal cortex, testes, and liver result in the clinical manifestations of this disorder.

Adrenoleukodystrophy has an incidence of approximately one in 25,000 and is an X-linked disorder (chromosome Xq28) with incomplete penetrance. Molecular analysis is available clinically and can be used both in family screening and in prenatal evaluation. Two clinical phenotypes have been described. Cerebral adrenoleukodystrophy usually presents in childhood, and its neurologic symptoms include cognitive dysfunction, behavioral problems, emotional lability, and visual and gait disturbances. It may progress to dementia. Because 30% of these patients develop adrenal insufficiency before the onset of neurologic symptoms, a young man with primary adrenal insufficiency should always be screened for adrenoleukodystrophy. A clinically milder phenotype, adrenomyeloneuropathy, usually presents in the second to fourth decades of life. Spinal cord and peripheral nerve demyelination occur over years and may result in loss of ambulation, cognitive dysfunction, urinary retention, and impotence. Once again, adrenal insufficiency may occur before the onset of neurologic symptoms.

The diagnosis of adrenoleukodystrophy can be confirmed by demonstration of the defect in fatty acid metabolism with the abnormal accumulation of saturated VLCFAs, especially C26:0 fatty acid.

E. Metastatic adrenal disease The adrenal glands are common sites of metastasis for lung, gastrointestinal, breast, and renal neoplasia. Bilateral adrenal involvement is present in approximately 50% of patients; however, adrenal insufficiency does not occur with unilateral metastatic disease. Even with bilateral involvement adrenal insufficiency appears to be uncommon. Despite being uncommon, patients with bilateral disease should be evaluated for adrenal insufficiency and then followed as adrenal insufficiency is a potentially life threatening condition. In addition, non-Hodgkin and Hodgkin lymphoma may present with involvement of the adrenal glands with bilateral adrenal enlargement and primary adrenal insufficiency.

F. Familial glucocorticoid deficiency and congenital adrenal hypoplasia Familial glucocorticoid deficiency is a rare disorder in which there is hereditary adrenocortical unresponsiveness to ACTH. This leads to adrenal insufficiency with subnormal glucocorticoid and adrenal androgen secretion as well as elevated plasma ACTH levels. As a rule, aldosterone secretion is preserved. At least two distinct types of this disorder have been described. One type is associated with mutations in the ACTH receptor on the cells of the adrenal cortex. Another type is often associated with achalasia and alacrima (Allgrove syndrome; triple A syndrome) and progressive neurologic impairment, but no mutations in the ACTH receptor have been seen in these patients. The responsible gene is on chromosome 12 (12q13) and encodes a protein belonging to the WD repeat proteins. Its function remains unknown. Congenital adrenal hypoplasia is a developmental abnormality usually presenting in the neonatal period. X-linked forms associated with mutations of DAX1 and autosomal recessive forms have been reported.

G. Cortisol resistance Primary cortisol resistance is an unusual disorder representing target cell resistance to cortisol due to either qualitative or quantitative abnormalities of the glucocorticoid receptor. This disorder is characterized by hypercortisolism.
without clinical manifestations of glucocorticoid excess. Pituitary resistance to cortisol results in hypersecretion of ACTH, which stimulates the adrenal gland to produce excessive amounts of cortisol, mineralocorticoids, and adrenal androgens. The increased production of cortisol and these non-glucocorticoid adrenal steroids may cause hypertension, hypokalemia, virilization, and sexual precocity. Because cortisol is essential for life, this disorder actually represents partial rather than complete resistance.

H. Drug-induced adrenal insufficiency Drugs associated with primary adrenal insufficiency include the azole antifungal agents, the anesthetic agent etomidate, the antiparasitic agent suramin as well as the steroid synthesis inhibitors aminoglutethimide, metyrapone, and mitotane. Mifepristone is a progesterone antagonist that also antagonizes the glucocorticoid receptor and may cause adrenal insufficiency if given in a sufficient dose. Megestrol acetate, a synthetic progesterone derivative used to stimulate appetite, binds to the glucocorticoid receptor and suppresses the HPA axis leading to adrenal insufficiency after withdrawal of therapy. Opioid narcotics cause a transient suppression of the HPA axis and can lead to suppression of plasma cortisol levels. Additionally, the use of protease inhibitors with exogenous glucocorticoids (from oral, injectable, inhaled, or even optic routes) can cause secondary adrenal insufficiency after cessation of glucocorticoid use.

I. Cortisol in critical illness In 2002 it was reported that 77% of 299 patients with severe sepsis had plasma cortisol increments of less than 9 μg/dL to standard ACTH-stimulation testing. These patients were classified as having relative adrenal insufficiency (also termed partial adrenal insufficiency or decreased adrenal reserve) and randomized to therapy with hydrocortisone and fludrocortisone with a modest survival benefit. The study led to a widespread recommendation that all severely ill patients with sepsis be tested with ACTH and treated with corticosteroids. However, the study was compromised by two major issues. First, 30% of the patients classified as relatively adrenal insufficient had received etomidate (a drug which causes adrenal insufficiency) within 12 hours of enrollment. Second, the authors did not recognize that total plasma cortisol levels and their response to ACTH are lowered in severely ill patients who frequently have hypoalbuminemia and low corticosteroid-binding globulin levels. Subsequent studies have shown that both plasma free cortisol and salivary cortisol are appropriately elevated and respond normally to ACTH in patients with sepsis. In addition, several studies have shown no survival benefit following corticosteroid therapy. Thus, there is no convincing evidence that adrenal insufficiency is frequent in critically ill patients.

Pathophysiology Loss of more than 90% of both adrenal cortices results in the clinical manifestations of adrenocortical insufficiency. Gradual destruction, such as occurs in the idiopathic and invasive forms of the disease, leads to chronic adrenocortical insufficiency. However, more rapid destruction occurs in many cases; about 25% of patients are in crisis or impending crisis at the time of diagnosis. With gradual adrenocortical destruction, the initial phase is that of decreased adrenal reserve; that is, basal steroid secretion is normal, but secretion does not increase in response to stress. Thus, acute adrenal crisis can be precipitated by the stresses of surgery, trauma, or infection, which require increased corticosteroid secretion.

Clinical Features

A. Symptoms and signs Cortisol deficiency causes weakness, fatigue, anorexia, nausea and vomiting, hypotension, hypotension, hypoglycemia. Mineralocorticoid deficiency produces renal sodium wasting and potassium retention and can lead to severe dehydration, hypotension, hypokalemia, hyperkalemia, and acidosis.

1. Chronic primary adrenocortical insufficiency—The chief symptoms (Table 9-4) are hyperpigmentation, weakness and fatigue, weight loss, anorexia, and gastrointestinal disturbances.

Hyperpigmentation is the classic physical finding, and its presence in association with the above manifestations should suggest primary adrenocortical insufficiency. Generalized hyperpigmentation of the skin and mucous membranes is one of the earliest manifestations of Addison disease. It is increased in sun-exposed areas and accentuated over pressure areas such as the knuckles, toes, elbows, and knees. It is accompanied by increased numbers of black or dark-brown freckles. The classic hyperpigmentation of the buccal mucosa and gums is preceded by generalized hyperpigmentation of the skin; adrenal insufficiency should also be suspected when there is increased pigmentation of the palmar creases, nail beds, nipples, areolae,

| Gastrointestinal disturbances | 56 |
| Salt craving | 19 |
| Postural symptoms | 12 |

and perivaginal and perianal mucosa. Scars that have formed after the onset of ACTH excess become hyperpigmented, whereas older ones do not.

General weakness, fatigue and malaise, anorexia, and weight loss are invariable features of the disorder. Weight loss may reach 15 kg with progressive adrenal failure. Gastrointestinal disturbances, especially nausea and vomiting, occur in most patients; diarrhea is less frequent. An increase in gastrointestinal symptoms during an acute adrenal crisis may confuse the diagnosis by suggesting a primary intra-abdominal process.

Hypotension is present in about 90% of patients and is accompanied by orthostatic symptoms and occasionally syncope. In more severe chronic cases and in acute crises, recumbent hypotension or shock is almost invariably present. Vitiligo occurs in 4% to 17% of patients with autoimmune Addison disease but is rare in Addison disease due to other causes. Salt craving occurs in about 20% of patients.

Severe hypoglycemia may occur in children. This finding is unusual in adults but may be provoked by fasting, fever, infection, or nausea and vomiting, especially in acute adrenal crisis. Hypoglycemia occurs more commonly in secondary adrenal insufficiency.

Amenorrhea is common in Addison disease. It may be due to weight loss and chronic illness or to primary ovarian failure. Loss of axillary and pubic hair may occur in women as a result of decreased secretion of adrenal androgens.

Partial adrenal insufficiency may have subtle clinical manifestations. Adrenal insufficiency should be considered in the differential diagnosis of unexplained weight loss and in patients with hypotension and fever.

2. Acute adrenal crisis—Acute adrenal crisis represents a state of acute adrenocortical insufficiency and occurs in patients with Addison disease who are exposed to the stress of infection, trauma, surgery, or dehydration due to salt deprivation, vomiting, or diarrhea.

The symptoms are listed in Table 9–5. Anorexia and nausea and vomiting increase and worsen the volume depletion and dehydration. Hypovolemic shock frequently occurs, and adrenal insufficiency should be considered in any patient with unexplained vascular collapse. Abdominal pain may occur and mimic an acute abdominal emergency. Weakness, apathy, and confusion are common. Fever is also common and may be due to infection or to hypoadrenalism per se. Hyperpigmentation is present unless the onset of adrenal insufficiency is rapid and should suggest the diagnosis.

Additional findings that suggest the diagnosis are hypotension, hyperkalemia, lymphocytosis, eosinophilia, and hypoglycemia.

Shock and coma may rapidly lead to death in untreated patients (see Chapter 24).

3. Acute adrenal hemorrhage (Table 9–6)—Bilateral adrenal hemorrhage and acute adrenal destruction in an already compromised patient with major medical illness follow a progressively deteriorating course. The usual manifestations are abdominal, flank, or back pain and abdominal tenderness. Abdominal distention, rigidity, and rebound tenderness are less frequent. Hypotension, shock, fever, nausea and vomiting, confusion, and disorientation are common; tachycardia and cyanosis are less frequent.

With progression, severe hypotension, volume depletion, dehydration, hyperpyrexia, cyanosis, coma, and death ensue.

The diagnosis of acute adrenal hemorrhage should be considered in the deteriorating patient with unexplained abdominal or flank pain, vascular collapse, hyperpyrexia, or hypoglycemia, particularly in the setting of an underlying coagulopathy.

### B. Laboratory and electrocardiographic findings and imaging studies

1. Gradual adrenal destruction—Hyponatremia and hyperkalemia are classic manifestations of the glucocorticoid and mineralocorticoid deficiency of primary adrenal insufficiency and should suggest the diagnosis. Hematologic manifestations include normocytic, normochromic anemia, neutropenia, eosinophilia, and a relative lymphocytosis. Azotemia with increased concentrations of blood urea nitrogen and serum creatinine is due to volume depletion and dehydration. Mild acidosis is frequently present. Hypercalcemia of mild to moderate degree occurs in about 6% of patients.

Abdominal radiographs reveal adrenal calcification in half the patients with tuberculous Addison disease and in some patients with other invasive or hemorrhagic causes of adrenal insufficiency. CT is a more sensitive detector of adrenal calcification and adrenal enlargement. Bilateral adrenal enlargement in association with adrenal insufficiency may be seen with tuberculosis, fungal infections, cytomegalovirus, malignant and nonmalignant infiltrative diseases, and adrenal hemorrhage.

Electrocardiographic features are low voltage, a vertical QRS axis, and nonspecific ST-T wave abnormalities secondary to abnormal electrolytes.
2. **Acute adrenal hemorrhage**—Hyponatremia and hyperkalemia occur in only a small number of cases, but azotemia is a usual finding. Increased circulating eosinophils may suggest the diagnosis. The diagnosis is frequently established only when imaging studies reveal bilateral adrenal enlargement.

**SECONDARY ADRENOCORTICAL INSUFFICIENCY**

**Etiology**
Secondary adrenocortical insufficiency due to ACTH deficiency is most commonly a result of exogenous glucocorticoid therapy. Pituitary or hypothalamic tumors are the most common causes of naturally occurring pituitary ACTH hyposecretion. These and other less common causes are reviewed in Chapter 4.

**Pathophysiology**
ACTH deficiency is the primary event and leads to decreased cortisol and adrenal androgen secretion. Aldosterone secretion remains normal except in a few cases. In the early stages, basal ACTH and cortisol levels may be normal; however, ACTH reserve is impaired, and ACTH and cortisol responses to stress are, therefore, subnormal. With further loss of basal ACTH secretion, there is atrophy of the zone fasciculata and reticularis of the adrenal cortex; and, therefore, basal cortisol secretion is decreased. At this stage, the entire pituitary adrenal axis is impaired; that is, there is not only decreased ACTH responsiveness to stress but also decreased adrenal responsiveness to acute stimulation with exogenous ACTH.

The manifestations of glucocorticoid deficiency are similar to those described for primary adrenocortical insufficiency. However, because aldosterone secretion by the zona glomerulosa is usually preserved, the manifestations of mineralocorticoid deficiency are absent.

**Clinical Features**

**A. Symptoms and signs** Secondary adrenal insufficiency is usually chronic, and the manifestations may be nonspecific. However, acute crisis can occur in undiagnosed patients or in corticosteroid-treated patients who do not receive increased steroid dosage during periods of stress.

The clinical features of secondary adrenal insufficiency differ from those of primary adrenocortical insufficiency in that pituitary secretion of ACTH is deficient and hyperpigmentation is, therefore, not present. In addition, mineralocorticoid secretion is usually normal. Thus, the clinical features of ACTH and glucocorticoid deficiency are nonspecific.

Volume depletion, dehydration, and hyperkalemia are usually absent. Hypotension is usually not present except in acute presentations. Hyponatremia may occur, as a result of water retention and inability to excrete a water load, but is not accompanied by hyperkalemia. Prominent features are weakness, lethargy, easy fatigability, anorexia, nausea, and occasionally vomiting. Arthralgias and myalgias also occur. Hypoglycemia is occasionally the presenting feature. Acute decompensation with severe hypotension or shock unresponsive to vasopressors may occur.

**B. Associated features** Patients with secondary adrenal insufficiency commonly have additional features that suggest the diagnosis. A history of glucocorticoid therapy, or if this is not available, the presence of cushingoid features suggests prior glucocorticoid use. Hypothalamic or pituitary tumors leading to ACTH deficiency usually cause loss of other pituitary hormones (hypogonadism and hypothyroidism). Hypersecretion of GH or prolactin (PRL) from a pituitary adenoma may be present.

**C. Laboratory findings** Findings on routine laboratory examination consist of normochromic, normocytic anemia, neutropenia, lymphocytosis, and eosinophilia. Hyponatremia is not uncommon and may be the presenting laboratory abnormality. Hyponatremia is due to the lack of glucocorticoid-negative feedback on AVP as well as the reduction in glomerular filtration associated with hypocortisolism. Serum potassium, creatinine, and bicarbonate and blood urea nitrogen are usually normal; plasma glucose may be low, although severe hypoglycemia is unusual.

**DIAGNOSIS OF ADRENOCORTICAL INSUFFICIENCY**

Although the diagnosis of adrenal insufficiency should be confirmed by assessment of the pituitary adrenal axis, therapy should not be delayed, and the patient should not be subjected to procedures that may increase volume loss and dehydration and further contribute to hypotension. If the patient is acutely ill, therapy should be instituted and the diagnosis established when the patient is stable.

**Diagnostic Tests**
Because basal levels of adrenocortical steroids in either urine or plasma may be normal in partial adrenal insufficiency, tests of adrenocortical reserve are necessary to establish the diagnosis (Figure 9-10). These tests are described in the section on laboratory evaluation and in Chapter 4.

**Rapid ACTH Stimulation Test**
The rapid ACTH stimulation test assesses adrenal reserve and is the initial procedure in the assessment of possible adrenal insufficiency, either primary or secondary. As previously discussed, the low-dose ACTH (1-µg cosynrropin) stimulation test has been suggested to represent a more physiologic stimulus to the adrenal cortex; however, many experienced clinicians continue to employ the standard 250-µg cosynrropin dose.

Subnormal responses to exogenous ACTH administration are an indication of decreased adrenal reserve and establish the diagnosis of adrenocortical insufficiency. Further diagnostic procedures
are not required, because subnormal responses to the rapid ACTH stimulation test indicate lack of responsiveness to metyrapone, insulin-induced hypoglycemia, or stress. However, this test does not permit differentiation of primary and secondary causes. This is best accomplished by measurement of basal plasma ACTH levels, as discussed later.

A normal response to the rapid ACTH stimulation test excludes primary adrenal failure, because a normal cortisol response indicates normal cortical function. However, normal responsiveness does not exclude partial secondary adrenocortical insufficiency in those few patients with decreased pituitary reserve and decreased stress responsiveness of the HPA axis who maintain sufficient basal ACTH secretion to prevent adrenocortical atrophy. If this situation is suspected clinically, pituitary ACTH responsiveness may be tested directly with metyrapone or insulin-induced hypoglycemia (see section "Laboratory Evaluation" and below).

**Plasma ACTH Levels**

If adrenal insufficiency is present, plasma ACTH levels are used to differentiate primary and secondary forms. In patients with primary adrenal insufficiency, plasma ACTH levels exceed the upper limit of the normal range (>52 pg/mL [11 pmol/L]) and usually exceed 200 pg/mL (44 pmol/L). Plasma ACTH concentrations are inappropriately normal or less than 10 pg/mL (2.2 pmol/L) in patients with secondary adrenal insufficiency (Figure 9-11). However, basal ACTH levels must always be interpreted in light of the clinical situation, especially because of the episodic nature of ACTH secretion and its short plasma half-life. For example, ACTH levels frequently exceed the normal range during the recovery of the HPA axis from secondary adrenal insufficiency and may be confused with levels seen in primary adrenal insufficiency. Patients with primary adrenal insufficiency consistently have elevated ACTH levels. In fact, the ACTH concentration is elevated early in the course of adrenal insufficiency even before a significant reduction in the basal cortisol level or its response to exogenous ACTH occurs. Therefore, plasma ACTH measurements serve as a valuable screening study for primary adrenal insufficiency.

**Partial ACTH Deficiency**

When partial ACTH deficiency and decreased pituitary reserve are suspected despite normal responsiveness to the rapid ACTH stimulation test, the following procedures may be used for more direct assessment of hypothalamic-pituitary function.

**A. Methods of testing**  
The overnight metyrapone test is used in patients with suspected hypothalamic or pituitary disorders when
hypoglycemia is contraindicated and in those with prior glucocorticoid therapy. Insulin-induced hypoglycemia is used in patients with suspected hypothalamic or pituitary tumors, because both ACTH and GH responsiveness can be assessed (see Chapter 4).

B. Interpretation  A normal response to either metyrapone or hypoglycemia excludes secondary adrenocortical insufficiency (see section “Laboratory Evaluation”). Subnormal responses, even in the presence of a normal response to ACTH administration, establish the diagnosis of secondary adrenal insufficiency.

TREATMENT OF ADRENOCORTICAL INSUFFICIENCY

The aim of treatment of adrenocortical insufficiency is to produce levels of glucocorticoids and mineralocorticoids equivalent to those achieved in an individual with normal HPA function under similar circumstances.

Acute Addisonian Crisis (Table 9–7)

Treatment for acute Addisonian crisis should be instituted as soon as the diagnosis is suspected. Therapy includes administration of glucocorticoids, correction of dehydration, hypovolemia, and

TABLE 9–7 Treatment of acute adrenal crisis.
gradually reduced to approximately 10 mg two to three times daily gives satisfactory responses in most patients; however, some patients may require only a single morning dose, and others may require three doses daily (eg, 10-5-5) to maintain well-being and normal energy levels. Insomnia is a side-effect of glucocorticoid administration and can usually be prevented by administering the last dose in the early afternoon.

Fludrocortisone (9α-fluorocortisol) is used for mineralocorticoid therapy; the usual doses are 0.05 to 0.2 mg/d orally in the morning. Because of the long half-life of this agent, divided doses are not required. About 10% of addisonian patients can be managed with cortisol and adequate dietary sodium intake alone and do not require fludrocortisone.

Secondary adrenocortical insufficiency is treated with the cortisol dosages described above for the primary form. Fludrocortisone is rarely required. The recovery of normal function of the HPA axis following suppression by exogenous glucocorticoids may take weeks to years, and its duration is not readily predictable. Consequently, prolonged replacement therapy may be required. Recent studies in women have pointed to the potential benefits of DHEA in doses of 50 mg/d in terms of improvement in well-being, although this remains controversial.

**Response to Therapy**

General clinical signs, such as good appetite and sense of well-being, are the guides to the adequacy of replacement. Obviously, signs of Cushing syndrome indicate overtreatment. It is generally expected that the daily dose of hydrocortisone should be doubled during periods of minor stress, and the dose needs to be increased to as much as 200 to 300 mg/d during periods of major stress, such as a surgical procedure. Patients receiving excessive doses of glucocorticoids are also at risk for increased bone loss and clinically significant osteoporosis. Therefore, the replacement dose of glucocorticoid should be maintained at the lowest amount needed to provide the patient with a proper sense of well-being. Two major factors have prompted a reassessment of the issue of appropriateness and possible excess glucocorticoid replacement for patients with adrenal insufficiency. First, there is a greater appreciation of the potential risks of overtreatment or undertreatment. Recent evidence suggests that subclinical Cushing syndrome associated with adrenal incidentalomas contributes to poor control of blood sugar and blood pressure in diabetic patients, decreased bone density, and increased serum lipid levels. The levels of cortisol secretion by many incidentalomas are similar to those observed in patients with adrenal insufficiency receiving mild cortisol overreplacement. In addition, studies in patients receiving

**Maintenance Therapy (Table 9-8)**

Patients with Addison disease require life-long glucocorticoid and mineralocorticoid therapy. Cortisol (hydrocortisone) is the glucocorticoid preparation of choice. The basal production rate of cortisol is approximately 8 to 12 mg/m²/d. The maintenance dose of hydrocortisone is usually 15 to 25 mg daily in adults. The oral dose is usually divided into 10 to 15 mg in the morning on arising and 5 to 10 mg later in the day. Cortisol in twice-daily doses gives satisfactory responses in most patients; however, some patients may require only a single morning dose, and others may require three doses daily (eg, 10-5-5) to maintain well-being and normal energy levels. Insomnia is a side-effect of glucocorticoid
glucocorticoid replacement therapy demonstrate an inverse relationship between dose and bone mineral density and a positive correlation between dose and markers of bone resorption. Second, there is recognition that there is considerable variation among individuals in terms of the plasma levels of cortisol achieved with orally administered hydrocortisone or cortisol.

The measurement of urine free cortisol does not provide a reliable index for appropriate glucocorticoid replacement. Similarly, ACTH measurements are not a good indication of the adequacy of glucocorticoid replacement; marked elevations of plasma ACTH in patients with chronic adrenal insufficiency are often not suppressed into the normal range despite adequate hydrocortisone replacement. In fact, plasma ACTH values that fall to low normal or low levels suggest overreplacement with glucocorticoids. Plasma cortisol day curves—multiple samples for plasma cortisol concentration—have been proposed but not yet widely adopted. Therefore, it is prudent to use clinical assessment of the patient’s response to therapy, rather than biochemical criteria, to gauge the adequacy of steroid replacement.

Adequate treatment results in the disappearance of weakness, malaise, and fatigue. Anorexia and other gastrointestinal symptoms resolve, and weight returns to normal. The hyperpigmentation invariably improves but may not entirely disappear. Inadequate cortisol administration leads to persistence of these symptoms of adrenal insufficiency, and excessive pigmentation remains.

Adequate mineralocorticoid replacement may be determined by assessment of blood pressure and electrolyte composition. With adequate treatment, the blood pressure is normal without orthostatic change, and serum sodium and potassium remain within the normal range. Some endocrinologists monitor plasma renin activity (PRA) as an objective measure of fludrocortisone replacement. Upright PRA levels are usually less than 5 ng/mL/h in adequately replaced patients. Hypertension and hypokalemia result if the fludrocortisone dose is excessive. Conversely, undertreatment may lead to fatigue and malaise, orthostatic symptoms, and subnormal supine or upright blood pressure, with hyperkalemia and hyponatremia.

**Prevention of Adrenal Crisis**

The development of acute adrenal insufficiency in previously diagnosed and treated patients is almost entirely preventable in compliant individuals. The essential elements are patient education and increased glucocorticoid dosages during illness.

The patient should be informed about the necessity for lifelong therapy, the possible consequences of acute illness, and the necessity for increased therapy and medical assistance during acute illness. An identification card or bracelet should be carried or worn at all times.

The cortisol dose should be increased by the patient to 60 to 80 mg/d with the development of minor illnesses; the usual maintenance dosage may be resumed in 24 to 48 hours if improvement occurs. Increased mineralocorticoid therapy is not required.

If symptoms persist or become worse, the patient should continue increased cortisol doses and call the physician.

**TABLE 9–9 Steroid coverage for surgery.**

| (1) Correct electrolytes, blood pressure, and hydration if necessary |
| (2) Give hydrocortisone sodium phosphate or sodium succinate, 100 mg intramuscularly, on call to operating room |
| (3) Give 50 mg intramuscularly or intravenously in the recovery room and then every 6 h for the first 24 h |
| (4) If progress is satisfactory, reduce dosage to 25 mg every 6 h for 24 h and then taper to maintenance dosage over 3-5 d. Resume previous fludrocortisone dose when the patient is taking oral medications |
| (5) Maintain or increase hydrocortisone dosage to 200-400 mg/d if fever, hypotension, or other complications occur |

Vomiting may result in inability to ingest or absorb oral cortisol, and diarrhea in Addisonian patients may precipitate a crisis because of rapid fluid and electrolyte losses. Patients must understand that if these symptoms occur, they should seek immediate medical assistance so that parenteral glucocorticoid therapy can be given.

**Steroid Coverage for Surgery (Table 9–9)**

The normal physiologic response to surgical stress involves an increase in cortisol secretion. The increased glucocorticoid activity may serve primarily to modulate the immunologic response to stress. Thus, patients with primary or secondary adrenocortical insufficiency scheduled for elective surgery require increased glucocorticoid coverage. This problem is most frequently encountered in patients with pituitary-adrenal suppression due to exogenous glucocorticoid therapy. The principles of management are outlined in Table 9–9.

**PROGNOSIS OF ADRENOCORTICAL INSUFFICIENCY**

Before glucocorticoid and mineralocorticoid therapy became available, primary adrenocortical insufficiency was invariably fatal, with death usually occurring within 2 years after onset. Survival now depends on the underlying cause of the adrenal insufficiency. In patients with autoimmune Addison disease, survival approaches that of the normal population, and most patients lead normal lives. In general, death from adrenal insufficiency now occurs only in patients with rapid onset of disease who may die before the diagnosis is established and appropriate therapy started.

Secondary adrenal insufficiency has an excellent prognosis with glucocorticoid therapy. Adrenal insufficiency due to bilateral adrenal hemorrhage may be fatal, with some cases being recognized only at autopsy.

**CUSHING SYNDROME**

Chronic glucocorticoid excess, whatever its cause, leads to the constellation of symptoms and physical features known as Cushing syndrome. It is most commonly iatrogenic, resulting...
from chronic glucocorticoid therapy. Spontaneous Cushing syndrome is caused by abnormalities of the pituitary or adrenal gland or may occur as a consequence of ACTH or CRH secretion by nonpituitary tumors (ectopic ACTH syndrome; ectopic CRH syndrome) (Figure 9–12). Cushing disease is defined as the specific type of Cushing syndrome due to excessive pituitary ACTH secretion from a pituitary tumor. This section will review the various types of spontaneous Cushing syndrome and discuss their diagnosis and therapy (see also Chapter 4).

### Classification and Incidence

Cushing syndrome is conveniently classified as either ACTH dependent or ACTH independent (Table 9–10). The ACTH-dependent types of Cushing syndrome—ectopic ACTH syndrome and Cushing disease—are characterized by chronic ACTH hypersecretion, which results in hyperplasia of the adrenal zonae fasciculata and reticularis and, therefore, increased secretion of cortisol, androgens, and DOC.

**FIGURE 9–12** Hypothalamic-pituitary axis in Cushing syndrome of different causes. These panels illustrate hormone secretion in the normal state (upper left), and four types of cortisol excess: Pituitary ACTH-dependent (with an ACTH-secreting pituitary tumor) (upper right), adrenal tumor (lower left), ectopic ACTH syndrome due to an ACTH-secreting lung cancer (lower middle), and ectopic CRH syndrome due to a CRH-secreting lung tumor. In contrast to normal secretion and hormone levels, decreased hormonal secretion is indicated by a dotted line and increased secretion by a dark solid line.
ACTH-independent Cushing syndrome may be caused by a primary adrenal neoplasm (adenoma or carcinoma) or nodular adrenal hyperplasia. In these cases, the cortisol excess suppresses pituitary ACTH secretion.

A. **Cushing disease**  
This is the most frequent type of Cushing syndrome and is responsible for about 80% of reported cases. Cushing disease is much more common in women than in men (female:male ratio of about 5:1) and the age at diagnosis is usually 20 to 40 years but may range from childhood to 70 years.

B. **Ectopic ACTH hypersecretion**  
This disorder accounts for approximately 10% of patients with ACTH-dependent Cushing syndrome. The production of ACTH from a tumor of nonpituitary origin may result in severe hypercortisolism, but many of these patients lack the classic features of glucocorticoid excess. This presumably reflects the acuteness of the clinical course in the ectopic ACTH syndrome. The clinical presentation of ectopic ACTH secretion is most frequently seen in patients with tumors of a thoracic origin. Bronchial carcinoid and small cell lung carcinoma are responsible for 50% of cases of this syndrome. The prognosis in patients with the ectopic ACTH syndrome is generally poor and largely a function of the primary tumor. Individuals with ectopic ACTH syndrome from small cell lung carcinoma have a mean survival of less than 12 months. The ectopic ACTH syndrome may also present in a fashion identical to classic Cushing disease and pose a challenging diagnostic dilemma. A wide variety of tumors has been reported to produce ectopic ACTH and may be radiologically apparent at the time of the presentation. The ectopic ACTH syndrome is more common in men, and the peak age incidence is 40 to 60 years.

C. **Primary adrenal tumors**  
Primary adrenal tumors cause approximately 10% of cases of Cushing syndrome. Most of these patients have benign adrenocortical adenomas. Adrenocortical carcinomas are uncommon, with an incidence of approximately 2 per million per year. Both adrenocortical adenomas and carcinomas are more common in women. Autonomous cortisol secretion without the classic features of Cushing syndrome occurs in about 5% of patients with adrenal incidentalomas (see later).

D. **Childhood Cushing syndrome**  
Cushing disease is more common in the adolescent population than in younger children. Most pediatric cases occur in patients over 10 years of age with an equal distribution between the sexes. Cushing disease remains the most common cause accounting for more than 80% of cases. Primary adrenal disease accounts for an additional 10% to 15% of all pediatric cases.

### Pathology

#### A. Anterior pituitary gland

1. **Pituitary adenomas**—Pituitary adenomas are present in over 90% of patients with Cushing disease. These tumors are typically smaller than those secreting GH or PRL; 80% to 90% are less than 10 mm in diameter. A small group of patients have larger tumors (>10 mm); these macroadenomas are frequently invasive, leading to extension outside the sella turcica. Malignant pituitary tumors occur rarely.

   Microadenomas are located within the anterior pituitary; they are not encapsulated but surrounded by a rim of compressed normal anterior pituitary cells. With routine histologic stains, these tumors are composed of compact sheets of well-granulated basophilic cells in a sinusoidal arrangement. ACTH, β-lipotropin (LPH), and β-endorphin have been demonstrated in these tumor cells by immunocytochemical methods. Larger tumors may appear chromophobic on routine histologic study; however, they also contain ACTH and its related peptides. These ACTH-secreting adenomas typically show Crooke changes (a zone of perinuclear hyalinization that is the result of chronic exposure of corticotroph cells to hypercortisolism). Electron microscopy demonstrates secretory granules that vary in size from 200 to 700 nm. The number of granules varies in individual cells; they may be dispersed throughout the cytoplasm or concentrated along the cell membrane. A typical feature of these adenomas is the presence of bundles of perinuclear microfilaments (average 7 nm in diameter) surrounding the nucleus; these are responsible for Crooke hyaline changes visible on light microscopy.

2. **Hyperplasia**—Diffuse hyperplasia of corticotroph cells has been reported rarely in patients with Cushing disease.

3. **Other conditions**—In patients with adrenal tumors or ectopic ACTH syndrome, the pituitary corticotrophs show prominent Crooke hyaline changes and perinuclear microfilaments. The ACTH content of corticotroph cells is reduced consistent with their suppression by excessive cortisol secretion present in these conditions.

#### B. Adrenocortical hyperplasia

Bilateral hyperplasia of the adrenal cortex occurs with chronic ACTH hypersecretion. Two types have been described: simple and bilateral nodular hyperplasia.

1. **Simple adrenocortical hyperplasia**—This condition is usually due to Cushing disease. Combined adrenal weight (normal, 8-10 g) is modestly increased, ranging from 12 to 24 g. On histologic study, there is equal hyperplasia of the compact cells of the zona reticularis and the clear cells of the zona fasciculata; consequently, the width of the cortex is increased. Electron microscopy reveals normal ultrastructural features. When ACTH levels are very high as in the ectopic ACTH syndrome, the adrenals are frequently larger, with combined weights up to or more than 50 g. The characteristic microscopic
growth has been shown in some of these patients to be mediated by the abnormal adrenal expression of receptors for a variety of adrenal hyperplasia (and occasionally unilateral adrenocortical glucose-dependent insulinotropic polypeptide (GIP), whose adrenal hormones. The best characterized appears to be the expression of nonhyp function include vasopressin, beta-adrenergic agonists, human chorionic gonadotropin-LH, serotonin, angiotensin II, and leptin (see also Chapter 21). The identification of an abnormal adrenal receptor raises the possibility of new pharmacologic approaches to control of hypercortisolism by suppressing the endogenous ligands or by blocking the abnormal receptor with specific antagonists. Another unusual adrenal-dependent cause of Cushing syndrome associated with bilateral adrenal nodular hyperplasia has been referred to as primary pigmented nodular adenocortical tumor. Other abnormal hormone receptors that have been described in association with endogenous hypercortisolism with this phenomenon include vasopressin, beta-adrenergic agonists, human chorionic gonadotropin-LH, serotonin, angiotensin II, and leptin (see also Chapter 21). The identification of an abnormal adrenal receptor raises the possibility of new pharmacologic approaches to control of hypercortisolism by suppressing the endogenous ligands or by blocking the abnormal receptor with specific antagonists.

Another unusual adrenal-dependent cause of Cushing syndrome associated with bilateral adrenal nodular hyperplasia has been referred to as primary pigmented nodular adenocortical disease. This is a familial disorder with an autosomal dominant inheritance pattern usually presenting in adolescence or young adulthood. The disorder is associated with unusual conditions such as myxomas (cardiac, cutaneous, and mammary), spotty skin pigmentation, endocrine overactivity, sexual precocity, acromegaly, and schwannomas—the Carney complex. Activating mutations in protein kinase A have recently been shown to be present in many of these patients. Interestingly, the adrenal glands in this syndrome are often small or normal in size and have multiple black and brown nodules with intranodular cortical atrophy.

Finally, in McCune-Albright syndrome, activating mutations of G\(_{\alpha}\) lead to constitutive steroidogenesis in adrenal nodules carrying the mutation.

### C. Adrenal tumors

Adrenal tumors causing Cushing syndrome are independent of ACTH secretion and are either adenomas or carcinomas.

#### 1. Glucocorticoid-secreting adrenal adenomas

These adenomas are encapsulated, weigh 10 to 70 g, and range in size from 1 to 6 cm. Microscopically, clear cells of the zona fasciculata type predominate, although cells typical of the zona reticularis are also seen.

#### 2. Adrenal carcinomas

Adrenal carcinomas are usually greater than 4 cm when diagnosed and often weigh more than 100 g, occasionally exceeding 1 kg. They may be palpable as abdominal masses. Grossly, they are encapsulated and highly vascular; necrosis, hemorrhage, and cystic degeneration are common, and areas of calcification may be present. The histologic appearance of these carcinomas varies considerably; they may appear to be benign or may exhibit considerable pleomorphism. Vascular or capsular invasion is predictive of malignant behavior, as is local extension. These carcinomas invade local structures (kidney, liver, and retroperitoneum) and metastasize hematogenously to liver and lung.

#### 3. Uninvolved adrenal cortex

The cortex contiguous to the tumor and that of the contralateral gland are atrophic in the presence of functioning adrenal adenomas and carcinomas. The cortex is markedly thinned, whereas the capsule is thickened. Histologically, the zona reticularis is virtually absent; the remaining cortex is composed of clear fasciculata cells. The architecture of the zona glomerulosa is normal.

### Etiology and Pathogenesis

#### A. Cushing disease

The causes and natural history of Cushing disease are reviewed in Chapter 4. Current evidence is consistent with the view that spontaneously arising corticotroph-cell pituitary adenomas are the primary cause and that the consequence ACTH hypersecretion and hypercortisolism lead to the characteristic endocrine abnormalities and hypothalamic dysfunction. This is supported by evidence showing that selective removal of these adenomas by pituitary microsurgery reverses the abnormalities and is followed by return of the HPA axis to normal. In addition, molecular studies have shown that nearly all corticotroph adenomas are monoclonal.

Although these primary pituitary adenomas are responsible for the great majority of cases, a few patients have been described in whom pituitary disease has been limited to corticotroph-cell hyperplasia; these may be secondary to excessive CRH secretion by rare, benign hypothalamic gangliocytoma.

#### B. Ectopic ACTH syndrome and ectopic CRH syndrome

Ectopic ACTH syndrome arises when nonpituitary tumors synthesize hypersecrete biologically active ACTH. The related peptides β-LPH and β-endorphin are also synthesized and secreted, as are inactive ACTH fragments. Production of CRH has also been demonstrated in ectopic tumors secreting ACTH, but whether CRH plays a role in pathogenesis is unclear. A few cases in which nonpituitary tumors produced only CRH have been reported.

Ectopic ACTH syndrome occurs predominantly in only a few tumor types (Figure 9–13); carcinoid tumors of lung and small cell carcinoma of the lung cause half of cases. Other tumors causing the syndrome originate from neuroendocrine tumors, thymus, gut, ovary, pancreatic islet cell tumors, or medullary thyroid...
carcinoma. Multiple other tumor types have also been reported to cause the ectopic ACTH syndrome, but are very rare (see Chapter 21).

C. Adrenal tumors Glucocorticoid-producing adrenal adenomas and carcinomas arise spontaneously. They are not under hypothalamic-pituitary control and autonomously secrete adrenocortical steroids. Rarely, adrenal carcinomas develop in the setting of chronic ACTH hypersecretion in patients with either Cushing disease and nodular adrenal hyperplasia or congenital adrenal hyperplasia.

Pathophysiology (Figures 9-12, 9-13)

A. Cushing disease In Cushing disease, ACTH hypersecretion is random and episodic and causes cortisol hypersecretion in the absence of the normal circadian rhythm. Feedback inhibition of ACTH (secreted from the pituitary adenoma) by physiologic levels of glucocorticoids is suppressed; thus, ACTH hypersecretion persists despite elevated cortisol secretion and results in chronic glucocorticoid excess. The episodic secretion of ACTH and cortisol results in variable plasma levels that may at times be within the normal range. However, elevation of urine free cortisol or demonstration of elevated late-night serum or salivary cortisol levels because of the absence of diurnal variability confirms cortisol hypersecretion (see sections on laboratory evaluation and diagnosis of Cushing syndrome). The overall increase in glucocorticoid secretion causes the clinical manifestations of Cushing syndrome. ACTH and β-LPH secretion are not usually elevated sufficiently to cause hyperpigmentation.

1. Abnormalities of ACTH secretion—Despite ACTH hypersecretion, stress responsiveness is absent; stimuli such as hypoglycemia or surgery fail to further elevate ACTH and cortisol secretion. This is probably due to suppression of hypothalamic function and CRH secretion by hypercortisolism, resulting in loss of hypothalamic control of ACTH secretion (see Chapter 4).

2. Effect of cortisol excess—Cortisol excess not only inhibits normal pituitary and hypothalamic function, affecting ACTH, TSH, GH, and gonadotropin release, but also results in all the systemic effects of glucocorticoid excess described in previous sections and in the section on clinical features later.

3. Androgen excess—Secretion of adrenal androgens is also increased in Cushing disease, and the degree of androgen excess parallels that of ACTH and cortisol. Thus, plasma levels of DHEA, DHEA sulfate, and androstenedione may be moderately elevated in Cushing disease; the peripheral conversion of these hormones to testosterone and dihydrotestosterone leads to androgen excess. In women, this causes hirsutism, acne, and amenorrhea. In men with Cushing disease, cortisol suppression of LH secretion decreases testosterone secretion by the testis, resulting in decreased libido and impotence. The increased adrenal androgen secretion is insufficient to compensate for the decreased gonadal testosterone production.

B. Ectopic ACTH syndrome Hypersecretion of ACTH and cortisol is usually greater in patients with ectopic ACTH syndrome than in those with Cushing disease. ACTH and cortisol hypersecretion is randomly episodic, and the levels are often greatly elevated. Usually, ACTH secretion by ectopic tumors is not subject to negative feedback control; that is, secretion of ACTH and cortisol is nonsuppressible with pharmacologic doses of glucocorticoids (see section on diagnosis later).
Plasma levels, secretion rates, and urinary excretion of cortisol, the adrenal androgens, and DOC are often markedly elevated; despite this, the typical features of Cushing syndrome may be absent, presumably because of rapid onset of hypercortisolism, anorexia, and other manifestations of the associated malignant disease. Features of mineralocorticoid excess (hypertension and hypokalemia) are frequently present and have been attributed to increased secretion of DOC and the mineralocorticoid effects of cortisol. With ectopic CRH secretion, pituitary corticotroph hyperplasia and ACTH hypersecretion are observed along with resistance to negative feedback by cortisol.

C. Adrenal tumors

1. Autonomous secretion—Primary adrenal tumors, both adenomas and carcinomas, autonomously hypersecrete cortisol. Circulating plasma ACTH levels are suppressed, resulting in cortical atrophy of the uninvolved adrenal. Secretion is randomly episodic, and these tumors are typically unresponsive to manipulation of the hypothalamic-pituitary axis with pharmacologic agents such as dexamethasone and metyrapone.

2. Adrenal adenomas—Adrenal adenomas causing Cushing syndrome typically present solely with clinical manifestations of glucocorticoid excess, because they usually secrete only cortisol. Thus, the presence of androgen or mineralocorticoid excess should suggest that the tumor is an adrenocortical carcinoma.

3. Adrenal carcinomas—Adrenal carcinomas frequently hypersecrete multiple adrenocortical steroids and their precursors. Cortisol and androgens are the steroids most frequently secreted in excess; 11-deoxycortisol is often elevated, and there may be increased secretion of DOC, aldosterone, or estrogens. Plasma cortisol and urine free cortisol are often markedly increased; androgen excess is usually even greater than that of cortisol. Thus, high levels of plasma DHEA, DHEA sulfate, and of testosterone typically accompany the cortisol excess. Clinical manifestations of hypercortisolism are usually severe and rapidly progressive in these patients. In women, features of androgen excess are prominent; virilism may occasionally occur. Hypertension and hypokalemia are frequent and most commonly result from the mineralocorticoid effects of cortisol; less frequently, DOC and aldosterone hypersecretion also contribute.

Clinical Features (Table 9–11)

A. Symptoms and signs

1. Obesity—Obesity is the most common manifestation, and weight gain is usually the initial symptom. It is classically central, affecting mainly the face, neck, trunk, and abdomen, with relative sparing of the extremities. Generalized obesity with central accentuation is equally common, particularly in children.

Accumulation of fat in the face leads to the typical moon facies, which is present in 75% of cases and is accompanied by facial plethora in most patients. Fat accumulation around the neck is prominent in the supraclavicular and dorsocervical fat pads; the latter is responsible for the buffalo hump.

Obesity is absent in a handful of patients who do not gain weight; however, they usually have central redistribution of fat and a typical facial appearance.

2. Skin changes—Skin changes are frequent, and their presence should arouse a suspicion of cortisol excess. Atrophy of the epidermis and its underlying connective tissue leads to thinning (a transparent appearance of the skin) and facial plethora. Easy bruising following minimal trauma is present in about 40%. Striae occur in 50% but are very unusual in patients over 40 years of age. These are typically red to purple, depressed below the skin surface secondary to loss of underlying connective tissue, and wider (not infrequently 0.5–2 cm) than the pinkish-white striae that may occur with pregnancy or rapid weight gain. These striae are most commonly abdominal but may also occur over the breasts, hips, buttocks, thighs, and axillae.

Acne presenting as pustular or papular lesions may result from glucocorticoid excess or hyperandrogenism.

Minor wounds and abrasions may heal slowly, and surgical incisions sometimes undergo dehiscence.

Mucocutaneous fungal infections are frequent, including tinea versicolor, involvement of the nails (onychomycosis), and oral candidiasis.

Hyperpigmentation of the skin is rare in Cushing disease or adrenal tumors but is common in ectopic ACTH syndrome.

3. Hirsutism—Hirsutism is present in about 80% of female patients owing to hypersecretion of adrenal androgens. Facial hirsutism is most common, but increased hair growth may also occur over the abdomen, breasts, chest, and upper thighs. Acne and seborrhea usually accompany hirsutism. Virilism is unusual except in cases of adrenal carcinoma, in which it occurs in about 20% of patients.

4. Hypertension—Hypertension is a classic feature of spontaneous Cushing syndrome; it is present in about 75% of cases, and the diastolic blood pressure is greater than 100 mm Hg.

in over 50%. Hypertension and its complications contribute greatly to the morbidity and mortality rates in spontaneous Cushing syndrome.

5. Gonadal dysfunction—This is very common as a result of elevated androgens (in females) and cortisol (in males) and to a lesser extent in females. Amenorrhea occurs in 75% of premenopausal women and is usually accompanied by infertility. Decreased libido is frequent in males, and some have decreased body hair and soft testes.

6. Central nervous system and psychologic disturbances—Psychologic disturbances occur in the majority of patients. Mild symptoms consist of emotional lability and increased irritability. Anxiety, depression, poor concentration, and poor memory may also be present. Euphoria is frequent, and occasionally patients manifest overtly manic behavior. Sleep disorders are present in most patients, with either insomnia or early morning awakening.

   Severe psychologic disorders occur in a few patients and include severe depression, psychosis with delusions or hallucinations, and paranoia. Some patients have committed suicide. Loss of brain volume that is at least partially reversible following correction of hypercortisolism has been observed.

7. Muscle weakness—This occurs in about 60% of cases; it is more often proximal and is usually most prominent in the lower extremities. Hypercortisolism is associated with both low fat-free muscle mass and low total body protein.

8. Osteoporosis—Owing to the profound effects of glucocorticoids on the skeleton, patients with Cushing syndrome frequently have evidence of significant osteopenia and osteoporosis. Patients may present with multiple fragility fractures—typically of the feet, ribs, or vertebrae. Back pain may be the initial complaint. Compression fractures of the spine are demonstrated radiographically in 15% to 20% of patients. In fact, unexplained osteopenia in any young or middle-aged adult should always prompt an evaluation for Cushing syndrome, even in the absence of any other signs or symptoms of cortisol excess. Although avascular necrosis of bone has been associated with exogenous glucocorticoid administration, the problem is rarely observed in patients with endogenous hypercortisolism, suggesting a role for the underlying disorders in patients for whom glucocorticoids are prescribed.

9. Renal calculi—Calculi secondary to glucocorticoid-induced hypercalcemia occur in approximately 15% of patients, and renal colic may occasionally be a presenting complaint.

10. Thirst and polyuria—Polyuria is rarely due to overt hyperglycemia but is usually caused by glucocorticoid inhibition of vasopressin (antidiuretic hormone) secretion and the direct enhancement of renal free water clearance by cortisol.

11. Growth deceleration—In children, nearly all (>95%) show decreasing linear growth. Weight gain accompanying decreasing linear growth in a child should prompt an evaluation for Cushing syndrome.

B. Laboratory findings Routine laboratory examinations are described here. Specific tests to establish the diagnosis of Cushing syndrome are discussed in the section on diagnosis.

   High normal hemoglobin, hematocrit, and red cell counts are usual; polycythemia is rare. The total white count is usually normal; however, both the percentage of lymphocytes and the total lymphocyte count may be subnormal. Eosinophils are also depressed, and a total eosinophil count less than 100/μL is present in most patients. Serum electrolytes, with rare exceptions, are normal in Cushing disease; however, hypokalemic alkalosis occurs when there is marked steroid hypersecretion with the ectopic ACTH syndrome or adrenocortical carcinoma.

   Although fasting hyperglycemia occurs in only 10% to 15% of patients, glucose intolerance is a relatively common finding and occurs in 60% of patients. Most patients have secondary hyperinsulinemia and abnormal glucose tolerance tests.

   Serum calcium is normal; serum phosphorus is low normal or slightly depressed. Hypercalciumia is present in 40% of cases.

C. Imaging studies Routine radiographs may reveal cardiomegaly due to hypertensive or atherosclerotic heart disease or mediastinal widening due to central fat accumulation. Vertebral compression fractures, rib fractures, and renal calculi may be present.

D. Electrocardiographic findings Hypertensive, ischemic, and electrolyte-induced changes may be present on the electrocardiogram.

Features Suggesting a Specific Cause

A. Cushing disease Cushing disease typifies the classic clinical picture: female predominance, onset generally between ages 20 and 40, and a slow progression over several years. Hyperpigmentation and hypokalemic alkalosis are rare; androgenic manifestations are limited to acne and hirsutism. Secretion of cortisol and adrenal androgens is only moderately increased.

B. Ectopic ACTH syndrome (carcinoma) In contrast, this syndrome occurs predominantly in males, with the highest incidence between ages 40 and 60. The clinical manifestations of hypercortisolism are frequently limited to weakness, hypertension, and glucose intolerance; the primary tumor is usually apparent. Hyperpigmentation, hypokalemia, and alkalosis are common, as are weight loss and anemia. The hypercortisolism is of rapid onset, and steroid hypersecretion is frequently severe, with equally elevated levels of glucocorticoids, androgens, and DOC.

C. Ectopic ACTH syndrome (benign tumor) A minority of patients with ectopic ACTH syndrome due to more benign tumors, especially bronchial carcinoids, present a more slowly progressive course, with typical features of Cushing syndrome. These patients may be clinically identical to those with pituitary-dependent Cushing disease, and the responsible tumor may not be apparent. Hyperpigmentation, hypokalemic alkalosis, and anemia are variably present. Further confusion may arise, since a number of these patients with occult ectopic tumors may have ACTH and steroid dynamics typical of Cushing disease (see below).

D. Adrenal adenomas The clinical picture in patients with adrenal adenomas is usually that of glucocorticoid excess alone, and androgenic effects such as hirsutism are absent. Onset is
gradual, and hypercortisolism is mild to moderate. Plasma androgens are usually in the low normal or subnormal range.

E. Adrenal carcinomas In general, adrenal carcinomas have a rapid onset of the clinical features of excessive glucocorticoid, androgen, and mineralocorticoid secretion and are rapidly progressive. Marked elevations of both cortisol and androgens are usual; hypokalemia is common, as are abdominal pain, palpable masses, and hepatic and pulmonary metastases.

Diagnosis

The clinical suspicion of Cushing syndrome must be confirmed with biochemical studies. Initially, a general assessment of the patient regarding the presence of other illnesses, drugs, alcohol, or psychiatric problems must be done since these factors may confound the evaluation. In the majority of cases, the biochemical differential diagnosis of Cushing syndrome can be easily performed in the ambulatory setting (Figure 9-14).

A. Dexamethasone suppression test The overnight 1-mg dexamethasone suppression test is a valuable screening test in patients with suspected hypercortisolism. This study employs the administration of 1 mg of dexamethasone at bedtime (11:00 PM), with determination of a plasma cortisol early the following morning. Normal subjects should suppress plasma cortisol to less than 1.8 μg/dL (50 nmol/L) following an overnight 1-mg test. Although a level of less than 5 μg/dL has been used in the past, several false-negative studies have been discovered using this test criterion. False-negative results may occur in some patients with mild hypercortisolism and exquisite negative feedback sensitivity to glucocorticoids and in those with intermittent hypercortisolism. This test should only be employed as a screening tool for the consideration of Cushing syndrome, and biochemical confirmation must rely on additional biochemical testing. False-positive results with the overnight 1-mg dexamethasone suppression test may be caused by patients receiving drugs that accelerate dexamethasone metabolism (phenytoin, phenobarbital, rifampin). False-positive results also occur in patients with renal failure, depression, alcoholism, or in patients undergoing a stressful event or serious illness.

B. Urine free cortisol Another study in the confirmation of Cushing syndrome is the determination of urine free cortisol measured by HPLC or LC/MS/MS in a 24-hour urine collection.

These methods are highly accurate and specific. Commonly used drugs and medications do not interfere; however, carbamazepine and fenofibrate can cause falsely elevated results with HPLC since they elute with cortisol. Urinary free cortisol is usually less than 50 μg/24 h (<135 nmol/24 h) when measured by HPLC or LC/MS/MS. Urine free cortisol determinations usually provide clear discrimination between patients with hypercortisolism and obese non-Cushing patients, although exceptions occur. Less than 5% of obese subjects have mild elevations of urine free cortisol. The major liability of urine free cortisol is its poor sensitivity for detecting patients with mild hypercortisolism (sensitivity <75%). Consequently, this modality should not be used alone to exclude Cushing syndrome.

C. Late-night serum and salivary cortisol  The absence of diurnal rhythm has been considered a hallmark of the diagnosis of Cushing syndrome. Normally, cortisol is secreted episodically with a diurnal rhythm paralleling the secretion of ACTH. Levels are usually highest early in the morning and decrease gradually throughout the day, reaching the nadir in the late evening between 11:00 PM and midnight. Several studies have demonstrated that an elevated midnight plasma cortisol level (>5.2–7.0 μg/dL [140–190 nmol/L]) is highly accurate in differentiating patients with Cushing syndrome from normal subjects and from patients with pseudo-Cushing conditions such as depression or alcoholism.

Because obtaining such plasma cortisol measurements is impractical on an ambulatory basis, the measurement of salivary cortisol provides a simple and more convenient means of probing nighttime cortisol secretion. Saliva can easily be sampled at home by the patient using a variety of techniques. Reference ranges for late-night salivary cortisol concentrations are dependent on the assay employed; however, using a radioimmunoassay, normal subjects should have values less than 0.15 μg/dL (4 nmol/L).

Problems in Diagnosis

A major diagnostic problem is distinguishing patients with mild Cushing syndrome from those with mild physiologic hypercortisolism due to conditions that are classified as pseudo-Cushing syndrome. These include the depressed phase of affective disorder, alcoholism, withdrawal from alcohol intoxication, or eating disorders such as anorexia and bulimia nervosa. These conditions may have biochemical features of Cushing syndrome, including elevations of urine free cortisol, disruptions in the normal diurnal pattern of cortisol secretion, and lack of suppression of cortisol after the overnight 1-mg dexamethasone suppression test. Although the history and physical examination may provide specific clues to the appropriate diagnosis, definitive biochemical confirmation may be difficult and may require repeated testing. Another study to distinguish mild Cushing syndrome from pseudo-Cushing conditions is the use of dexamethasone suppression followed by CRH stimulation. This test takes advantage of differential response of patients with Cushing syndrome and pseudo-Cushing syndrome to both dexamethasone and CRH by combining these tests to provide greater accuracy in the diagnosis. This study involves the administration of dexamethasone, 0.5 mg every 6 hours for eight doses, followed immediately by a CRH stimulation test, starting 2 hours after the completion of the low-dose dexamethasone suppression. A plasma cortisol concentration greater than 1.4 μg/dL (38.6 nmol/L) measured 15 minutes after administration of CRH correctly identifies the majority of patients with Cushing syndrome. After administration of high-dose dexamethasone, patients with pseudo-Cushing syndrome do not have a rise in cortisol or ACTH in response to CRH. However, it is now appreciated that some patients with pseudo-Cushing syndrome (eg, anorexia nervosa) may have abnormal dexamethasone CRH suppression tests.

Differential Diagnosis

The differential diagnosis of Cushing syndrome is usually difficult and should always be performed with consultation by an endocrinologist. The introduction of several technologic advances, including a specific and sensitive IRMA or ICMA for ACTH, CRH stimulation test, inferior petrosal sinus sampling (IPSS), CT and magnetic resonance imaging (MRI) of the pituitary and adrenal glands have all provided means for an accurate differential diagnosis.

A. Plasma ACTH  Initially, the differential diagnosis for Cushing syndrome must distinguish between ACTH-dependent Cushing syndrome (pituitary or nonpituitary ACTH-secreting neoplasm) and ACTH-independent hypercortisolism. The best way to distinguish these forms of Cushing syndrome is measurement of plasma ACTH by IRMA or ICMA. The development of this sensitive and specific test has made it possible to reliably identify patients with ACTH-independent Cushing syndrome. The ACTH level is less than 5 pg/mL (1.1 pmol/L) and exhibits a blunted response to CRH (peak response <10 pg/mL [2.2 pmol/L]) in patients with cortisol-producing adrenal neoplasms, autonomous bilateral adrenal cortical hyperplasia, and factitious Cushing syndrome (Figure 9–15). Patients with ACTH-secreting neoplasms usually have plasma ACTH levels greater than 10 pg/mL (2.2 pmol/L) and frequently greater than 52 pg/mL (11.5 pmol/L). The major challenge in the differential diagnosis of ACTH-dependent Cushing syndrome is identifying the source of the ACTH-secreting tumor. The vast majority of these patients (90%) have a pituitary tumor, whereas the others harbor a nonpituitary neoplasm. Diagnostic studies needed to differentiate these two entities must yield nearly perfect sensitivity, specificity, and accuracy. Although plasma ACTH levels are usually higher in patients with ectopic ACTH than those with pituitary ACTH-dependent Cushing syndrome, there is considerable overlap between these two entities. Many of the ectopic ACTH-secreting tumors are radiologically occult at the time of presentation and may not become clinically apparent for many years after the initial diagnosis. However, an enhanced ACTH response for CRH administration is more frequently found in pituitary Cushing syndrome compared with ectopic ACTH syndrome.

B. Pituitary MRI  When ACTH-dependent Cushing syndrome is present, MRI of the pituitary gland with gadolinium enhancement
should be performed and will identify an adenoma in at least 50% to 60% of the patients. If the patient has classic clinical laboratory findings of ACTH-dependent hypercortisolemia and an unequivocal pituitary lesion on MRI, the likelihood of Cushing disease is 98% to 99%. However, it must be emphasized that approximately 10% of the population in the age group from 20 to 50 years will have incidental tumors of the pituitary demonstrable by MRI. Therefore, some patients with ectopic ACTH syndrome will have radiographic evidence of a pituitary lesion.

C. High-Dose dexamethasone suppression Traditionally, the high-dose dexamethasone suppression test has been utilized in the differential diagnosis of Cushing syndrome. However, the diagnostic accuracy of this procedure is only 70% to 80%, which is actually less than the pretest probability of Cushing disease---on average about 90%. As a result, this study is no longer recommended.

D. Inferior petrosal sinus sampling The most definitive means of accurately distinguishing pituitary from nonpituitary ACTH-dependent Cushing syndrome is the use of bilateral simultaneous IPSS with CRH stimulation, and this procedure is the next step in the evaluation of patients with ACTH-dependent Cushing syndrome when MRI does not reveal a definite adenoma. This study takes advantage of the means by which pituitary hormones reach the systemic circulation. Blood leaves the anterior lobe of the pituitary and drains into the cavernous sinuses, which then empty into the inferior petrosal sinuses and subsequently into the jugular bulb and vein. Simultaneous inferior petrosal sinus and peripheral ACTH measurement before and after CRH stimulation can reliably confirm the presence or absence of an ACTH-secreting pituitary tumor. An inferior petrosal sinus to peripheral (IPS-P) ratio greater than 2.0 prior to CRH and greater than 3.0 after CRH is consistent with a pituitary ACTH-secreting tumor, and an IPS-P ratio less than 1.8 supports the diagnosis of ectopic ACTH. Anatomical variants can cause false-negative studies; however, simultaneous measurement of PRL can be used to construct a PRL-normalized ACTH ratio which can eliminate false negatives caused by anatomical variants. Bilateral IPSS with CRH stimulation does require a skilled interventional radiologist. However, in experienced hands, the procedure has yielded a diagnostic accuracy approaching 100% in identifying the source of ACTH-dependent Cushing syndrome.

E. Occult ectopic ACTH If the IPSS study is consistent with a nonpituitary ACTH-secreting tumor, a search for an occult ectopic ACTH-secreting tumor is needed. Because the majority of these lesions are in the thorax, high-resolution CT of the chest may be useful; MRI of the chest may have even better sensitivity in finding these lesions, which are usually small bronchial carcinoid tumors. Unfortunately, utilization of a radiolabeled somatostatin analog scan (octreotide acetate scintigraphy) has met with only mixed results in localizing these tumors.

F. Adrenal localizing procedures CT (Figure 9–16) and MRI are used to define adrenal lesions. Their primary use is to localize adrenal tumors in patients with ACTH-independent Cushing syndrome. Most adenomas exceed 2 cm in diameter; carcinomas are usually much larger.

TREATMENT

A. Cushing disease The aim of treatment of Cushing syndrome is to remove or destroy the basic lesion and thus correct hypersecretion of adrenal hormones without inducing pituitary or
adrenal damage, which requires permanent replacement therapy for hormone deficiencies.

Treatment of Cushing disease is currently directed at the pituitary to control ACTH hypersecretion; available methods include microsurgery, various forms of radiation therapy, and pharmacologic inhibition of ACTH secretion. Treatment of hypercortisolism per se by surgical or medical adrenalectomy is less commonly used. These methods are discussed in Chapter 4.

B. Ectopic ACTH syndrome Cure of ectopic ACTH syndrome is usually possible only in cases involving the more benign tumors such as bronchial or thymic carcinoids or pheochromocytomas. Treatment is made difficult by the presence of metastatic tumors and accompanying severe hypercortisolism. Therapy directed to the primary tumor is usually unsuccessful, and other means must be used to correct the steroid-excess state.

Severe hypokalemia may require potassium replacement in large doses and spironolactone to block mineralocorticoid effects.

Drugs that block steroid synthesis (ketoconazole and metyrapone) are useful, but they may produce hypoadrenalism, and steroid secretion must be monitored and replacement steroids given if necessary. The dosage of ketoconazole is 400 to 800 mg/d in divided doses and is usually well tolerated. Because of its slow onset of action, narrow therapeutic window, and possible serious side-effects, mitotane is less useful. If used, several weeks of therapy may be required before control of cortisol secretion is achieved.

Bilateral adrenalectomy may be necessary if hypercortisolism cannot be controlled in other ways.

C. Adrenal tumors

1. Adrenal adenomas— Patients with adrenal adenomas are successfully treated by unilateral adrenalectomy, and the outlook is excellent. Laparoscopic adrenal surgery has become widely used in patients with benign or small adrenal tumors and has significantly reduced the duration of the hospital stay. Because the hypothalamic-pituitary axis and the contralateral adrenal are suppressed by prolonged cortisol secretion, these patients have postoperative adrenal insufficiency and require glucocorticoid therapy both during and following surgery until the remaining adrenal recovers.

2. Adrenal carcinomas— Therapy in cases of adenocortical carcinoma is less satisfactory, because the tumor has frequently already metastasized (usually to the retroperitoneum, liver, and lungs) by the time the diagnosis is made.

a. Operative treatment—Surgical cure is rare, but excision serves to reduce the tumor mass and the degree of steroid hypersecretion. Persisting nonsuppressible steroid secretion in the immediate postoperative period indicates residual or metastatic tumor.

b. Medical treatment—Mitotane is the drug of choice. The dosage is 6 to 12 g/d orally in three or four divided doses. The dose must often be reduced because of side-effects in 80% of patients (diarrhea, nausea and vomiting, depression, somnolence). About 70% of patients achieve a reduction of steroid secretion, but only 35% achieve a reduction in tumor size.

Ketoconazole and metyrapone (singly or in combination) are useful in controlling steroid hypersecretion in patients who do not respond to mitotane. Radiotherapy and conventional chemotherapy have not been useful in this disease.

D. Nodular adrenal hyperplasia When pituitary ACTH dependency can be demonstrated, macronodular hyperplasia may be treated like other cases of Cushing disease. When ACTH dependency is not present, as in micronodular hyperplasia and in some cases of macronodular hyperplasia, bilateral adrenalectomy is appropriate.
PROGNOSIS

A. Cushing syndrome  Untreated Cushing syndrome is frequently fatal, and death may be due to the underlying tumor itself, as in the ectopic ACTH syndrome and adrenal carcinoma. However, in most cases, death is the consequence of sustained hypercortisolism and its complications, including hypertension, cardiovascular disease, stroke, thromboembolism, and susceptibility to infection.

B. Cushing disease  In contrast to patients with untreated Cushing syndrome, individuals with Cushing disease who achieve normalization of cortisol levels as result of therapy have a standard mortality ratio (SMR) similar to age-matched populations. However, patients with persistent hypercortisolism despite treatment continue to have an increased SMR (3.8- to 5.0-fold), when compared to the general population.

With current refinements in pituitary microsurgery and irradiation, the great majority of patients with Cushing disease can be treated successfully, and the operative mortality and morbidity rates that attended bilateral adrenalectomy are no longer a feature of the natural history of this disease. Reduction in health-related quality of life, especially related to psychological functioning, may persist. Patients with Cushing disease, who have large pituitary tumors at the time of diagnosis, have a much less satisfactory prognosis and may die as a consequence of tumor invasion or persistent hypercortisolism.

C. Adrenal tumors  The prognosis in adrenal adenomas is excellent. In adrenal carcinoma, the prognosis is almost universally poor, and the median survival from the date of onset of symptoms is about 4 years.

D. Ectopic ACTH syndrome  Prognosis is also poor in patients with ectopic ACTH syndrome due to the nature of the malignancy producing the hormone, and in these patients with severe hypercortisolism, survival is frequently only days to weeks. Some patients respond to tumor resection or chemotherapy. The prognosis is better in patients with benign tumors producing the ectopic ACTH syndrome.

HIRSUTISM AND VIRILISM

Excessive adrenal or ovarian secretion of androgens or excessive conversion of weak androgens to testosterone and dihydrotestosterone in peripheral tissues leads to hirsutism and virilism (see Chapter 13). As previously discussed, the adrenal secretory products DHEA, DHEA sulfate, and androstenedione are weak androgens; however, the peripheral conversion to testosterone and dihydrotestosterone can result in a state of androgen excess.

Excessive androgen production is seen in both adrenal and ovarian disorders. Adrenal causes include Cushing syndrome, adrenal carcinoma, and congenital adrenal hyperplasia (see previous sections and Chapter 14). Mild adult-onset cases of congenital adrenal enzyme deficiencies have been described; these appear to be relatively uncommon. Biochemical diagnosis of late-onset 21-hydroxylase deficiency is best achieved by measurement of the 17-hydroxyprogesterone response to ACTH. Ovarian causes are discussed in Chapter 13.

In children, androgen excess is usually due to premature adrenarche, congenital adrenal hyperplasia, or adrenal carcinoma. In women, hirsutism accompanied by amenorrhea, infertility, ovarian enlargement, and elevated plasma LH levels is typical of the polycystic ovary syndrome, whereas in Cushing syndrome hirsutism is accompanied by features of cortisol excess. Late-onset 21-hydroxylase deficiency is accompanied by elevated levels of plasma 17-hydroxyprogesterone, especially following ACTH administration. Virilism and severe androgen excess in adults are usually due to androgen-secreting adrenal or ovarian tumors; virilism is unusual in the polycystic ovary syndrome and rare in Cushing disease. In the absence of these syndromes, hirsutism in women is usually idiopathic or due to milder forms of polycystic ovary syndrome. Exogenous androgen administration (eg, DHEA) should also be considered.

The diagnosis and therapy of hirsutism are discussed in Chapter 13.

INCIDENTAL ADRENAL MASS

The incidental adrenal mass has become a common diagnostic problem, because approximately 2% to 4% of patients undergoing CT studies of the abdomen are found to have focal enlargement of the adrenal gland. Adrenal masses in an adult may represent functional or nonfunctional cortical adenomas or carcinoma, pheochromocytomas, cysts, myelolipomas, or metastasis from other tumors. Congenital adrenal hyperplasia may also present as a focal enlargement of the adrenal gland, and adrenal hemorrhage also causes enlargement, although usually bilateral.

The appropriate diagnostic approach to patients with an incidentally discovered adrenal mass is unresolved. The roentgenographic appearance taken in context with the clinical setting may provide some insight. The size of the lesion is important. Primary adrenocortical carcinoma is rare in adrenal masses smaller than 4 cm. The presence of unilateral or bilateral adrenal masses (>3 cm) in a patient with a known malignancy (particularly lung, gastrointestinal, renal, or breast) probably represents metastatic disease. Adrenal lesions smaller than 3 cm in patients with a known malignancy actually represent metastases in only 20% to 30% of cases.

Other CT findings may be informative. The presence of fat within the adrenal mass may suggest a myelolipoma, which is usually a benign lesion. Adrenocortical adenomas are usually round masses with smooth margins, and adrenal cysts can also be identified with either CT or ultrasound examination. Lesions with low density (<10 Hounsfield units) on unenhanced CT scans are usually benign. Adrenal hemorrhage usually has irregular borders with some lack of homogeneity. Primary adrenocortical carcinoma usually presents as a lesion greater than 5 cm with irregular borders. MRI of the adrenal gland is usually not necessary but may be helpful in selected patients. Typically, malignancies and
pheochromocytomas tend to have bright signal intensity with T2-weighted images, in contrast to benign lesions of the adrenal gland; however, exceptions to this rule have been seen, limiting the clinical utility of this technique.

**Malignancy**

Primary adrenocortical carcinoma usually presents with a large lesion, and most authorities recommend removing all adrenal masses greater than 4 cm. One series of 45 adrenal masses greater than 5 cm showed 30 benign lesions (16 pheochromocytomas, 6 adenomas, 4 adrenal cysts, 2 myelolipomas, 1 hematoma, 1 ganglioneuroma) and 15 malignancies (7 adrenocortical carcinomas, 5 adrenal metastases, and 3 adrenal lymphomas. Lesions less than 4 to 5 cm in diameter are of concern only in patients with a known malignancy or in those in whom there is a high index of suspicion based on other clinical information. In patients with primary malignancies of the lung, gastrointestinal tract, kidney, or breast, an ultrasound or CT-guided needle biopsy may be helpful in establishing the presence or absence of metastatic disease once pheochromocytoma has been excluded. Metastatic disease can be identified with an accuracy of 75% to 85% in such patients; however, there are both false-negative and false-positive findings. Percutaneous adrenal biopsy really has no demonstrated efficacy in patients with adrenal masses and no history of a malignancy. Percutaneous adrenal biopsy should be reserved for patients in whom the presence or absence of adrenal metastases may alter the therapy or prognosis of the patient.

**Endocrine Evaluation**

The appropriate biochemical evaluation of an incidental adrenal mass is also controversial. An expert panel from the National Institutes of Health found that the available evidence suggests that an overnight (1-mg) dexamethasone suppression test and determination of fractionated urinary or plasma metanephrines should be performed, and that in patients with hypertension, serum potassium and a plasma aldosterone concentration-PRA ratio should be determined to evaluate for primary aldosteronism. However, good clinical judgment is essential, and repeat CT imaging in 6 to 12 months was also recommended to exclude neoplastic disease. Hormonal abnormalities may develop over time, and follow-up testing has been recommended by some depending on the clinical context.

**Cortisol-Producing Adenoma**

The most common functioning lesion in patients with an incidentally discovered adrenal mass appears to be an adenoma with autonomous secretion of cortisol. Approximately 6% to 9% of patients with adrenal incidentalomas ranging from 2 to 5 cm in diameter have autonomous cortisol hypersecretion. These benign adrenal adenomas secrete small amounts of cortisol that are often not sufficient to elevate urine cortisol excretion but are able to cause some suppression of the hypothalamic-pituitary axis. These patients can be easily identified by their failure to suppress cortisol to less than 1.8 µg/dL (50 nmol/L) following an overnight 1-mg dexamethasone suppression test. In addition, the basal levels of ACTH in these patients are subnormal or frankly suppressed. DHEA sulfate levels are also usually decreased in patients with cortisol-secreting adenomas, likely reflecting ACTH suppression. The cortisol secretion by the tumor probably results in blunting of diurnal variation and eventually in lack of suppression by dexamethasone. The low plasma ACTH level manifests in a blunted response to CRH administration. Removal of these silent adrenocortical adenomas may be followed by clinically significant secondary adrenal insufficiency. Therefore, an overnight dexamethasone suppression test or measurement of plasma ACTH should be performed before surgical removal of any unknown adrenal neoplasm. These patients have been described as having preclinical or subclinical Cushing syndrome. The natural history of this autonomous cortisol secretion is unknown. Many of these patients described with this problem have hypertension, obesity, or diabetes, and improvements in these clinical problems have been reported following resection of these cortisol-producing adenomas. Consequently, adrenalectomy is recommended in young patients with preclinical Cushing syndrome and in patients with clinical problems that might potentially be aggravated by glucocorticoid excess.

**Pheochromocytoma**

Pheochromocytoma is a potentially life-threatening tumor that may present as an incidental adrenal mass. Surprisingly, pheochromocytoma may account for as many as 2% to 3% of incidental adrenal lesions. Many of these patients have hypertension and symptoms associated with catecholamine excess such as headache, diaphoresis, palpitations, or nervousness (see Chapter 11).

**Aldosterone-Producing Adenoma**

Although aldosterone-producing adenomas are more common than either pheochromocytomas or cortisol-producing adenomas, they actually represent a very unusual cause of an incidentally discovered adrenal mass. This appears to be due to the fact that aldosterone-producing adenomas are usually small and frequently missed with CT imaging of the adrenal gland. Because most of these patients have hypertension, this diagnosis needs to be considered only in patients with hypertension. The presence of hypokalemia should arouse suspicion of this diagnosis, but hypokalemia is not invariably present. It is usually present in patients with aldosterone-producing adenomas greater than 3 cm. Hyperaldosteronism can be excluded by the measurement of aldosterone and PRA. If the aldosterone (ng/dL)-PRA (ng/mL/h) ratio is less than 30 and plasma aldosterone is less than 20 ng/dL, an aldosterone-producing adenoma is excluded.

**GLUCOCORTICOID THERAPY FOR NONENDOCRINE DISORDERS**

**Principles**

Glucocorticoids have been used for their anti-inflammatory and immunosuppressive activity in treatment of a wide variety of disorders. These include rheumatologic disorders (eg, rheumatoid
arthrits and systemic lupus erythematosus), pulmonary diseases (eg, asthma), renal disease (eg, glomerulonephritis), and many others. Because of their side-effects, glucocorticoids should be used in the minimum effective dose and for the shortest possible duration of therapy.

**Synthetic Glucocorticoids**

Steroid compounds have been synthesized, taking advantage of chemical alterations to the steroid nucleus that enhances glucocorticoid activity relative to mineralocorticoid activity. For example, prednisone has a double bond between positions 1 and 2 of cortisol and an 11-keto group instead of a hydroxyl group. It has three additional double bonds, a fluoro atom in the 9α position and an 11-keto group instead of a hydroxyl group. Many other compounds have been synthesized. Although most synthetic glucocorticoids exhibit little binding to CBG, their plasma half-lives are longer than that of cortisol.

**Modes of Administration**

Glucocorticoids may be administered parenterally, orally, topically, and by inhalation. Absorption rates from intramuscular and intra-articular sites depend on the particular glucocorticoid and its formulation. Transdermal absorption also depends on the severity of the inflammatory disorder, the area of the body to which the drug is applied, the presence of vehicles that enhance absorption (eg, urea), and the use of an occlusive dressing. Inhaled glucocorticoids vary in their bioavailability; the technique of administration (eg, use of spacers) also affects the amount of drug delivered to the lungs.

**Side-Effects**

In general, the severity of the side-effects is a function of dose and duration of therapy, but there is marked individual variation.

**A. Hypothalamic-pituitary-adrenal axis suppression**

Glucocorticoids suppress CRH and ACTH secretion (negative feedback). Suppression of the HPA axis may occur with doses of prednisone greater than 5 mg/d. It is difficult, however, to predict the development or degree of suppression in any given individual. In general, patients who develop clinical features of Cushing syndrome or who have received glucocorticoids equivalent to 10 to 20 mg of prednisone per day for 3 weeks or more should be assumed to have clinically significant HPA axis suppression. Patients treated with alternate-day steroid regimens exhibit less suppression than those who receive steroids daily.

**B. Cushing syndrome**

Glucocorticoid administration results in the development of cushingoid features. Of special concern is steroid-induced osteoporosis, particularly in patients for whom a long course of steroid therapy is anticipated. The severity of systemic effects of inhaled glucocorticoids varies among different preparations. However, they are associated with both local effects (dysphonia and oral candidiasis) and systemic effects, especially glaucoma, cataracts, osteoporosis, and growth retardation in children. Protease inhibitors are now well recognized to decrease the metabolism of exogenous glucocorticoids. When the two are used in combination, the resultant increase in circulating glucocorticoid can lead to exogenous Cushing syndrome.

**C. Steroid withdrawal**

Because of their adverse effects, glucocorticoids must be tapered downward as the clinical situation permits. Tapering regimens are essentially empirical. Factors that may limit the ability to taper the dose down to physiologic replacement levels include recrudescence of disease and steroid withdrawal syndrome. The latter appears in a variety of patterns. Patients may develop fatigue, arthralgias, and desquamation of the skin. Psychologic dependence has also been described. Even after the dose has been reduced to physiologic levels, HPA axis suppression (ie, secondary adrenal insufficiency) persists for an average of 9 to 10 months but may continue for as long as 1 to 2 years.

Endocrine Hypertension

William F. Young, Jr, MD, MSc

Hypertension affects one in four adults in the developed world. Although hypertension is essential or idiopathic in most cases, a cause can be detected in approximately 15% of the hypertensive population. The secondary causes of hypertension can be divided into renal (eg, renal vascular or parenchymal disease) and endocrine causes. There are at least 14 endocrine disorders in which hypertension may be the initial clinical presentation (Table 10–1). The diagnosis of endocrine hypertension presents the clinician an opportunity to provide a surgical cure or to achieve a marked response with targeted pharmacologic therapy. Pheochromocytoma and Cushing syndrome are reviewed in detail in Chapters 11 and 9, respectively. The renin-angiotensin-aldosterone system, the diagnostic and therapeutic approaches to mineralocorticoid hypertension (eg, primary aldosteronism), and less common forms of endocrine hypertension are reviewed in this chapter.

**RENIN-ANGIOTENSIN-ALDOSTERONE SYSTEM**

The components of the renin-angiotensin-aldosterone system are shown in Figure 10–1. Aldosterone is secreted from the zona glomerulosa under the primary control of angiotensin II, potassium, and corticotropin (ACTH). The secretion of aldosterone is restricted to the zona glomerulosa because of zonal-specific expression of aldosterone synthase (CYP11B2). Atrial natriuretic peptide (ANP), dopamine, and heparin inhibit aldosterone secretion.

**Renin and Angiotensin**

Renin is an enzyme produced in the juxtaglomerular apparatus of the kidney, stored in granules, and released in response to specific secretagogues. The first 43 amino acids of the 340 amino acid renin protein are a prosegment cleaved to produce the active enzyme. The release of renin into the circulation is the rate-limiting step in the activation of the renin-angiotensin-aldosterone system. Renal renin release is controlled by juxtaglomerular cells acting as pressure transducers that sense stretch of the afferent arteriolar wall and thus renal perfusion pressure; the macula densa, a specialized group of convoluted distal tubular cells that function as chemoreceptors for monitoring the sodium and chloride loads present in the distal tubule; the sympathetic nervous system, which modifies the release of renin, particularly in response to upright posture; and humoral factors, including potassium, angiotensin II, and ANPs. Thus, renin release is maximized in conditions of low renal perfusion pressure or low tubular sodium...

Content (e.g., renal artery stenosis, hemorrhage, dehydration). Renin release is suppressed by elevated perfusion pressure at the kidney (e.g., hypertension) and high sodium diets. Renin release is increased directly by hypokalemia and decreased by hyperkalemia.

Angiotensinogen, an α5-globulin synthesized in the liver, is the substrate for renin and is broken down into the angiotensin peptides. Angiotensinogen consists of 485 amino acids, 33 of which constitute a signal peptide that is cleaved prior to secretion. The action of renin on angiotensinogen produces angiotensin I. Angiotensin I is composed of the first 10 amino acid sequence following the signal peptide and does not have biologic activity. Angiotensin II, the main form of biologically active angiotensin, is formed by cleavage of the two carboxyl-terminal amino acids of angiotensin I by angiotensin-converting enzyme (ACE) (Figure 10–2). ACE is localized to cell membranes in the lung and intracellular granules in certain tissues that produce angiotensin II. Amino peptidase A removes the amino-terminal aspartic acid to produce the heptapeptide, angiotensin III. Angiotensin II and angiotensin III have equivalent efficacy in promoting aldosterone secretion and modifying renal blood flow. The half-life in the circulation of angiotensin II is short (<60 seconds). Elements of the renin-angiotensin-aldosterone system are present in the adrenal glands, the kidneys, the heart, and the brain. For example, the adrenal glomerulosa cells contain the proteins needed to produce and secrete angiotensin II. Other tissues contain one or more components of the renin-angiotensin system and require other cells or circulating components, or both, to generate angiotensin II.

Angiotensin II functions through the angiotensin receptor to maintain normal extracellular volume and blood pressure by (a) increasing aldosterone secretion from the zona glomerulosa by increasing transcription of CYP11B2; (b) constriction of vascular smooth muscle, thereby increasing blood pressure and reducing renal blood flow; (c) enhancing the release of norepinephrine and epinephrine from the adrenal medulla; (d) enhancement of the activity of the sympathetic nervous system by increasing central sympathetic outflow, thereby increasing norepinephrine discharge from sympathetic nerve terminals; and (e) promotion of the release of vasopressin.

FIGURE 10–1  Renin-angiotensin-aldosterone and potassium-aldosterone feedback loops. Zona glomerulosa aldosterone production and secretion are determined by input from each loop (ACE, angiotensin-converting enzyme; ACTH, corticotropin; ANP, atrial natriuretic peptide; BP, blood pressure; K+, potassium; Na+, sodium).
**Aldosterone**

Aldosterone is produced in the zona glomerulosa of the adrenal cortex. Approximately 50% to 70% of aldosterone circulates bound to either albumin or corticosteroid-binding globulin; 30% to 50% of total plasma aldosterone is free. Aldosterone is rapidly inactivated to tetrahydroaldosterone in the liver and has a half-life of 15 to 20 minutes. Aldosterone regulates extracellular volume and potassium homeostasis by binding to renal cortical collecting duct principal epithelial cell mineralocorticoid receptors (Figure 10–3). The mineralocorticoid receptor—a member of the nuclear receptor family and also found in the heart, colon, and hippocampus—is localized to the cytoplasm prior to activation, undergoes a conformation change on binding to aldosterone, and translocates into the nucleus where it functions as a transcription factor. The aldosterone-regulated serum- and glucocorticoid-inducible kinase appears to be a key intermediary (see Figure 10–3). Aldosterone increases expression of this kinase which phosphorylates and inactivates neural-precursor-cell-expressed, developmentally down regulated (Nedd) 4-2, a ubiquitin ligase which is responsible for degrading the epithelial sodium channel. This, in turn, leads to an increased number of open

**FIGURE 10–3** Aldosterone regulates extracellular volume and potassium homeostasis by binding to the renal cortical collecting duct principal epithelial cell mineralocorticoid receptor (MR). The activated MR translocates into the nucleus where it binds to the glucocorticoid response element (GRE) and functions as a transcription factor. Aldosterone increases expression of serum- and glucocorticoid-inducible kinase (Sgk1), which phosphorylates and inactivates neural-precursor-cell-expressed, developmentally downregulated gene (Nedd) 4-2, a ubiquitin ligase which is responsible for degrading the epithelial sodium channel (ENaC). Another mediator of mineralocorticoid receptor transcriptional response is the activation is the sodium-potassium ATPase (Na⁺/K⁺ ATPase) at the basolateral membrane, which drives the uptake of potassium and export of sodium. Although glucocorticoids and mineralocorticoids bind equally to the mineralocorticoid receptor, specificity of action is due to the glucocorticoid-degrading enzyme, 11β-hydroxysteroid dehydrogenase type 2 (11β-HSD2), which prevents glucocorticoids from interacting with the receptor. (Adapted from Odermatt A, Atanasov AG. Mineralocorticoid receptors: Emerging complexity and functional diversity. Steroids 2009; 74:163-171.)
sodium channels in the luminal membrane of the principal cells in the cortical collecting tubule, resulting in increased sodium ion reabsorption. The sodium loss increases luminal electronegativity, which augments tubular secretion of potassium by the renal tubular cells and hydrogen ion by the renal interstitial cells. Another mediator of the mineralocorticoid receptor transcripational response is the activation of the sodium-potassium ATPase at the basolateral membrane, which drives the uptake of potassium and export of sodium (see Figure 10–3). Although glucocorticoids and mineralocorticoids bind equally to the mineralocorticoid receptor, specificity of action is due to the glucocorticoid-degrading enzyme, 11β-hydroxysteroid dehydrogenase, which is strongly expressed in the kidney and prevents glucocorticoids from interacting with the receptor.

Aldosterone has nonclassic effects that, although probably genomic and therefore mediated by activation of the cytosolic mineralocorticoid receptor, do not include modification of sodium-potassium balance. Aldosterone-mediated actions include the expression of several collagen genes; activation of genes controlling tissue growth factors, such as transforming growth factor β and plasminogen activator inhibitor type 1; or increased expression of genes mediating inflammation. The resultant actions lead to microangiopathy, necrosis (acutely), and fibrosis in various tissues such as the heart, the vasculature, and the kidney. Increased levels of aldosterone are not necessary to cause this damage; an imbalance between the volume or sodium balance state and the level of aldosterone appear to be the critical factors. Spironolactone and eplerenone are mineralocorticoid receptor antagonists. Mineralocorticoid receptor blockade has proven to be clinically important in patients with cardiovascular disease. For example, when spironolactone was added to the treatment program for patients with New York Heart Association class IV heart failure or class III heart failure, it resulted in a significant 30% reduction in overall mortality due to reductions in death from heart failure and sudden death. When eplerenone was added to the treatment program for patients who had a myocardial infarction 3 to 14 days previously and had a left ventricular ejection fraction of ≤40 percent, it resulted in a significantly lower rate of cardiovascular mortality and sudden cardiac death. The effect of mineralocorticoid receptor antagonists on survival in patients with primary aldosteronism has not yet been studied.

The action of angiotensin II on aldosterone synthesis and secretion involves a feedback loop that also includes extracellular fluid volume (see Figure 10–1). A decrease in circulating blood volume results in decreased renal perfusion pressure that is detected by the renal juxtaglomerular cells. Activation of the juxtaglomerular cells increases renin release, which catalyzes the conversion of angiotensinogen to angiotensin I. Angiotensin-converting enzyme (ACE) in the pulmonary and renal endothelium catalyzes the conversion of angiotensin I to angiotensin II and III, which act on the adrenal zona glomerulosa angiotensin receptor to stimulate aldosterone release. Aldosterone acts at the renal mineralocorticoid receptors to stimulate sodium and water retention to preserve the circulating blood volume. Renin release can also be triggered by catecholamines, hypokalemia, and a decrease in sodium chloride absorption in the macula densa cells. Aldosterone secretion can be directly stimulated by ACTH and hyperkalemia. Thus, sodium restriction activates and sodium overload suppresses the renin-angiotensin-aldosterone axis. Mineralocorticoid escape refers to the counterregulatory mechanisms that occur after 3 to 5 days of excessive mineralocorticoid administration. Several mechanisms contribute to this escape, including renal hemodynamic factors and increased release of ANP.

Excess aldosterone secretion causes hypertension through two main mechanisms: (1) mineralocorticoid-induced expansion of plasma and extracellular fluid volume; and (2) increase in total peripheral vascular resistance.

**PRIMARY ALDOSTERONISM**

Hypertension, suppressed plasma renin activity (PRA), and increased aldosterone excretion characterize the syndrome of primary aldosteronism. Aldosterone-producing adenoma (APA) and bilateral idiopathic hyperaldosteronism (IHA) are the two most common subtypes of primary aldosteronism (Table 10–2).

**Primary hyperaldosteronism**

- Familial hyperaldosteronism (FH)
  - Glucocorticoid-remediable aldosteronism (FH type I) | <1% of cases |
  - FH type II (APA or IHA) | <2% of cases |
  - Ectopic aldosterone-producing adenoma or carcinoma | <0.1% of cases |

**Low Renin and Low Aldosterone**

- Hyperaldosteronism
  - Congenital adrenal hyperplasia
  - 11β-Hydroxylase deficiency
  - 17α-Hydroxylase deficiency
  - Deoxycorticosterone-producing tumor
  - Primary cortisol resistance

**Apparent Mineralocorticoid Excess (AME)/11β-Hydroxysteroid Dehydrogenase Deficiency**

- Genetic
  - Type 1 AME
  - Type 2 AME
- Acquired
  - Licorice or carbeneoxolone ingestion (type 1 AME)
  - Cushing syndrome (type 2 AME)

**Cushing Syndrome**

- Exogenous glucocorticoid administration—most common cause
  - ACTH-dependent | 85% of cases |
  - Pituitary
  - Ectopic
  - ACTH-independent | 15% of cases |
  - Unilateral adrenal disease
  - Bilateral adrenal disease
  - Massive macronodular hyperplasia (rare)
  - Primary pigmented nodular adrenal disease (rare)

ACTH, corticotropin; AME, apparent mineralocorticoid excess; APA, aldosterone-producing adenoma; FH, familial hyperaldosteronism; IHA, idiopathic hyperaldosteronism.
A much less common form, unilateral hyperplasia, is caused by micronodular or macronodular hyperplasia of the zona glomerulosa of predominantly one adrenal gland. Unilateral hyperplasia is referred to as primary adrenal hyperplasia (PAH). Familial hyperaldosteronism (FH) is also rare and two types have been described: FH type I and FH type II. FH type I, or glucocorticoid-remediable aldosteronism (GRA), is autosomal dominant in inheritance and associated with variable degrees of hyperaldosteronism, high levels of hybrid steroids (eg, 18-hydroxycortic and 18-oxocortisol), and suppression with exogenous glucocorticoids. FH type II refers to the familial occurrence of APA or IHA or both.

**Prevalence**

In the past, clinicians would not consider the diagnosis of primary aldosteronism unless the patient presented with spontaneous hypokalemia, and then the diagnostic evaluation would require discontinuing antihypertensive medications for at least 2 weeks. The spontaneous hypokalemic/no antihypertensive drug diagnostic approach resulted in predicted prevalence rates of less than 0.5% of hypertensive patients. However, it is now recognized that most patients with primary aldosteronism are not hypokalemic and that case-detection testing can be completed with a simple blood test (plasma aldosterone concentration [PAC]-to-plasma renin activity [PRA] ratio) while the patient is taking most antihypertensive drugs. Using the PAC-PRA ratio as a case-detection test, followed by aldosterone suppression confirmatory testing, has resulted in much higher prevalence estimates (5%-10% of all patients with hypertension) for primary aldosteronism.

**Clinical Presentation**

The diagnosis of primary aldosteronism is usually made in patients who are in the third to sixth decade of life. Few symptoms are specific to the syndrome. Patients with marked hypokalemia may have muscle weakness and cramping, headaches, palpitations, polydipsia, polyuria, nocturia, or a combination of these. Periodic paralysis is a very rare presentation in Caucasians, but it is not an infrequent presentation in patients of Asian descent. The polyuria and nocturia are a result of a hypokalemia-induced renal concentrating defect and the presentation is frequently mistaken for prostatism in men. There are no specific physical findings. Edema is not a common finding because of mineralocorticoid escape. The degree of hypertension is usually moderate to severe and may be resistant to usual pharmacologic treatments. Although not common, primary aldosteronism may present with hypertensive urgencies. Patients with APA tend to have higher blood pressures than those with IHA. Hypokalemia is frequently absent; thus, all patients with hypertension are candidates for this disorder. In other patients, the hypokalemia only becomes evident with addition of a potassium-wasting diuretic (eg, hydrochlorothiazide, furosemide). Aldosterone excess also leads to a mild metabolic alkalosis because of increased urinary hydroxigen excretion mediated both by hypokalemia and by the direct stimulatory effect of aldosterone on distal renal tubule acidification. Because of a reset osmostat, the serum sodium concentration tends to be high-normal or slightly above the upper limit of normal—this clinical finding is very useful when initially assessing the potential for primary aldosteronism.

Several studies have shown that patients with primary aldosteronism may be at higher risk than other patients with hypertension for target organ damage of the heart and kidney. When matched for age, blood pressure, and duration of hypertension, patients with primary aldosteronism have greater left ventricular mass by echocardiographic measurements than patients with other types of hypertension (eg, pheochromocytoma, Cushing syndrome, or essential hypertension). In patients with APA, the left ventricular wall thickness and mass decreases markedly 1 year after adrenalectomy. Patients presenting with either APA or IHA have a significantly higher rate of cardiovascular events (eg, stroke, atrial fibrillation, and myocardial infarction) than matched patients with essential hypertension who have similar degrees of hypertension duration and control.

**Diagnosis**

The diagnostic approach to primary aldosteronism can be considered in three parts: case-detection tests, confirmatory tests, and subtype evaluation tests.

A. **Case-detection tests**

Spontaneous hypokalemia is uncommon in patients with uncomplicated hypertension and, when present, strongly suggests associated mineralocorticoid excess. However, most patients with primary aldosteronism have baseline serum levels of potassium in the normal range. Therefore, hypokalemia is not and should not be the only criterion used to determine whom to test for primary aldosteronism. Patients with hypertension and hypokalemia (regardless of presumed cause), treatment-resistant hypertension (three antihypertensive drugs and poor control), severe hypertension (≥2160 mm Hg systolic or ≥110 mm Hg diastolic), hypertension and an incidental adrenal mass, and onset of hypertension at a young age should undergo case-detection testing for primary aldosteronism (Figure 10–4). In addition, primary aldosteronism should be tested for when considering a secondary hypertension evaluation (eg, when testing for renovascular disease or pheochromocytoma).

In patients with suspected primary aldosteronism, case detection can be accomplished by measuring a morning (preferably between 8 AM and 10 AM) ambulatory paired random PAC and PRA (see Figure 10–4). This test may be performed while the patient is taking most antihypertensive medications and without posture stimulation. Hypokalemia reduces the secretion of aldosterone, and it is optimal in patients with hypokalemia to restore the serum level of potassium to normal before performing diagnostic studies. Mineralocorticoid receptor antagonists (eg, spironolactone and eplerenone) are the only medications that absolutely interfere with interpretation of the ratio and should be discontinued at least 6 weeks before testing. ACE-inhibitors and angiotensin receptor blockers (ARB) have the potential to falsely elevate PRA. Therefore, in a patient treated with an ACE inhibitor or ARB, the finding of a detectable PRA level or a low PAC-PRA ratio does not exclude the diagnosis of primary aldosteronism. However, a very
Consider testing for primary aldosteronism in the following settings:
- Hypertension and hypokalemia
- Resistant hypertension (three drugs and poor BP control)
- Adrenal incidentaloma and hypertension
- Onset of hypertension at a young age (< 30 y)
- Severe hypertension (≥ 160 mm Hg systolic or ≥ 100 mm Hg diastolic)
- Whenever considering secondary hypertension

Case-detection testing:
- Morning blood sample in seated ambulant patient
- Plasma aldosterone concentration (PAC)
- Plasma renin activity (PRA) or plasma renin concentration (PRC)

↑ PAC (≥ 15 ng/dL; ≥ 416 pmol/L)
↓ PRA (< 1.0 ng/mL/h)

and

PAC-PRA ratio ≥ 20 ng/dL per ng/mL/h (≥ 555 pmol/L per ng/mL/h)

Confirmatory testing

FIGURE 10-4 When to consider testing for primary aldosteronism and use of the plasma aldosterone concentration to plasma renin activity ratio as a case-finding tool (BP, blood pressure, PAC, plasma aldosterone concentration, PRA, plasma renin activity, PRC, plasma renin concentration).

Useful clinical point is that when a PRA level is undetectably low in a patient taking an ACE inhibitor or ARB, primary aldosteronism is likely. A second important clinical point is that PRA is suppressed (<1.0 ng/mL/h) in almost all patients with primary aldosteronism, regardless of concurrent medications.

The PAC-PRA ratio is based on the concept of paired hormone measurements. For example, in a hypertensive hypokalemic patient: (a) secondary hyperaldosteronism should be considered when both PRA and PAC are increased and the PAC-PRA ratio is less than 10 (eg, renovascular disease); (b) an alternate source of mineralocorticoid receptor agonism should be considered when both PRA and PAC are suppressed (eg, hypercortisolism); and (c) primary aldosteronism should be suspected when PRA is suppressed (<1.0 ng/mL/h) and PAC is increased (Figure 10–5). Although there is some uncertainty about test characteristics and lack of standardization, the PAC-PRA ratio is widely accepted as the case-detection test of choice for primary aldosteronism. It is important to understand that the lower limit of detection varies among different PRA assays and can have a dramatic effect on the PAC-PRA ratio. As an example, if the lower limit of detection for PRA is 0.6 ng/mL/h and the PAC is 18 ng/dL, then the PAC-PRA ratio would be 30; however, if the lower limit of detection for PRA is 0.1 ng/mL/h and the PAC is 18 ng/dL, then the PAC-PRA ratio would be 180. Thus, the cutoff for a high PAC-PRA ratio is laboratory dependent and, more specifically, PRA assay dependent. At Mayo Clinic, a PAC (in ng/dL)-PRA (in ng/mL/h) ratio of 20 or more and PAC of at least 15 ng/dL are found in more than 90% of patients with surgically confirmed APA. In patients without primary aldosteronism, most of the variation occurs within the normal range. The sensitivity and specificity of the PAC-PRA ratio in the diagnosis of primary aldosteronism are approximately 80% and 75%, respectively. A high PAC-PRA ratio with a PAC of at least 15 ng/dL is a positive case-detection test result, a finding that warrants further testing. Other initial case-detection strategies include measurement of isolated plasma renin activity or 24-hour urinary aldosterone excretion.

FIGURE 10–5 Use of the plasma aldosterone concentration-to-plasma renin activity ratio to differentiate among different causes of hypertension and hypokalemia (DOC, deoxycorticosterone; OHSD, hydroxysteroid dehydrogenase; PAC, plasma aldosterone concentration; PRA, plasma renin activity; SI units, International System of Units). (Adapted from Young WF Jr, Hogan MJ. Renin-independent hypermineralocorticoidism. Trends Endocrinol Metab. 1994;5:97-106.)
B. Confirmatory tests  An increased PAC-PRA ratio is not diagnostic by itself, and primary aldosteronism must be confirmed by demonstrating lack of normal suppressibility of aldosterone secretion. The list of drugs and hormones capable of affecting the renin-angiotensin-aldosterone axis is extensive and frequently a medication-contaminated evaluation is unavoidable. Calcium channel blockers and α₁-adrenergic receptor blockers do not affect the diagnostic accuracy in most cases. It is impossible to interpret data obtained from patients receiving treatment with mineralocorticoid receptor antagonists (eg, spironolactone, eplerenone) when PRA is not suppressed. Therefore, treatment with a mineralocorticoid receptor antagonist should not be initiated until the evaluation has been completed and the final decisions about treatment have been made. If primary aldosteronism is suspected in a patient receiving treatment with spironolactone or eplerenone, the treatment should be discontinued for at least 6 weeks before further diagnostic testing. Aldosterone suppression testing can be performed with orally administered sodium chloride and measurement of urinary aldosterone or with intravenous sodium chloride loading and measurement of PAC:

a. Oral sodium loading test—After hypertension and hypokalemia are controlled, patients should receive a high-sodium diet (supplemented with sodium chloride tablets if needed) for 3 days, with a goal sodium intake of 5000 mg of sodium (equivalent to 12.8 g sodium chloride or 218 mEq of sodium). The risk of increasing dietary sodium in patients with severe hypertension must be assessed in each case. Because the high-sodium diet can increase kaliuresis and hypokalemia, vigorous replacement of potassium chloride may be needed, and the serum level of potassium should be monitored daily. On the third day of the high-sodium diet, a 24-hour urine specimen is collected for measurement of aldosterone, sodium, and creatinine. To document adequate sodium repletion, the 24-hour urinary sodium excretion should exceed 200 mEq. Urinary aldosterone excretion more than 12 mcg/24 h is consistent with autonomous aldosterone secretion. The sensitivity and specificity of the oral sodium loading test are 96% and 93%, respectively.

b. Intravenous saline infusion test—The intravenous saline infusion test has also been used for the confirmation of primary aldosteronism. Normal subjects show suppression of PAC after volume expansion with isotonic saline; subjects with primary aldosteronism do not show this suppression. The risks associated with rapid intravenous volume expansion should be assessed in each case. The test is done after an overnight fast. Two liters of 0.9% sodium chloride solution are infused intravenously with an infusion pump over 4 hours into the recumbent patient. Blood pressure and heart rate are monitored during the infusion. At the completion of the infusion, blood is drawn for measurement of PAC. PAC levels in normal subjects decrease to less than 5 ng/dL; most patients with primary aldosteronism do not suppress to less than 10 ng/dL; postsaline infusion PAC values between 5 and 10 ng/dL are indeterminate and can be seen in patients with IHA.

C. Subtype studies  Following case-detection and confirmatory testing, the third management step guides the therapeutic approach by distinguishing APA and PAH from IHA and GRA. Unilateral adrenalectomy in patients with APA or PAH results in normalization of hypokalemia in all: hypertension is improved in all and is cured in approximately 30% to 60% of them. In IHA and GRA, unilateral or bilateral adrenalectomy seldom corrects the hypertension. IHA and GRA should be treated medically. APA is found in approximately 35% of cases and bilateral IHA in approximately 60% of cases (see Table 10–2). APAs are usually hypodense nodules (<2 cm in diameter) on CT and are golden yellow in color on cut section. IHA adrenal glands may be normal on CT or show nodular changes. Aldosterone-producing adrenal carcinomas are almost always greater than 4 cm in diameter and have a suspicious imaging phenotype on CT. Patients with aldosterone-producing adrenocortical carcinomas usually have severe aldosterone excess with serum potassium concentrations frequently less than 2.0 mEq/L.

a. Adrenal CT—Primary aldosteronism subtype evaluation may require one or more tests, the first of which is imaging the adrenal glands with CT (Figure 10–6). This imaging test is usually ordered as CT of the abdomen limited to the adrenal glands with 2-mm contiguous cuts. Although contrast enhancement is not necessary, contrast administration results in improved discrimination between normal adrenal cortex and the small lipid-rich cortical adenoma. When a solitary unilateral hypodense (Hounsfield units [HU] <10) macroadenoma (>1 cm) and normal contralateral adrenal morphology are found on CT in a young patient (adrenal incidentalomas are uncommon in patients <40 years) with primary aldosteronism, unilateral adrenalectomy is a reasonable therapeutic option (Figure 10–7). However, in many cases, CT may show normal-appearing adrenals, minimal unilateral adrenal limb thickening, unilateral microadenomas (<1 cm), bilateral macroadenomas, or a large (eg, >2 cm) unilateral macroadenomas that would be atypical for primary aldosteronism. In these cases, when the patient wants to pursue the surgical treatment option for primary aldosteronism, additional testing is required to determine the source of excess aldosterone secretion (Figure 10–8). Small APAs may be labeled incorrectly as IHA on the basis of CT findings of bilateral nodularity or normal-appearing adrenals. Also, apparent adrenal microadenomas may actually represent areas of hyperplasia, and unilateral adrenalectomy would be inappropriate. In addition, nonfunctioning unilateral adrenal macroadenomas are not uncommon, especially in individuals more than 40 years of age. Unilateral PAH may be visible on CT or the PAH adrenal may appear normal on CT. In general, patients with APAs have more severe hypertension, more frequent hypokalemia, higher plasma (>25 ng/dL) and urinary (>30 mcg/24 h) levels of aldosterone than those with IHA.

Adrenal CT is not accurate in distinguishing between APA and IHA. In one study of 203 patients with primary aldosteronism who were evaluated with both CT and adrenal venous sampling (AVS), CT was accurate in only 53% of patients based on CT findings, 42 patients (22%) would have been incorrectly excluded as candidates for adrenalectomy and 48 (25%) might have had unnecessary or inappropriate surgery. Therefore, AVS is essential to direct appropriate therapy in patients older than 40 years of age with primary aldosteronism who have a high probability of...
APA and who seek a potential surgical cure. However, it is important to recognize that the surgical option is not mandatory in patients with APA—pharmacologic therapy with a mineralocorticoid receptor antagonist is the medication equivalent of adrenalectomy (see later).

b. Adrenal venous sampling—AVS is the criterion standard test to distinguish between unilateral and bilateral disease in patients with primary aldosteronism who want to pursue surgical management for their hypertension. AVS is an intricate procedure because the right adrenal vein is small and may be difficult to locate and cannulate—the success rate depends on the proficiency of the angiographer. The five keys to a successful AVS program are (1) appropriate patient selection; (2) careful patient preparation; (3) focused technical expertise; (4) defined protocol; and (5) accurate data interpretation. A center-specific, written protocol is mandatory. The protocol should be developed by an interested group of endocrinologists, hypertension specialists, internists, radiologists, and laboratory personnel. Safeguards should be in place to prevent mislabeling of the blood tubes in the radiology suite and to prevent sample mix-up in the laboratory. At Mayo Clinic, we use continuous cosyntropin infusion during AVS (50 µg/h started 30 minutes before sampling and continued throughout the procedure) for the following reasons: (a) to minimize stress-induced fluctuations in aldosterone secretion during nonsimultaneous AVS; (b) to maximize the gradient in cortisol from adrenal vein to inferior vena cava (IVC) and thus confirm successful sampling of the adrenal veins; and (c) to maximize the secretion of aldosterone from an APA. The adrenal veins are catheterized through the percutaneous femoral vein approach, and the position of the catheter tip is verified by gentle injection of a small amount of nonionic contrast medium and radiographic documentation (see Figure 10-8). Blood is obtained from both adrenal veins and the IVC below the renal veins and assayed for aldosterone and cortisol concentrations. To be sure there is no cross-contamination, the IVC sample should be obtained from the external iliac vein. The venous sample from the left side typically is obtained from the common phrenic vein immediately adjacent to the entrance of the adrenal vein. The cortisol concentrations from the adrenal veins and IVC are used to confirm successful catheterization; the adrenal vein-IVC cortisol ratio is typically more than 10:1.

Dividing the right and left adrenal vein PACs by their respective cortisol concentrations corrects for the dilutional effect of the inferior phrenic vein flow into the left adrenal vein; these are termed cortisol-corrected ratios (see Figure 10-8). In patients with APA, the mean cortisol-corrected aldosterone ratio (APA-side PAC/cortisol: normal adrenal PAC/cortisol) is 18:1. A cutoff of the cortisol-corrected aldosterone ratio from high side to low side more than 4:1 is used to indicate unilateral aldosterone excess (see Figure 10-8). In patients with IHA, the mean cortisol-corrected aldosterone ratio is 1.8:1 (high side:low side); a ratio less than 3:1 is suggestive of bilateral aldosterone excess.

FIGURE 10–6 Subtype evaluation of primary aldosteronism. For patients who want to pursue a surgical treatment for their hypertension, adrenal venous sampling is frequently a key diagnostic step. See text for details (APA, aldosterone-producing adenoma; AVS, adrenal venous sampling; CT, computed tomography; IHA, idiopathic hyperaldosteronism; PAH, primary adrenal hyperplasia). (Adapted from Young WF Jr, Hogan MJ. Renin-independent hypermineralocorticidism. Trends Endocrinol Metab. 1994;5:97-106).
FIGURE 10–7 A 30-year-old woman had a 7-year history of hypertension and hypokalemia. Her blood pressure was not well controlled despite a four-drug program that included a calcium channel blocker, ACE-inhibitor, thiazide diuretic, and a β-adrenergic blocker. To correct her hypokalemia, she took 420 mEq of potassium per day. The case-detection test for primary aldosteronism was positive, with a plasma aldosterone concentration (PAC) of 34 ng/dL and low plasma renin activity (PRA) at less than 0.6 ng/ml/h (PAC-PRA ratio >56). The confirmatory test for primary aldosteronism was also positive, with 24-hour urinary excretion of aldosterone of 77 μg on a high-sodium diet (urinary sodium, 205 mEq/24 h). A. Adrenal CT axial image showing a 15-mm low-density mass (arrow) within the right adrenal gland. She underwent laparoscopic right adrenalectomy. B. Right adrenal gland (6.2 g, 6.1 cm x 3.7 cm x 1.4 cm) with a 1.8-cm cortical adenoma arising from the surface. C. Cut sections of the yellow adrenal cortical adenoma forming a 1.8 cm x 1.7 cm x 1.3 cm nodule. The postoperative plasma aldosterone concentration was less than 1.0 ng/dL. Hypokalemia was resolved. Four years after surgery, her blood pressure was normal without the aid of antihypertensive medications.

Some centers and clinical practice guidelines recommend that AVS should be performed in all patients who have the diagnosis of primary aldosteronism. However, a more practical approach is to consider the use of AVS based on patient preferences, patient age, clinical comorbidities, and clinical probability of finding an APA (see Figure 10–6).

c. Glucocorticoid-remediable aldosteronism—familial hyperaldosteronism type I—This syndrome is inherited in an autosomal dominant fashion and is extremely rare (responsible for fewer than 1% of cases of primary aldosteronism) (see Table 10–2). GRA is characterized by hypertension of early onset that is usually severe and refractory to conventional antihypertensive therapies, aldosterone excess,
suppressed PRA, and excess production of 18-hydroxycortisol and 18-oxycortisol. GRA is caused by a chimeric gene duplication that results from unequal crossing over between the promoter sequence of \( CYP11B1 \) gene (encoding 11\( \beta \)-hydroxylase) and the coding sequence of \( CYP11B2 \) (encoding aldosterone synthase). This chimeric gene contains the 3' ACTH-responsive portion of the promoter from the 11\( \beta \)-hydroxylase gene fused to the 5' coding sequence of the aldosterone synthase gene. The result is ectopic expression of aldosterone synthase activity in the cortisol-producing zona fasciculata. Thus, mineralocorticoid production is regulated by ACTH instead of the normal secretagogue, angiotensin II. Aldosterone secretion can be suppressed by glucocorticoid therapy. In the absence of glucocorticoid therapy, this mutation results in overproduction of aldosterone and the hybrid steroids 18-hydroxycortisol and 18-oxycortisol, which can be measured in the urine to make the diagnosis.

Genetic testing is a sensitive and specific means of diagnosing GRA and obviates the need to measure the urinary levels of 18-oxocortisol and 18-hydroxycortisol or to perform dexamethasone suppression testing. Genetic testing for GRA should be considered for primary aldosteronism patients with a family history of primary aldosteronism or onset of primary aldosteronism at a young age (e.g., <20 years), or in primary aldosteronism patients who have a family history of strokes at a young age. Cerebrovascular complications (e.g., hemorrhagic stroke) associated with intracranial aneurysms affect approximately 20% of all patients with GRA—a frequency of cerebral aneurysm similar to that found in adult polycystic kidney disease.

d. Familial hyperaldosteronism type II—FH type II is autosomal dominant and may be monogenic. The hyperaldosteronism in FH type II does not suppress with dexamethasone, and GRA mutation testing is negative. FH type II is more common than FH type I, but it still represents less than 2% of all patients with primary aldosteronism. The molecular basis for FH type II is unclear, although a recent linkage analysis study showed an association with chromosomal region 7p22.
Treatment

The treatment goal is to prevent the morbidity and mortality associated with hypertension, hypokalemia, and cardiovascular damage. The cause of the primary aldosteronism helps to determine the appropriate treatment. Normalization of blood pressure should not be the only goal in managing a patient who has primary aldosteronism. In addition to the kidney and colon, mineralocorticoid receptors occur in the heart, brain, and blood vessels. Excessive secretion of aldosterone is associated with increased risk of cardiovascular disease and morbidity. Therefore, normalization of circulating aldosterone or mineralocorticoid receptor blockade should be part of the management plan for all patients with primary aldosteronism. However, clinicians must understand that most patients with long-standing primary aldosteronism have some degree of renal insufficiency that is masked by the glomerular hyperfiltration associated with aldosterone excess. The true degree of renal insufficiency may only become evident after effective pharmacologic or surgical therapy.

A. Surgical treatment of aldosterone-producing adenoma and unilateral hyperplasia

Unilateral laparoscopic adrenalectomy is an excellent treatment option for patients with APA or PAH (unilateral hyperplasia). Although blood pressure control improves in nearly 100% of patients postoperatively, average long-term cure rates of hypertension after unilateral adrenalectomy for APA range from 30% to 60%. Persistent hypertension following adrenalectomy is correlated directly with having more than one first-degree relative with hypertension, use of more than two antihypertensive agents preoperatively, older age, increased serum creatinine level, and duration of hypertension.

Laparoscopic adrenalectomy is the preferred surgical approach and is associated with shorter hospital stays and less long-term morbidity than the open approach. Because APAes are small and may be multiple, the entire adrenal gland should be removed. To decrease the surgical risk, hypokalemia should be corrected with potassium supplements and/or a mineralocorticoid receptor antagonist preoperatively. The mineralocorticoid receptor antagonist and potassium supplements should be discontinued postoperatively. PAC should be measured 1 to 2 days after the operation to confirm a biochemical cure. Serum potassium levels should be monitored weekly for 4 weeks after surgery and a generous sodium diet should be followed to avoid the hyperkalemia of hypoaldosteronism that may occur because of the chronic suppression of the renin-angiotensin-aldosterone axis. In approximately 5% of APA patients clinically significant hyperkalemia may develop after surgery and short-term fludrocortisone supplementation may be required. Typically, the component of hypertension that was associated with aldosterone excess resolves in 1 to 3 months postoperatively.

B. Pharmacologic treatment

IHA and GRA should be treated medically. In addition, APA patients may be treated medically if the medical treatment includes mineralocorticoid receptor blockade. A sodium-restricted diet (<100 mEq of sodium per day), maintenance of ideal body weight, tobacco avoidance, and regular aerobic exercise contribute significantly to the success of pharmacologic treatment. No placebo-controlled randomized trials have evaluated the relative efficacy of drugs in the treatment of primary aldosteronism. Spironolactone, available as 25-, 50-, and 100-mg tablets, has been the drug of choice to treat primary aldosteronism for more than four decades. The initial dosage is 12.5 to 25 mg/d and is increased to 400 mg/d if necessary to achieve a high-normal serum potassium concentration without the aid of oral potassium chloride supplementation. Hypokalemia responds promptly, but hypertension may take as long as 4 to 8 weeks to correct. After several months of therapy, the dosage often can be decreased to as little as 25 to 50 mg/d; dosage titration is based on a goal serum potassium level in the high-normal range. Serum potassium and creatinine should be monitored frequently during the first 4 to 6 weeks of therapy (especially in patients with renal insufficiency or diabetes mellitus). Spironolactone increases the half-life of digoxin, and for patients taking this drug, the dosage may need to be adjusted when treatment with spironolactone is started. Concomitant therapy with salicylates should be avoided because they interfere with the tubular secretion of an active metabolite and decrease the effectiveness of spironolactone. Spironolactone is not selective for the mineralocorticoid receptor. For example, antagonism at the testosterone receptor may result in painful gynecomastia, erectile dysfunction, and decreased libido in men; agonist activity at the progesterone receptor results in menstrual irregularity in women.

Eplerenone is a steroid-based antimineralocorticoid that acts as a competitive and selective mineralocorticoid receptor antagonist. It has a marked reduction in gestational and antiandrogenic actions compared with spironolactone. Treatment trials comparing the efficacy of eplerenone versus spironolactone for the treatment of primary aldosteronism have not been published. Eplerenone is available as 25- and 50-mg tablets. For primary aldosteronism, it is reasonable to start with a dose of 25 mg twice daily (twice daily because of the shorter half-life of eplerenone compared to spironolactone) and titrated upward for a target high-normal serum potassium concentration without the aid of potassium supplements. Potency studies with eplerenone show 50% less milligram per milligram potency when compared with spironolactone. As with spironolactone, it is important to follow blood pressure, serum potassium, and serum creatinine levels closely.

Patients with IHA frequently require a second antihypertensive agent to achieve adequate blood pressure control. Hypervolemia is a major reason for resistance to drug therapy, and low doses of a thiazide (eg, 12.5-50 mg of hydrochlorothiazide daily) or a related sulphonamide diuretic are effective in combination with the mineralocorticoid receptor antagonist. Because these agents often lead to further hypokalemia, serum potassium levels should be monitored.

Before initiating treatment, GRA should be confirmed with genetic testing. In the GRA patient, chronic treatment with physiologic doses of a glucocorticoid normalizes blood pressure and corrects hypokalemia. The clinician should avoid iatrogenic Cushing syndrome with excessive doses of glucocorticoids,
especially with the use of dexamethasone in children. The smallest effective dose of shorter acting agents such as prednisone or hydrocortisone should be prescribed in relation to body surface area (e.g., effective dose of shorter acting agents such as prednisone or hydrocortisone, 10-12 mg/m²/d). Target blood pressure in children should be guided by age-specific blood pressure percentiles. Children should be monitored by pediatricians with expertise in glucocorticoid therapy, with careful attention paid to preventing retardation of linear growth by overtreatment. Treatment with mineralocorticoid receptor antagonists in these patients may be just as effective and avoids the potential disruption of the hypothalamic-pituitary-adrenal axis and risk of iatrogenic side effects. In addition, glucocorticoid therapy or mineralocorticoid receptor blockade may even have a role in normotensive GRA patients.

OTHER FORMS OF MINERALOCORTICOID EXCESS OR EFFECT

The medical disorders associated with excess mineralocorticoid effect from 11-deoxycorticosterone (DOC) and cortisol are listed in Table 10-2. These diagnoses should be considered when PAC and PRA are low in patients with hypertension and hypokalemia.

Hyperdeoxycorticosteronism

A. Congenital adrenal hyperplasia Congenital adrenal hyperplasia (CAH) is caused by enzymatic defects in adrenal steroidogenesis that result in deficient secretion of cortisol (see Chapter 14). The lack of inhibitory feedback by cortisol on the hypothalamus and pituitary produces an ACTH-driven buildup of cortisol precursors proximal to the enzymatic deficiency. A deficiency of 11β-hydroxylase (CYP11B) or 17α-hydroxylase (CYP17) causes hypertension and hypokalemia because of hypersecretion of the mineralocorticoid DOC. The mineralocorticoid effect of increased circulating levels of DOC also decreases PRA and aldosterone secretion. These defects are autosomal recessive in inheritance and typically are diagnosed in childhood. However, partial enzymatic defects have been shown to cause hypertension in adults.

a. 11β-Hydroxylase deficiency—Approximately 5% of all cases of CAH are due to 11β-hydroxylase deficiency; the prevalence in Caucasians is 1 in 100,000. More than 40 mutations have been described in CYP11B1, the gene encoding 11β-hydroxylase. There is an increased prevalence among Sephardic Jews from Morocco, suggestive of a founder effect. The impaired conversion of DOC to corticosterone results in high levels of DOC, 11-deoxycortisol, and adrenal androgens (see Chapter 14). Females present in infancy or childhood with hypertension, hypokalemia, acne, hirsutism, and virilization. Males present with pseudoprecocious puberty. Approximately two-thirds of patients have mild to moderate hypertension. Markedly increased levels of DOC, 11-deoxycortisol, and adrenal androgens confirm the diagnosis. Glucocorticoid replacement normalizes the steroid abnormalities and hypertension.

b. 17α-Hydroxylase deficiency—17α-Hydroxylase deficiency is a rare cause of CAH. 17α-Hydroxylase is essential for the synthesis of cortisol and gonadal hormones, and deficiency results in decreased production of cortisol and sex hormones. Genetic 46,XY males present with either pseudohermaphroditism or as phenotypic females, and 46,XX females present with primary amenorrhea. Therefore, a person with this form of CAH may not come to medical attention until puberty. Patients present with eunuchoid proportions and appearance. The biochemical findings include low concentrations of plasma adrenal androgens, plasma 17α-hydroxyprogesterone and cortisol. The plasma concentrations of DOC, corticosterone, and 18-hydroxycorticosterone (all produced in the zona fasciculata) are increased. Aldosterone (produced in zona glomerulosa) and PRA are suppressed. Although rare, there is an increased prevalence among Dutch Mennonites. As with 11β-hydroxylase deficiency, glucocorticoid replacement normalizes the steroid abnormalities and hypertension.

B. Deoxycorticosterone-producing tumor DOC-producing adrenal tumors are usually large and malignant. Some of them secrete androgens and estrogens in addition to DOC, which may cause virilization in women and feminization in men. A high level of plasma DOC or urinary tetrahydrodeoxycorticosterone and a large adrenal tumor seen on CT confirm the diagnosis. Aldosterone secretion in these patients is typically suppressed. Optimal treatment is complete surgical resection.

C. Primary cortisol resistance Increased cortisol secretion and plasma cortisol concentrations without evidence of Cushing syndrome are found in patients with primary cortisol resistance (or glucocorticoid resistance), a rare familial syndrome. Cortisol resistance leads to elevations in ACTH secretion which, in turn, increases adrenal steroid production. The syndrome is characterized by hypokalemic alkalosis, hypertension, increased plasma concentrations of DOC, as well as cortisol, and increased adrenal androgen secretion. The hypertension and hypokalemia are likely due to the combined effects of excess DOC and increased cortisol access to the mineralocorticoid receptor (high rates of cortisol production that overwhelm 11β-hydroxysteroid dehydrogenase type 2 [11β-HSD2] activity). Primary cortisol resistance is caused by defects in glucocorticoid receptors and assembly of the steroid-receptor complex. The treatment for the mineralocorticoid-dependent hypertension is blockade of the mineralocorticoid receptor with a mineralocorticoid receptor antagonist or suppression of ACTH secretion with dexamethasone.

Apparent Mineralocorticoid Excess Syndrome

Type 1 apparent mineralocorticoid excess (AME) is the result of impaired activity of the microsomal enzyme 11β-HSD2, which normally inactivates cortisol in the kidney by converting it to cortisone (Figure 10-9). Cortisol can be a potent mineralocorticoid, and as a result of the enzyme deficiency, high levels of cortisol accumulate in the kidney. Thus, 11β-HSD2 normally excludes physiologic glucocorticoids from the nonselective mineralocorticoid receptor by converting them to the inactive 11-keto compound, cortisone. The characteristic abnormal urinary cortisol-cortisone
FIGURE 10–9 Interconversion of hormonally active cortisol to inactive cortisone is catalyzed by two isozymes of 11β-hydroxysteroid dehydrogenase (11β-HSD). 11β-HSD1 converts cortisone to cortisol and 11β-HSD2 inactivates cortisol to cortisone.

metabolite profile seen in apparent mineralocorticoid excess reflects decreased 11β-HSD2 activity (ratio of cortisol to cortisone increased 10-fold from normal).

Decreased 11β-HSD2 activity may be hereditary or secondary to pharmacologic inhibition of enzyme activity by glycyrrhizic acid, the active principle of licorice root (Glycyrrhiza glabra) and some chewing tobaccos. The congenital form is a rare autosomal recessive disorder, and children present with low birth weight, failure to thrive, hypertension, polyuria and polydipsia, and poor growth. The clinical phenotype of patients with AME includes hypertension, hypokalemia, metabolic alkalosis, low PRA, low PAC, and normal plasma cortisol levels. The diagnosis is confirmed by demonstrating an abnormal ratio of cortisol to cortisone in a 24-hour urine collection. Treatment includes blockade of the mineralocorticoid receptor with a mineralocorticoid receptor antagonist or suppression of endogenous cortisol secretion with dexamethasone.

Carbenoxolone (18β-glycyrrhetinic acid sodium hemisuccinate) is a glycyrrhizic acid metabolite that is used in some countries to treat gastroesophageal reflux disorder. Carbenoxolone acts by protecting the gastrointestinal mucosal barrier from acid-pepsin attack and increasing mucosal mucin production. However, carbenoxolone is also an inhibitor of 11β-HSD2 and side effects include sodium retention, hypokalemic alkalosis, suppressed plasma renin, and hypertension.

Type 2 AME caused by ectopic ACTH secretion, seen in patients with Cushing syndrome, is related to the high rates of cortisol production that overwhelm 11β-HSD2 activity. DOC levels may also be increased in severe ACTH-dependent Cushing syndrome and contribute to the hypertension and hypokalemia in this disorder.

**Liddle Syndrome—Abnormal Renal Tubular Ionic Transport**

In 1963, Liddle described an autosomal dominant renal disorder that appeared to be primary aldosteronism with hypertension, hypokalemia, and inappropriate kaliuresis. However, PAC and PRA were very low in patients with Liddle syndrome; thus, another name for this disorder is "pseudoaldosteronism." Liddle syndrome is caused by mutations in the β or γ subunits of the amiloride-sensitive epithelial sodium channel—resulting in enhanced activity of the epithelial sodium channel with increased sodium reabsorption, potassium wasting, hypertension, and hypokalemia. Clinical genetic testing is available (www.genetests.org). As would be predicted, amiloride and triamterene are very effective agents to treat the hypertension and hypokalemia. However, spironolactone is ineffective in these patients. Liddle syndrome can easily be distinguished from AME based on a good clinical response to amiloride or triamterene, lack of efficacy of spironolactone and dexamethasone, and normal 24-hour urine cortisone-cortisol ratio.

**Hypertension Exacerbated by Pregnancy**

Hypertension exacerbated by pregnancy is a rare autosomal dominant disorder found in women with early-onset hypertension with suppressed levels of aldosterone and renin. During pregnancy, both the hypertension and hypokalemia are severely exacerbated. These patients have an activating mutation in the gene encoding the mineralocorticoid receptor which allows progesterone and other mineralocorticoid antagonists to become agonists.

**OTHER ENDOCRINE DISORDERS ASSOCIATED WITH HYPERTENSION**

**Cushing Syndrome**

Hypertension occurs in 75% to 80% of patients with Cushing syndrome (see Chapter 9). Most patients with endogenous Cushing syndrome have ACTH-dependent disease due to a corticotroph pituitary adenoma (see Table 10–2). Ectopic ACTH secretion is the second most common cause of endogenous Cushing syndrome. The ACTH-independent causes (eg, adrenal cortisol-secreting adenoma or carcinoma) of Cushing syndrome are less common. ACTH-independent macronodular hyperplasia is associated with massive hyperplasia of both adrenal glands—usually a result of activation of one or several G protein–coupled receptors aberrantly expressed in the adrenal cortex. ACTH-independent primary pigmented nodular adrenal disease (PPNAD) is a bilateral form of micronodular adrenal hyperplasia that leads to Cushing syndrome. Germline mutations in PRKARIA cause PPNAD in the setting of Carney complex (see Chapter 9). The mechanisms of hypertension in the setting of Cushing syndrome include increased production of DOC, enhanced pressor sensitivity to endogenous vasoconstrictors (eg, epinephrine and angiotensin II),
increased cardiac output, activation of the renin-angiotensin system by increasing the hepatic production of angiotensinogen, and overload of the cortisol inactivation system with stimulation of the mineralocorticoid receptor. The source of excess glucocorticoids may be exogenous (iatrogenic) or endogenous. Mineralocorticoid production is usually normal in endogenous Cushing syndrome; aldosterone and renin levels are usually normal and DOC levels are normal or mildly increased. In patients with adrenal carcinoma, DOC and aldosterone may be elevated.

The case-detection studies for endogenous cortisol excess include: (a) measurement of free cortisol in a 24-hour urine collection; (b) midnight salivary cortisol measurement; and (c) 1-mg overnight dexamethasone suppression test. Further studies to confirm Cushing syndrome and to determine the cause of the cortisol excess state are outlined in Chapter 9.

The hypertension associated with Cushing syndrome should be treated until a surgical cure is obtained. Mineralocorticoid receptor antagonists, at dosages used to treat primary aldosteronism, are effective in reversing the hypokalemia. Second-step agents (e.g., thiazide diuretics) may be added for optimal control of blood pressure. The hypertension associated with the hypercortisolism usually resolves over several weeks after a surgical cure, and antihypertensive agents can be tapered and withdrawn.

Thyroid Dysfunction

A. Hyperthyroidism When excessive amounts of circulating thyroid hormones interact with thyroid hormone receptors on peripheral tissues, both metabolic activity and sensitivity to circulating catecholamines increase. Thyrotoxic patients usually have tachycardia, high cardiac output, increased stroke volume, decreased peripheral vascular resistance, and increased systolic blood pressure. The initial management of patients with hyperthyroidism who have hyperthyroidism includes a β-adrenergic blocker to treat hypertension, tachycardia, and tremor. The definitive treatment of hyperthyroidism is cause specific (see Chapter 7).

B. Hypothyroidism The frequency of hypertension, usually diastolic, is increased three fold in hypothyroid patients and may account for as much as 1% of cases of diastolic hypertension in the population. The mechanisms for the elevation in blood pressure include increased systemic vascular resistance and extracellular volume expansion. Treatment of thyroid hormone deficiency decreases blood pressure in most patients with hypertension and normalizes blood pressure in one-third of them. Synthetic levothyroxine is the treatment of choice for hypothyroidism (see Chapter 7).

Acromegaly

Chronic growth hormone (GH) excess from a GH-producing pituitary tumor results in the clinical syndrome of acromegaly. The effects of chronic excess of GH include acral and soft tissue overgrowth, progressive dental malocclusion, degenerative arthritis related to chondral and synovial tissue overgrowth within joints, low-pitched sonorous voice, excessive sweating and oily skin, perineural hypertrophy leading to nerve entrapment (eg, carpal tunnel syndrome), cardiac dysfunction, and hypertension (see Chapter 4). Hypertension occurs in 20% to 40% of the patients and is associated with sodium retention and extracellular volume expansion. Pituitary surgery is the treatment of choice; if necessary, it is supplemented with medical therapy or irradiation or both. The hypertension of acromegaly is treated most effectively by eliminating GH excess. If a surgical cure is not possible, the hypertension usually responds well to diuretic therapy.

VIP  Vasoactive intestinal polypeptide
VMA  Vanillylmandelic acid (3-methoxy-4-hydroxymandelic acid)

The adrenal medulla and paraganglia are part of the autonomic/sympathetic nervous system. The endocrine and nervous systems are alike in that they exert their actions by releasing hormones/neurotransmitters that bind to cell surface receptors in the target tissue, thereby inducing an effect.

*Autonomic nerves* are not under conscious control. They innervate the heart, adrenal medulla, vascular smooth muscle, and smooth muscle in visceral organs, thereby controlling cardiac rate and output, adrenal medullary secretion of catecholamines, blood pressure, the genitourinary tract, and intestinal motility. Autonomic nerves originate within the central nervous system and have two major divisions according to their anatomic locations:

1. **Parasympathetic** preganglionic nerves exit the central nervous system via the cranial nerves and sacral spinal nerves. They terminate in nonchromaffin paraganglia that are most numerous in the neck and associated with the glossopharyngeal and vagus nerves. These ganglia serve as chemoreceptors that are involved in the control of respiration. An important paraganglion at the carotid bifurcation is known as the *carotid body*. They are also found along the jugular vein and in the jugulo-tymppanic region. Head-neck paragangliomas are tumors that arise from these parasympathetic paraganglia.

2. **Sympathetic** preganglionic nerves exit the central nervous system via the thoracic and lumbar spinal nerves. The
The sympathetic nervous system coordinates the body’s automatic \textit{fight-flight} response by stimulating the adrenal medulla to secrete catecholamines and by directly stimulating cardiac output and blood flow to muscles while diverting blood flow away from visceral organs.

Sympathetic preganglionic nerves terminate mainly in paravertebral and prevertebral nerve ganglia where they secrete acetylcholine as their neurotransmitter; they are, therefore, known as \textit{cholinergic} nerves. These nerve ganglia are collectively known as \textit{paraganglia} and contain neuroendocrine cells that are similar to adrenal medullary cells on light microscopy by chromaffin and immunohistochemical staining. Paraganglia are also found in the mediastinum, particularly adjacent to the cardiac atria, and in the abdomen along the sympathetic nerve chains in paravertebral and prevertebral positions. Paraganglia are plentiful along the aorta, particularly around the celiac axis, adrenal glands, renal medullae, and aortic bifurcation (organ of Zuckerkandl). Paraganglia are also abundant in the pelvis, particularly adjacent to the bladder. Preganglionic nerves also terminate in the adrenal medulla, which is basically a sympathetic ganglion that is surrounded by adrenal cortex.

Sympathetic postganglionic nerve fibers originate from the paraganglia and run to the tissues being innervated. They secrete norepinephrine as their neurotransmitter at synaptic junctions. Adrenal medullary cells are basically modified postganglionic nerves that lack axons and secrete their neurotransmitter (mainly epinephrine) directly into the blood; thus, the bloodstream acts like a giant synapse, carrying epinephrine to receptors throughout the body. Synonyms for epinephrine and norepinephrine are \textit{adrenalin} and \textit{noradrenaline}, respectively (see later).

Although the adrenal medulla is not essential for survival, its secretion of epinephrine and other compounds helps maintain the body’s homeostasis during stress. Investigations of the adrenal medulla and the sympathetic nervous system have led to the discovery of different catecholamine receptors and the production of a wide variety of sympathetic agonists and antagonists with diverse clinical applications.

\textbf{Pheochromocytomas} are tumors that arise from the adrenal medulla, whereas non–head-neck \textit{paragangliomas} arise from extra-adrenal sympathetic ganglia. Pheochromocytomas can secrete excessive amounts of both epinephrine and norepinephrine, whereas paragangliomas secrete only norepinephrine. The excessive secretion of catecholamines can result in a dangerous exaggeration of the stress response.

\section*{ANATOMY}

\section*{Embyrology (Figure 11–1)}

The sympathetic nervous system arises in the fetus from the primitive cells of the neural crest (sympathogonia). At about the fifth week of gestation, these cells migrate from the spinal ganglia in the thoracic region to form the sympathetic chain posterior to the dorsal aorta. They then begin to migrate anteriorly to form the remaining ganglia.

![Diagram](Figure 11-1) The embryonic development of adrenergic cells and tumors that develop from them (in parentheses). Sympathogonia are primitive cells derived from the neural crest. Neuroblasts are also called sympathoblasts; ganglion cells are the same as sympathocytes; and pheochromocytes are mature chromaffin cells.

At 6 weeks of gestation, groups of these primitive cells migrate along the central vein and enter the fetal adrenal cortex to form the adrenal medulla, which is detectable by the eighth week. The adrenal medulla at this time is composed of sympathogonia and pheochromoblasts, which then mature into pheochromocytes. The cells appear in rosette-like structures, with the more primitive cells occupying a central position. Storage granules can be found in these cells at 12 weeks. The adrenal medullas are very small and amorphous at birth but develop into recognizable adult form by the sixth month of postnatal life.

Pheochromoblasts and pheochromocytes also collect on both sides of the aorta to form the paraganglia. These cells collect principally at the origin of the mesenteric arteries and at the aortic bifurcation where they fuse anteriorly to form the organ of Zuckerkandl, which is quite prominent during the first year of life. Pheochromocytes (chromaffin cells) also are found scattered throughout the abdominal sympathetic plexi as well as in other parts of the sympathetic nervous system.

\section*{Gross Structure}

The anatomic relationships between the adrenal medulla and the adrenal cortex differ in different species. In mammals, the medulla is surrounded by the adrenal cortex, and in humans, the adrenal medulla occupies a central position in the widest part of the gland, with only small portions extending into the narrower parts. The mass of adrenal medullary tissue in both adult adrenal glands averages about 1000 mg (about 15% of the total weight of both adrenal glands), although the proportions vary from individual to individual. There is no clear demarcation between cortex and medulla. A cuff of adrenal cortical cells usually surrounds the central vein within the adrenal medulla, and there may be islands of cortical cells elsewhere in the medulla.

\section*{Microscopic Structure}

The \textit{chromaffin cells} or \textit{pheochromocytes} of the adrenal medulla are large ovoid columnar cells arranged in nests, alveoli,
or cords around a rich network of capillaries and venous sinuoids that drain blood from the adrenal cortex. Pheochromocytes have large nuclei and a well-developed Golgi apparatus. Their cytoplasm contains large numbers of vesicles (granules) that measure 100 to 300 nm in diameter and appear similar to the neurosecretory granules seen in peripheral sympathetic nerves. Catecholamines (epinephrine and/or norepinephrine) comprise about 20% of the mass of neurosecretory vesicles. Vesicles containing norepinephrine appear darker than those containing epinephrine. The vesicles also contain proteins, lipids, and adenosine triphosphate (ATP), as well as chromogranins, neuropeptide Y, enkephalins, and proopiomelanocortin (along with related peptides such as adrenocorticotropic hormone [ACTH] and β-endorphin).

**Nerve Supply**

The cells of the adrenal medulla are innervated by preganglionic fibers of the sympathetic nervous system, which release acetylcholine and enkephalins at the synapses. Most of these fibers arise from a plexus in the capsule of the posterior surface of the gland and enter the adrenal glands in bundles of 30 to 50 fibers without synapsing. They follow the course of the blood vessels into the medulla without branching into the adrenal cortex. Some reach the wall of the central vein, where they synapse with small autonomic ganglia. However, most fibers end in relationship to the pheochromocytes.

**Blood Supply**

The adrenal gland is perfused by the superior, middle, and inferior adrenal branches of the inferior phrenic artery, directly from the aorta and from the renal arteries. On reaching the adrenal gland, these arteries branch to form a plexus under the capsule supplying the adrenal cortex. A few of these vessels, however, penetrate the cortex, passing directly to the medulla. The medulla is also nourished by branches of the arteries supplying the central vein and cuff of cortical tissue around the central vein. Capillary loops passing from the subcapsular plexus of the cortex also supply blood as they drain into the central vein. Most of the blood supply to adrenal medullary cells is via a portal vascular system that arises from the capillaries in the cortex. There is also a capillary network of lymphatics that drain into a plexus around the central vein.

Norepinephrine is converted to epinephrine by the enzyme phenylethanolamine-N-methyltransferase (PNMT). In mammals, the expression of PNMT is induced by cortisol. Chromaffin cells that produce epinephrine are exposed to higher concentrations of cortisol from capillaries draining adrenocortical cells, whereas chromaffin cells containing norepinephrine are supplied by arteries that course directly to the adrenal medulla (see sections on biosynthesis and decrion, later).

The central vein of the right adrenal is short and drains directly into the vena cava with about 5% having multiple veins. About 5% of right adrenal veins drain into the hepatic vein. For the left adrenal gland, the vein is somewhat longer and drains into the left renal vein.

**HORMONES OF THE ADRENAL MEDULLA AND PARAGANGLIA**

**CATECHOLAMINES**

**Biosynthesis (Figure 11–2)**

Catecholamines are molecules that have a catechol nucleus consisting of benzene with two hydroxyl side groups plus a side-chain amine. Catecholamines include dopamine, norepinephrine, and epinephrine (see Figure 11–2).

![Figure 11-2](https://example.com/figure11-2.png)

**FIGURE 11–2** Biosynthesis of catecholamines (DOPA: L-dihydroxyphenylalanine; PNMT: phenylethanolamine-N-methyltransferase). Epinephrine is not produced in paraganglia.
Epinephrine is the main hormone secreted by the normal adrenal medulla. The proportions of epinephrine and norepinephrine found in the adrenal medulla vary with the species; in humans, the adrenal medulla contains 15% to 20% norepinephrine.

Norepinephrine is found primarily in the central nervous system and in peripheral sympathetic paraganglia and nerves. Dopamine is found in the adrenal medulla and in sympathetic neurons as a precursor to norepinephrine. It is present in high concentrations in the brain, in specialized neurons in the sympathetic ganglia, and in the carotid body, where it serves as a neurotransmitter. Dopamine is also present in the proximal renal tubule where it promotes sodium excretion and in the gastrointestinal tract where it serves a paracrine function.

Chromogranin A (CgA) is a peptide that is stored and released with catecholamines during exocytosis; catestatin is a fragment of the CgA prohormone that inhibits further catecholamine release by acting as an antagonist at the neuronal cholinergic receptor. CgA levels tend to be somewhat higher in patients with hypertension than in matched normotensive individuals. CgA has become a valuable tumor marker, particularly for patients with paragangliomas that are otherwise nonsecretory.

A. Conversion of tyrosine to DOPA  The catecholamines are synthesized from tyrosine, which may be derived from ingested food or synthesized from phenylalanine in the liver. Tyrosine circulates at a concentration of 1 to 1.5 mg/dL of blood. It enters neurons and chromaffin cells by an active transport mechanism and is converted to L-dihydroxyphenylalanine (L-DOPA). The reaction is catalyzed by tyrosine hydroxylase, which is transported via axonal flow to the nerve terminal. Tyrosine hydroxylase is the rate-limiting step in catecholamine synthesis. It is transcriptionally activated by acetylcholine through the nicotinic cholinergic receptor, which in turn activates protein kinase A via cAMP. Tyrosine hydroxylase activity may be inhibited by a variety of compounds; alpha methyltyrosine (metyrosine) is an inhibitor that is sometimes used in the therapy of metastatic or unresectable pheochromocytomas.

B. Conversion of DOPA to dopamine  DOPA is converted to dopamine by the enzyme aromatic L-amino acid decarboxylase (DOPA decarboxylase). This enzyme is found in all tissues, with the highest concentrations in liver, kidney, brain, and vas deferens. The various enzymes have different substrate specificities depending on the tissue source. Competitive inhibitors of DOPA decarboxylase, such as methyldopa, are converted to substances (an example is 0-t-methylnorepinephrine) that are then stored in granules in the nerve cell and released in place of norepinephrine. These products (false transmitters) were thought to mediate the antihypertensive action of drugs at peripheral sympathetic synapses but are now believed to stimulate the alpha receptors of the inhibitory corticobulbar system, reducing sympathetic discharge peripherally.

C. Conversion of dopamine to norepinephrine  Dopamine enters granulated storage vesicles where it is hydroxylated to norepinephrine by the enzyme dopamine-β-hydroxylase (DBH), which is found within the vesicle membrane. Norepinephrine is then actively transported into the vesicle by vesicular monoamine transferase (VMAT), which is located in the lipid bilayer of the vesicle wall. Norepinephrine constantly diffuses out of the vesicle, so it is best to consider it being concentrated in the vesicle, rather than being stored there. The granulated storage vesicle migrates to the cell surface and secretes its contents via exocytosis; both norepinephrine and DBH are released during exocytosis. After secretion, most norepinephrine is avidly recycled back into the nerve. Normally, about 93% of circulating norepinephrine originates from diffusion out of nonadrenal sympathetic nerve cells and synapses, while only 7% originates from the adrenal medulla.

D. Conversion of norepinephrine to epinephrine  Norepinephrine constantly diffuses out from storage granules into the cytoplasm. In most cells of the adrenal medulla, cytoplasmic norepinephrine is converted to epinephrine, catalyzed by PNMT. Epinephrine can then return to the vesicle, diffuse from the cell, or undergo catabolism. High concentrations of cortisol enhance the expression of the gene encoding PNMT. Cortisol is present in high concentrations in most areas of the adrenal medulla due to venous blood flow from the adjacent adrenal cortex. This accounts for the fact that in the normal human adrenal medulla, about 80% of the catecholamine content is epinephrine and only 20% is norepinephrine. In mouse models, the administration of exogenous corticosteroids appears to increase adrenal medullary PNMT expression, despite suppression of ACTH and endogenous adrenal cortisol production.

Paragangliomas rarely secrete epinephrine, because they do not have high local concentrations of cortisol to induce PNMT expression. Pheochromocytomas secrete epinephrine and norepinephrine in various ratios. Interestingly, after adrenalectomy, recurrent pheochromocytoma can secrete epinephrine without any surrounding adrenal cortex, indicating that the induction of PNMT may continue in subsequent cell lineages without high local levels of cortisol. After both adrenal glands are resected, serum epinephrine levels abruptly fall to nearly zero, whereas norepinephrine concentrations do not decline significantly, since most circulating norepinephrine originates from leakage out of sympathetic nerves and synapses.

The enzyme PNMT is found in many tissues outside the adrenal medulla. PNMT that is identical to adrenal PNMT has been found in the lung, kidney, pancreas, and cancer cells. Therefore, nonadrenal tissue is capable of synthesizing epinephrine if norepinephrine is available as a substrate. However, nonadrenal production of epinephrine usually contributes minimally to circulating levels. PNMT is found in human lung, and glucocorticoids increase its expression, thereby increasing lung epinephrine. This may possibly contribute to the bronchial dilation that is induced by glucocorticoids (inhaled or systemic). PNMT activity is also found in red blood cells, where its activity is increased in hypertension and decreased in hypothyroidism. Renal PNMT activity is such that up to one-half of the epinephrine found in normal urine may be the product of renal conversion from norepinephrine.
In the adrenal medulla, catecholamine stores can be depleted during prolonged hypoglycemia. Biosynthesis of catecholamines increases during nerve stimulation by activation of tyrosine hydroxylase. Prolonged stimulation leads to the induction of increased amounts of this rate-limiting enzyme.

**Storage of Catecholamines**

Catecholamines are not truly stored in intracellular vesicles. Rather, they exist in a dynamic equilibrium between the vesicle and the surrounding cytoplasm. Catecholamines continuously leak out of the vesicles into the cytoplasm but reenter and become concentrated in the vesicles by the action of two vesicular monoamine transporters: VMAT-1 and VMAT-2. Both are expressed in the adrenal medulla, but only VMAT-2 is expressed in sympathetic nerves.

In the adrenal medulla, the percentage of stored epinephrine (vs total catecholamines) varies widely among different species. In the human adrenal medulla, epinephrine comprises about 80% of stored catecholamines. Epinephrine and norepinephrine are stored in different cells. Morphologic differences in epinephrine and norepinephrine storage vesicles are visible on light microscopy after proper staining. Cells that store predominantly epinephrine tend to be adjacent to intramural sinusoidal vessels that bathe the cells in blood from the adrenal cortex; such blood contains cortisol that induces the enzyme PNMT that catalyzes the conversion of norepinephrine to epinephrine in the cytoplasm such that these vesicles contain predominantly epinephrine. Adrenal medullary cells that contain predominantly norepinephrine tend to be farther away from such vessels.

Norepinephrine is also found in the synaptic vesicles of postganglionic autonomic nerves in organs that have rich sympathetic innervations: the heart, salivary glands, vascular smooth muscle, liver, spleen, kidneys, and muscles. A single sympathetic nerve cell may have up to 25,000 synaptic bulges along the length of its axon; each synapse synthesizes norepinephrine and stores it in adrenergic synaptic vesicles adjacent to target cells.

Catecholamine biosynthesis is coupled to secretion, so that the stores of norepinephrine at the nerve endings remain relatively unchanged even in the presence of marked nerve activity. The adrenal medulla contains catecholamines at a concentration of about 0.5 mg/g; the spleen, vas deferens, brain, spinal cord, and heart contain 1 to 5 μg/g; and the liver, gut, and skeletal muscle contain 0.1 to 0.5 μg/g. Catecholamines are stored in electron-dense granules approximately 1 μm in diameter that contain catecholamines and ATP in a 4:1 molar ratio, as well as several neurotransmitters, calcium, magnesium, and water-soluble proteins called chromogranins (see earlier). The interior surface of the membrane contains DBH and ATPase. The Mg2+-dependent ATPase facilitates the uptake and inhibits the release of catecholamines by the granules. Adrenal medullary granules appear to contain and release a number of active peptides including adrenomedullin, ACTH, vasoactive intestinal peptide (VIP), chromogranins, and enkephalins. The peptides derived from chromogranins are physiologically active and may modulate catecholamine release.

### Secretion of Catecholamines (Figure 11–3 and Table 11–1)

Preganglionic nerve fibers terminate in adrenal medullary cells, where they release acetylcholine at synapses and stimulate adrenal medullary receptors. Activation of the receptors depolarizes the cell membrane and causes an influx of calcium ions. The increased intracellular concentration of calcium triggers exocytosis of the neurosecretory vesicles with consequent release of their contents: catecholamines, chromogranins, and soluble DBH. Vesicular membrane-bound DBH is not released during exocytosis.

**Adrenal medulla.** In the adrenal medulla, exocytosis of the neurosecretory vesicles releases epinephrine and norepinephrine into the circulation. In normals, over 90% of circulating epinephrine is derived from the adrenal medulla, whereas adrenal medullary secretion accounts for only about 7% of circulating norepinephrine. Catecholamines also diffuse out of the neurosecretory vesicles into the cytoplasm. Catecholamines in the cytoplasm may reenter a vesicle via VMAT or may be metabolized by COMT into catecholamine metabolites: metanephrine and normetanephrine, which gradually diffuse out of the cell and enter the circulation.

Adrenal medullary catecholamine secretion increases with exercise, angina pectoris, myocardial infarction, hemorrhage, ether anesthesia, surgery, hypoglycemia, anoxia and asphyxia, and many other stressful stimuli. The rate of secretion of epinephrine increases more than that of norepinephrine in the presence of hypoglycemia and most other stimuli. However, during hypoxia, the adrenal medullary cells preferentially release norepinephrine. Such release is mainly not by exocytosis but rather by leakage of norepinephrine from neurosecretory vesicles into the cytoplasm and out of the cell into the circulation. The preferential release of norepinephrine may be because the adrenal medullary cells that concentrate norepinephrine are located farther from blood vessels and may be more susceptible to hypoxic injury. (See Storage of Catecholamines, earlier.)

**Sympathetic neurons.** In sympathetic neurons, exocytosis of the neurosecretory vesicle releases norepinephrine into the synapse. Norepinephrine that has been secreted into a synapse by exocytosis is either reabsorbed via norepinephrine transporters (NETs) or leaks out of the synapse into the circulation. Such synaptic leakage accounts for the majority of circulating norepinephrine in normal individuals.

### Metabolism and Excretion of Catecholamines (Figure 11–4)

#### A. Catecholamine metabolism in cells of origin

**Adrenal medulla.** In the adrenal medulla, catecholamines are metabolized to metanephrines primarily by membrane-bound catecholamine-O-methyltransferase (COMT); epinephrine to metanephrine and norepinephrine to normetanephrine. The metanephrine metabolites subsequently leak into the circulation.
FIGURE 11-3 Schematic diagram of a noradrenergic junction of the peripheral sympathetic nervous system (not to scale). The neural axons form synaptic junctions with cells in target organs. The neurotransmitter is norepinephrine, which originates through de novo synthesis from tyrosine or from norepinephrine that has been secreted and reabsorbed by a norepinephrine transporter (NET). Tyrosine is transported into the noradrenergic endings or varicosities by a sodium-dependent carrier (A). In the cytoplasm, tyrosine hydroxylase converts tyrosine to DOPA that is converted by DOPA decarboxylase to dopamine. Dopamine, as well as norepinephrine (NE) is transported into the vesicles by vesicular monoamine transferase (VMAT). Dopamine is converted to NE in the vesicle by dopamine-β-hydroxylase. Exocytosis of the neurosecretory vesicle with release of transmitter occurs when an action potential opens voltage-sensitive calcium channels and increases intracellular calcium. Fusion of vesicles with the surface membrane results in expulsion of norepinephrine, cotransmitters, and dopamine-β-hydroxylase. After release, norepinephrine diffuses out of the cleft or is transported into the cytoplasm of the nerve itself (uptake 1) or transported into the postjunctional target cell (uptake 2). Regulatory receptors are present on the presynaptic terminal (SNAPs, synaptosome-associated proteins; VAMPs, vesicle-associated membrane protein). Not shown: In adrenal medullary and pheochromocytoma cells, norepinephrine constantly diffuses from the vesicle into the cytoplasm where it may be converted to epinephrine by phenylethanolamine-N-methyltransferase (PNMT). Alternatively, cytoplasmic membrane-bound catecholamine-O-methyltransferase (COMT) can metabolize epinephrine and norepinephrine directly into metanephrine and normetanephrine, respectively, which are then released. (Reproduced, with permission, from Katzung BJ, ed. Basic & Clinical Pharmacology. 11th ed. McGraw-Hill; 2009.)

Over 90% of circulating metanephrine and about 40% of circulating normetanephrine is produced by the adrenal medulla.

**Sympathetic nerves.** Catecholamines that are released at the synapse bind to their receptors with relatively low affinity and dissociate rapidly (see Figure 11-4). About 10% of norepinephrine escapes from synapses into the systemic circulation (see later). About 90% of synaptic norepinephrine is reabsorbed by the nerves from which they were released or by the target cells. Cytoplasmic norepinephrine is metabolized to 3,4-dihydroxyphenylglycol (DHPG) at the outer mitochondrial membrane by the enzyme monoamine oxidase (MAO) that regulates the norepinephrine content of neurons. DHBG leaks from the neuron and is absorbed by the liver and other tissues that convert it to VMA (see later) that is excreted in the urine. In normals, most urinary VMA is derived from DHPG that leaks from sympathetic nerves.

Sympathetic nerves in abdominal organs, particularly the intestines and pancreas, account for nearly half the body's production of norepinephrine. Intestinal cells contain sulfatases that conjugate norepinephrine to norepinephrine-SO₄ that enters the portal vein and bypasses the liver to be excreted in the urine. Intestinal cells also conjugate normetanephrine to normetanephrine-SO₄.

![Figure 11-4: Metabolism of catecholamines by catechol-O-methyltransferase (COMT), monoamine oxidase (MAO), aldehyde dehydrogenase (AD), and phenol-sulfotransferase (PST). (1) Adrenal medulla or pheochromocytoma; (2) sympathetic nerves; (3) liver and kidneys; (4) GI, platelets, lungs.](image-url)
**Pheochromocytomas.** In pheochromocytomas, catecholamines that leak out of the neurosecretory vesicles are methylated by membrane-bound COMT: epinephrine to metanephrine and norepinephrine to normetanephrine. These metanephrine metabolites continuously leak directly into the circulation, in contrast to catecholamines that are secreted intermittently. The pheochromocytoma’s continuous excretion of metanephrines accounts for the superior sensitivity of plasma or urine-fractionated free metanephrine testing in the diagnosis of pheochromocytoma. In patients with pheochromocytoma, over 90% of circulating total metanephrines are derived from the tumor itself, rather than from peripheral metabolism.

**B. Circulating catecholamine uptake and metabolism** Following release into the circulation, catecholamines bind to albumin and other proteins with low affinity and high capacity. Catecholamines are quickly removed from the bloodstream and have a circulating half-life of less than 2 minutes. Although some free catecholamines are excreted directly into the urine, most are actively transported from the circulation into other cells where they are metabolized. Organic cation transporters (OCTs) are largely responsible for removing catecholamines from the circulation; they are expressed in many tissues, particularly the liver. Following active transport into a cell, catecholamines and their immediate metabolites undergo further metabolism. The main extra-adrenal/neuronal catecholamine metabolic pathway is initially via the enzyme MAO that converts both epinephrine and norepinephrine to DHPG. DHPG is further metabolized by soluble COMT to 3-methoxy-4-hydroxyphenylglycol (MHPG) that is excreted in the urine.

Catecholamines, metanephrines, and MHPG also undergo conjugation of their phenolic hydroxyl group with sulfate or glucuronide; this reaction occurs mainly in gastrointestinal cells. To a lesser extent, catecholamines are also converted to metanephrines via a soluble form of COMT, an enzyme found in most tissues, especially blood cells, liver, kidney, and vascular smooth muscle. The soluble form of COMT is less active than the membrane-bound form of COMT found in the adrenal medulla and pheochromocytomas.

Catecholamines, their metabolites, and conjugates are excreted in the urine. Normally, the proportions of urine catecholamines and metabolites are approximately 50% metanephrines, 35% VMA, 10% conjugated catecholamines and other metabolites, and less than 5% free catecholamines.

### Catecholamine (Adrenergic) Receptors (Tables 11–2 and 11–3; Figures 11–5 and 11–6)

The adrenergic receptors are G protein–coupled receptors activated by norepinephrine and epinephrine. They mediate the sympathetic *fight or flight* response. The finding that most cells in the body have adrenergic receptors has led to an appreciation of the important regulatory role of the peripheral sympathetic nervous system and circulating catecholamines.

Adrenergic receptors were originally classified into two groups: α and β. This classification has been expanded as subtypes of the α and β receptors have been discovered and includes α<sub>1A</sub>, α<sub>1B</sub>, α<sub>1C</sub>, α<sub>2A</sub>, α<sub>2B</sub>, α<sub>2C</sub> as well as β<sub>1</sub> and β<sub>2</sub> and β<sub>3</sub>. Each receptor subtype is encoded by a different gene. Adrenergic receptors are variably distributed in the central nervous system and peripheral tissues.

Norepinephrine and epinephrine are roughly equipotent in activating α and β<sub>1</sub> receptors. Epinephrine is much more potent in activating β<sub>2</sub> receptors and norepinephrine is more potent in activating β<sub>3</sub> receptors (Table 11–2). The physiologic effects mediated by them are summarized in Table 11–3.

Adrenergic receptors are transmembrane proteins with an extracellular amino terminus and an intracellular carboxyl terminus. Each of their seven hydrophobic regions spans the cell membrane. Although these regions of the adrenergic receptor subtypes exhibit significant amino acid homology, differences in the fifth and sixth segments determine the specificity of agonist binding. Differences in the fifth and seventh segments determine which of the guanyl nucleotide binding proteins (G proteins) is coupled to the receptor. G proteins consist of α, β, and γ subunits. When a hormone binds to the receptor, the β and γ subunits dissociate from the α subunits, allowing GDP to be replaced by GTP on the α subunits and causing the β and γ subunits to dissociate from it. The GTP-bound α subunits activate the postreceptor pathways (see Figure 11–5).

of the guanylyl nucleotide-binding protein, G₂q, is released and activates phospholipase C. This enzyme catalyzes the conversion of phosphatidylinositol phosphate to 1,4,5-inositol triphosphate (IP₃) and diacylglycerol. IP₃ releases calcium ion from intracellular stores to stimulate physiologic responses. Diacylglycerol activates protein kinase C, which in turn phosphorylates a series of other proteins that initiate or sustain effects stimulated by the release of IP₃ and calcium ion (see Figure 11-5). Prazosin and phenoxybenzamine are selective antagonists of the α₁ receptor.

Alpha₂ receptors are postsynaptic (target organ) receptors that mediate diverse effects, particularly arteriolar vasoconstriction. Hepatic α₂ receptors stimulate glycoanalysis and gluconeogenesis. In the eye, α₂ receptors stimulate contraction of the radial muscle of the iris that dilates the pupil. In the skin, α₂ receptors mediate apocrine sweating and pilomotor contraction. In the genitourinary tract, α₂ receptors mediate ejaculation, gravid uterine contraction, and contraction of the bladder sphincter and trigone. In the intestines, α₂ receptors reduce smooth muscle contraction and increase sphincter tone, thereby promoting constipation. Alpha, receptors are also found in the splenic capsule and mediate the contraction of the capsule (particularly during hypoxia), which contracts the splenic volume up to 20% and can expel up to 125 mL of packed red blood cells into the circulation within 3 seconds of apnea.

Sympathetic nerves secrete norepinephrine into synaptic junctions where the concentration of norepinephrine is high, thereby stimulating synaptic effector organ α₁ receptors. Epinephrine has a similar effect upon α₁ receptors but is secreted only by the adrenal medulla such that circulating concentrations are usually much lower than concentrations of synaptic norepinephrine. At low plasma concentrations, epinephrine predominantly stimulates β₂-adrenergic receptors (causing vasodilation, see later), whereas at higher plasma concentrations, epinephrine stimulates α₁ receptors sufficiently to override vasodilation and cause vasoconstriction.

Alpha₂ receptors are G₂q-coupled receptors with three highly homologous subtypes: α₂A, α₂B, and α₂C. Agonist binding to the α₂ receptor releases G₂q alpha, which inhibits the enzyme adenylyl cyclase and reduces the formation of cAMP (Figure 11-6).
Presynaptic (nerve) $\alpha_2$ receptors are located near the synapses of sympathetic nerves. Synaptic norepinephrine binds to this receptor, resulting in feedback inhibition of its own release. Alpha receptors are also found in vascular smooth muscle where they mediate vasoconstriction. Alpha$_2$ receptors in platelets stimulate platelet aggregation and clotting. In the brain, $\alpha_2$ receptors are found in the locus ceruleus, cerebral cortex, and limbic system. Although their location is postsynaptic, stimulation of the $\alpha_2$ receptors results in reduced release of norepinephrine. Clonidine is a central $\alpha_2$ agonist. Yohimbine is a selective antagonist for the $\alpha_2$ receptor. Phentolamine is an antagonist for both $\alpha_1$ and $\alpha_2$ receptors.

In the pancreatic beta cells, activation of $\alpha_2$ receptors inhibits insulin secretion. This causes glucose intolerance in patients with pheochromocytoma. The gene Adra2a encodes the adrenergic $\alpha_{2A}$ receptor. A polymorphism in Adra2a increases the number of $\alpha_{2A}$ receptors on beta cells, which reduces insulin secretion and increases the risk of type 2 diabetes mellitus.

**B. Beta-adrenergic receptors** Beta-adrenergic receptors are postsynaptic (target organ) cell surface glycoproteins. Agonist binding to $\beta$-adrenergic receptors activates adenyl cyclase via the $G_\alpha$ alpha subunit to increase the production of cAMP, which in turn converts protein kinase A to its active form. Kinase A then phosphorylates a variety of proteins, including enzymes, ion channels, and receptors (see Figure 11–6).

**Beta$_1$-adrenergic receptors** are located primarily in the heart, kidneys, and adipose tissue. In the heart, $\beta_1$ receptors are located in the SA and AV nodes, atrium, ventricle, and conduction system; activation of these receptors mediates an increase in heart rate and cardiac contraction with an overall increase in cardiac output. Stimulation of $\beta_1$ receptors in the ventricles also increases the firing of idioventricular pacemakers such that excessive stimulation predisposes to ventricular ectopy. Triiodothyronine ($T_3$) increases the total number of cardiac $\beta_1$ receptors; this may contribute to the forceful cardiac contraction and tachyarrhythmias that are characteristic of hyperthyroidism. Beta$_2$ receptors in the renal juxtaglomerular apparatus stimulate the release of renin that, in turn, activates the renin-angiotensin system. In fat cells, activation of $\beta_2$ receptors increases lipolysis. In nerve cells, activation of $\beta_2$ receptors increases cell conduction velocity. In the brain, $\beta_3$ receptors are found particularly in the nucleus accumbens and the ventral putamen (striatum).

**Beta$_3$-adrenergic receptors** are particularly activated by epinephrine. They are located mainly in the smooth muscles of arterioles, veins, and bronchi where they mediate relaxation. In the
heart, \(\beta_2\) receptors are located in the same locations as \(\beta_1\) receptors (see earlier) and likewise mediate increases in cardiac rate and contraction. \(\beta_2\) Receptors are also located in smaller coronary arteries where they mediate dilation of the coronaries, thereby increasing blood flow to cardiac muscle. Vascular \(\beta_2\) receptors mediate vasodilation of arterioles, particularly in skeletal muscle and the hepatic artery. Stimulation of venous \(\beta_2\) receptors mediates venous dilation. Stimulation of \(\beta_2\) receptors also causes relaxation of other smooth muscles, resulting in bronchial dilation and relaxation of the nonpregnant uterus. During exercise or hypoglycemia, epinephrine is secreted and activates hepatic \(\beta_2\) receptors. This stimulates glycogenolysis and gluconeogenesis for the increased glucose production that is needed for increased cardiac and skeletal muscle activity. \(\beta_1\) receptors in skeletal muscle promote increased contraction speed, glycogenolysis, and tremor. The net effect of \(\beta_2\) agonists (e.g., epinephrine) upon liver and skeletal muscle is to increase serum glucose. \(\beta_2\)-adrenergic receptors are also expressed in various areas of the brain, particularly the right hippocampus, which normally has a higher density of \(\beta_2\) receptors than the left hippocampus.

\(\beta_2\) receptor polymorphisms have been associated with obesity in women and differences in sensitivity to albuterol in asthmatics. Other \(\beta_3\) receptor polymorphisms appear to account for individual differences in the vascular response to stress and increased risk for development of hypertension-induced left ventricular hypertrophy.

\(\beta_3\)-adrenergic receptors are expressed mainly in adipose tissue but also in the gallbladder, colon, central nervous system, and heart. Activation of this receptor increases energy expenditure, lipolysis, and intestinal motility. \(\beta_1\) receptor activation promotes lipolysis in adipose tissue and increased thermogenesis in skeletal muscle. Although \(\beta_3\)-adrenergic receptors are found in the brains of infants, by adulthood their concentration decreases by 100-fold. Pima Indians, who are homozygous for inactivating mutations in the \(\beta_3\) gene, have an earlier onset of type 2 diabetes.

FIGURE 11-6 Activation of \(\beta_1\) and \(\alpha_2\)-adrenergic responses: activation vs inhibition of adenyl cyclase. Beta receptor ligands activate the stimulatory G protein, \(G_s\), which leads to the dissociation of its \(G_{s1}\) subunit, charged with GTP. The activated \(G_{s1}\) subunit directly activates adenyl cyclase, resulting in increased cAMP that binds to the regulatory subunit (R) of the cAMP-dependent protein kinase, leading to the liberation of active catalytic subunits (C) that phosphorylate specific enzyme substrates and modify their activity. These catalytic units also phosphorylate the cAMP response element–binding protein (CREB), which modifies gene expression. \(\alpha_2\)-adrenoreceptor ligands inhibit adenyl cyclase by causing dissociation of the inhibitory G protein (\(G_i\)) into its subunits; that is, the \(\alpha_i\) subunit charged with GTP and a \(\beta_i\gamma\) unit. The mechanism by which these subunits inhibit adenyl cyclase is uncertain. See Table 11-3 and text for physiologic effects of \(\beta_1\) and \(\alpha_2\) receptor activation.

(Reproduced, with permission, from Katzung BG, ed. Basic and Clinical Pharmacology. 11th ed. McGraw-Hill; 2009.)
C. Dopamine receptors Five different dopamine receptors have been identified (D1 to D5), each encoded by a different gene. Dopamine receptors are found throughout the brain (including the anterior pituitary), arteries, proximal renal tubules, and gastrointestinal tract. D1 and D2 receptors are the predominant subtypes.

D1-like family of receptors (D1 and D5) couples to G protein, Gi, that inhibits adenyl cyclase, thereby reducing intracellular cAMP (cAMP). D1 receptors mediate vasodilation in the coronary, renal, cerebrovascular, and mesenteric arteries. D1 receptors in the proximal renal tubule enhance natriuresis. The D1 receptor is the most abundant dopamine receptor in the brain. Intravenous therapeutic dopamine at low doses predominately stimulates D1 receptors, causing vasodilation. (However, high-dose therapeutic dopamine sufficiently occupies α and β receptors to cause vasocostriction and increase blood pressure.) The A48G polymorphism of the D1 receptor gene has been associated with essential hypertension, with the 48G allele being found more frequently in hypertensive patients, presumably through a negative effect on the proximal renal tubule’s excretion of sodium.

D2-like family of receptors (D2, D3, D4) couple to a different G protein, G protein, Gi, that inhibits adenyl cyclase, thereby reducing intracellular cAMP, opening potassium channels, and decreasing the influx of calcium. D2 receptors are predominately presynaptic receptors that are located on sympathetic nerves. Activation of D2 receptors inhibits the synaptic release of norepinephrine and also inhibits the transmission of nerve impulses at sympathetic ganglia. Pituitary lactotroph cells also express D2 receptors, whose activation inhibits the secretion of prolactin. Activation of other D2 receptors in the brain causes vomiting. D2 receptors are also found throughout the stomach, small intestines, and proximal colon, where the dopaminergic system is believed to work in a paracrine fashion.

Regulation of Sympathoadrenal Activity

The rate of catecholamine secretion largely determines sympathoadrenal activity. However, adrenergic receptors and post-receptor events are sites of fine regulation.

As noted earlier, norepinephrine and epinephrine released during nerve stimulation bind to presynaptic α2 receptors and reduce the amount of norepinephrine released. CGA is secreted from neurosecretory vesicles, along with catecholamines. Catestatin, a fragment of CGA, blocks postreceptor cells’ cholinergic receptors, thereby inhibiting sympathoadrenal activity.

The binding of a catecholamine agonist to its receptor reduces the number of receptors on the effector cell surface by a process called down regulation. Catecholamine receptor antagonists do not cause down regulation of receptor expression. The mechanisms involved in some of these changes are known. For example, phosphorylation of the β-adrenergic receptor by β-adrenergic receptor kinase results in sequestration of the receptors into membrane vesicles, where they are internalized and degraded. The phosphorylated receptor also has a greater affinity for β-arrestin, another regulatory protein, which prevents its interaction with G protein, Gi.

Thyroid hormone increases the number of β receptors in the myocardium. Estrogen, which increases the number of alpha receptors in the myometrium, also increases the affinity of some vascular alpha receptors for norepinephrine.

Actions of Circulating Catecholamines (Tables 11-3 and 11-4)

Norepinephrine activates α1-adrenergic receptors, increasing the influx of calcium into the target cell. Vascular α1-adrenergic receptors are found in the heart, papillary dilator muscles, and smooth muscle. Activation of α1-adrenergic receptors causes hypertension, increased cardiac contraction, and dilation of the pupils. Alpha1-adrenergic activation stimulates sweating from nonthermoregulatory apocrine stress sweat glands, which are located on the palms, axillae, and forehead. Norepinephrine also activates β1-adrenergic receptors that increase cardiac contraction and rate; stimulation of the heart rate is opposed by simultaneous vagal stimulation. Norepinephrine has less affinity for β1-adrenergic receptors. However, with higher circulating norepinephrine levels, hypermetabolism and hyperglycemia are noted. Norepinephrine also activates β2-adrenergic receptors on fat cells, causing lipolysis and an increase in serum levels of free fatty acids.

Epinephrine also stimulates α and β-adrenergic receptors, with the same effects noted above for norepinephrine. However, epinephrine also activates β2 receptors, causing vasodilation in skeletal muscles. Epinephrine thus has a variable effect on blood pressure ranging from hypertension to hypotension (rare). Hypoglycemia is a strong stimulus for the adrenal medulla to secrete epinephrine, which increases hepatic glycogenolysis. Epinephrine stimulates lipolysis, resulting in increased serum levels of free fatty acids. Epinephrine also increases the basal metabolic rate. Epinephrine does not cross the blood–brain barrier well. However, high serum levels of epinephrine do stimulate the hypothalamus, resulting in unpleasant sensations ranging from nervousness to an overwhelming sense of impending doom.
Dopamine is an important central neurotransmitter and a precursor to norepinephrine and epinephrine. However, most circulating dopamine is actually derived from the gastrointestinal tract from local synthesis and dietary sources. Dopamine that is synthesized by the intestines does not function as a neurotransmitter but rather as a paracrine hormone, affecting intestinal motility, blood flow, and sodium transport. Dopamine is also synthesized in the proximal renal tubule where it is a natriuretic hormone. Dopamine synthesis is increased by a high-salt diet. The renal dopamine-paracrine system accounts for the relatively large amounts of dopamine that are normally found in the urine. Circulating dopamine is not normally a significant catecholamine. High serum concentrations of dopamine stimulate vascular D₁ receptors, causing vasodilation and increased renal blood flow. Extremely high serum levels of dopamine are required to sufficiently activate vascular α₁ receptors to cause vasoconstriction.

**Physiologic Effects of Catecholamines**

**A. Cardiovascular effects**  The release or injection of catecholamines generally increases heart rate and cardiac output and causes peripheral vasoconstriction, leading to an increase in blood pressure. The infusion of catecholamines also leads to a rapid reduction in plasma volume. These events are modulated by reflex mechanisms, so that, as the blood pressure increases, reflex vagal parasympathetic stimulation may slow the heart rate and tend to reduce cardiac output. Although norepinephrine usually has these effects, the effect of epinephrine may vary depending on the smooth muscle tone of the vascular system at the time. For example, in an individual with increased vascular tone, the net effect of small amounts of epinephrine may be to reduce the mean blood pressure through vasodilation, despite an increase in heart rate and cardiac output. In an individual with a reduction in vascular tone, epinephrine increases blood pressure. In addition cardiovascular function is integrated by the central nervous system, so that, under appropriate circumstances, one vascular bed may be dilated while others remain unchanged. The central organization of the sympathetic nervous system is such that its basal regulatory effects are quite discrete—in contrast to periods of stress, when stimulation may be rather generalized and accompanied by release of catecholamines into the circulation.

**B. Effects on extravascular smooth muscle**  Catecholamines have effects on smooth muscle in tissues other than blood vessels. These effects include constriction (α₁) and relaxation (β₂) of uterine myometrium, relaxation of intestinal and bladder smooth muscle (β₂), contraction of the smooth muscle in the bladder (α₁) and intestinal sphincters, relaxation of tracheal smooth muscle (β₂), and pupillary dilation (α₂).

**C. Metabolic effects**  Catecholamines increase oxygen consumption and heat production. This effect is mediated by β₁ receptors. Catecholamines also regulate glucose and fat mobilization from storage depots. Glycogenolysis in heart muscle and liver leads to an increase in available carbohydrate for utilization. Stimulation of adipose tissue leads to lipolysis and the release of free fatty acids and glycerol into the circulation. In humans, these effects are mediated by the β₁ receptor. Both α₁ and β₁ receptors stimulate hepatic glycogenolysis and gluconeogenesis, which causes the release of glucose into the circulation. Both receptors are activated by epinephrine, which is particularly effective in raising hepatic glucose production. Plasma levels of catecholamines required to produce some cardiovascular and metabolic effects in humans are shown in Table 11–5.

Catecholamines have effects on water, sodium, potassium, calcium, and phosphate excretion in the kidney. Stimulation of the β₁ receptor increases the secretion of renin from the renal juxtaglomerular apparatus, thereby activating the renin-angiotensin system. This leads to stimulation of aldosterone secretion.

### DISORDERS OF THE ADRENAL MEDULLA AND PARAGANGLIA

#### EPINEPHRINE AND NOREPINEPHRINE DEFICIENCY

Epinephrine is the major catecholamine secreted by the normal adrenal medulla, and its secretion is unique to the adrenal medulla. Epinephrine is usually deficient in cortisol deficiency of any cause, because high local concentrations of cortisol in the adrenal medulla are necessary for transcription of the enzyme PNMT, which catalyzes the conversion of norepinephrine to epinephrine in the catecholamine biosynthetic pathway. Primary autoimmune adrenal cortical insufficiency produces epinephrine deficiency. Hypothalamic/pituitary ACTH deficiency also causes cortisol deficiency and consequently epinephrine deficiency.

### Autonomic Insufficiency (Table 11–5 and Figure 11–6)

Autonomic insufficiency is also known as dysautonomia. It refers to a general reduction in autonomic activity. Since the adrenal medulla is part of the autonomic nervous system, there is usually an associated deficiency in circulating epinephrine. Autonomic

Reduced hypoglycemia (Figure 11-7), but in patients with diabetes E L- E L- . Familial dysautonomia can manifest as orthostatic tachycardia; adjustments occur that maintain blood pressure and ensure one cause of this condition. The causes of disorders associated with autonomic insufficiency are listed in Table 11-5.

When a normal individual stands, a series of physiologic adjustments occur that maintain blood pressure and ensure adequate circulation to the brain. The initial lowering of the blood pressure stimulates the baroreceptors, which then activate central reflex mechanisms that cause arterial and venous constriction, increase cardiac output, and activate the release of renin and vasopressin. Interruption of afferent, central, or efferent components of this autonomic reflex results in autonomic insufficiency.

Patients with generalized autonomic insufficiency usually have orthostatic hypotension; the reduction in blood pressure on standing that causes visual disturbances, lightheadedness, and even syncope. Symptoms tend to be worse upon awakening, after meals, in hot weather, and at high altitude. Many patients have supine hypertension, even when not taking hypertensive medication. Affected patients often have a fixed heart rate, sinus tachycardia, diminished sweating, reduced metabolic rate, heat intolerance, nocturia, and erectile dysfunction. Angina pectoris can sometimes occur in the absence of coronary atherosclerosis. Patients frequently have a neurogenic bladder with associated symptoms of frequency, nocturia, hesitancy, reduced urine stream, and recurrent urinary tract infections. Patients may also have gastroparesis and disordered gastrointestinal motility. Sleep apnea is common and death can occur during sleep from reduced respiratory drive.

The diagnosis of autonomic insufficiency can usually be made clinically in patients with typical symptoms and orthostatic blood pressure changes on examination. Additionally, plasma and urine norepinephrine levels are usually very low, sometimes only 10% of average normal in severely affected individuals. Plasma epinephrine levels are often low as well.

The treatment of symptomatic orthostatic hypotension is dependent on maintenance of an adequate blood volume. Physical measures should be employed, such as raising the foot of the bed at night, crossing the legs when sitting, and wearing full-leg fitted support stockings. Adequate hydration is important. Volume expansion with fludrocortisone is the most effective drug treatment. However, fludrocortisone can cause hypokalemia, supine hypertension, and edema. Midodrine is an a1-receptor agonist that must be administered every 8 hours, due to its short half-life of 3 to 4 hours. Midodrine’s use is limited by common side effects that include severe supine hypertension, bradycardia, and erythema multiforme. Therefore, midodrine should only be used for patients with very symptomatic orthostatic hypotension who have failed other therapies. Octreotide has been used, either alone or in combination with midodrine, for patients with severe autonomic failure where other treatment measures have failed.

**PHEOCHROMOCYTOMA AND PARAGANGLIOMA**

Both pheochromocytoma and non–head-neck paraganglioma are tumors of the sympathetic nervous system. Although they are similar tumors, they warrant distinction from each other to emphasize their differences in the following: (1) locations, (2) manifestations, (3) secretion profiles, (4) genetic syndromes, (5) difficulty of surgical resection, and (6) propensity to metastasize.
Pheochromocytomas are tumors that arise from the adrenal medulla, whereas non-head-neck paragangliomas arise from the ganglia of the sympathetic nervous system. Pheochromocytomas are more common (85%), and may be bilateral (17%). Patients with adrenal pheochromocytomas are less likely to develop detectable metastases (11%) compared to paragangliomas (30%).

**Incidence**

The yearly incidence of diagnosed pheochromocytoma/paraganglioma tumors is about 2 to 8 per million; nearly half of these present as an unexplained death. The National Cancer Registry in Sweden has reported that pheochromocytomas/paragangliomas are discovered in about 2 patients per million people yearly. However, autopsy series suggest a higher incidence. The reported incidence in autopsy series has varied from about 250 cases per million to 1300 cases per million in a Mayo Clinic autopsy series. Retrospectively, 61% of pheochromocytoma/paraganglioma tumors at autopsy occurred in patients who were known to have had hypertension; about 91% had the nonspecific symptoms associated with secretory pheochromocytoma/paraganglioma tumors. In one autopsy study, a large number of patients with these tumors had nonclassic symptoms such as abdominal pain, vomiting, dyspnea, heart failure, hypotension, or sudden death (Table 11–6). Considering these autopsy data, it is clear that the majority of pheochromocytoma/paraganglioma tumors are not diagnosed during life. Tumors occur in both sexes and at any age but are most commonly diagnosed in the fourth and fifth decades.

**Pheochromocytomas** are chromaffin tumors that arise from the adrenal medulla. They account for 90% of all pheochromocytoma/paraganglioma tumors in adults and 70% in children. Adrenal pheochromocytomas are usually unilateral (90%). Unilateral pheochromocytomas occur more frequently in the right (65%) versus the left adrenal (35%). Right-sided pheochromocytomas have been described as producing paroxysmal hypertension more often than sustained hypertension, whereas the opposite was true for tumors arising from the left adrenal. Adrenal pheochromocytomas are bilateral in about 10% of adults and 35% of children. Bilateral pheochromocytomas are particularly common (24% overall) in patients with familial pheochromocytoma syndromes caused by certain germline mutations (see later).

Basically, the adrenal medulla is a sympathetic ganglia whose neurons secrete neurotransmitters (epinephrine and norepinephrine) into capillaries instead of synapses. The adrenal medulla is surrounded by the adrenal cortex, with which it shares a portal system that bathes it in high concentrations of cortisol. Cortisol stimulates expression of the gene encoding PNMT, the enzyme that catalyzes the conversion of norepinephrine to epinephrine. Adrenal pheochromocytomas nearly always secrete catecholamines with variable amounts of epinephrine as well as norepinephrine and their metabolites. Metastases from adrenal pheochromocytomas usually secrete only norepinephrine and its metabolite normetanephrine; they may rarely secrete epinephrine.

Pheochromocytomas are typically encapsulated by a true capsule or a pseudocapsule, the latter being the adrenal capsule. Pheochromocytomas are firm in texture. Hemorrhages that occur within a pheochromocytoma can give the tumor a mottled or dark red appearance. A few black pheochromocytomas have been described, with the dark pigmentation believed to be due to an accumulation of neuromelanin, a catecholamine metabolite. Larger tumors frequently contain large areas of hemorrhagic necrosis that have undergone cystic degeneration; viable tumor may be found in the cyst wall. Calcifications are often present. Pheochromocytomas can invade adjacent organs, and tumors may extend into the adrenal vein and the vena cava, resulting in pulmonary tumor emboli. Pheochromocytomas vary tremendously in size, ranging from microscopic to 3600 g. The average pheochromocytoma weighs about 100 g and is 4.5 cm in diameter.

**Non–head-neck paragangliomas** arise from sympathetic ganglia (Figure 11–8). They account for about 10% of all pheochromocytoma/paraganglioma tumors in adults and about 30% in

children. About 75% are intra-abdominal where they are often mistaken for adrenal pheochromocytomas. Paragangliomas are sometimes nonsecretory and may be confused with other neuroendocrine tumors. They arise most commonly in the perinephric, periaortic, and bladder regions but often found in the chest (25%), arising in the anterior or posterior mediastinum or the heart. Pelvic paragangliomas may involve the bladder wall, obstruct the ureters, and metastasize to regional lymph nodes. About 36% to 60% of paragangliomas are functional, secreting norepinephrine and normetanephrine. Functional status is not known to affect survival. Nonfunctional paragangliomas can often concentrate metaiodobenzylguanidine (MIBG) or secrete CgA. Paragangliomas of the bladder can cause symptoms associated with micturition. Large perinephric tumors can cause renal artery stenosis and elevations in plasma renin activity. Vaginal tumors may cause dysfunctional vaginal bleeding. Paragangliomas can rarely arise in central nervous system locations, including the sella turcica, petrous ridge, and pineal region. Cauda equina paragangliomas can cause increased intracranial pressure.

Paragangliomas commonly metastasize (30%-50%) and present with pain or a mass. They tend to metastasize to the liver, lungs, lymph nodes, and bone. PGLs can be locally invasive and may destroy adjacent vertebrae and cause spinal cord and nerve root compression. PGL metastases usually secrete norepinephrine and normetanephrine. They do not secrete epinephrine and therefore do not typically cause significant weight loss, hyperglycemia, anxiety, or tremor.

Nonchromaffin parasympathetic paragangliomas are typically found in the head and neck. Unlike chromaffin sympathetic paragangliomas, only about 5% of these tumors secrete catecholamines. Carotid body tumors are paragangliomas that arise near the carotid bifurcation. They usually present as a painless neck mass, but can injure the vagus or hypoglossal nerves. Glomus tympanicum paragangliomas arise in the middle ear and cause tinnitus and hearing loss. The tumor may be seen as a reddish mass behind an intact tympanic membrane (red drum) that blanches when pressure is applied with a pneumatic ear speculum (Brown sign). Glomus jugulare paragangliomas arise in the jugular foramen. They often cause tinnitus and hearing loss as well as compression of cranial nerves, resulting in dysphagia. Vagal paragangliomas are rare, usually presenting as a painless neck mass often associated with hoarseness or dysphagia. Head-neck paragangliomas can also arise in the larynx, nasal cavity, nasal sinuses, and thyroid gland. Head-neck PGLs themselves are of more interest to otolaryngologists than endocrinologists. But they may be seen along with sympathetic paragangliomas in familial paraganglioma syndromes, particularly those with germline succinate dehydrogenase subunit D (SDHD) mutations (see later).

Nonchromaffin paragangliomas behave differently from sympathetic paragangliomas and pheochromocytomas, although they are embryologically related to chromaffin sympathetic paragangliomas and may arise concurrently with sympathetic paragangliomas in familial paraganglioma syndromes. These tumors are less likely to be malignant, although their indolence can be deceiving; recurrence and metastases may not appear for many years. Metastases to local nodes, lungs, and bone can occur. Long-term surveillance for recurrence or metastases is recommended for all patients. These tumors can produce CgA, and preoperative determination of CgA is recommended to determine if it will be a good serum marker for tumor recurrence. Patients with cervical paragangliomas often have an underlying germline mutation in the gene encoding succinate dehydrogenase (SDH); SDHD, SDHC, and SDHB gene sequencing is recommended for all these patients (see later). Individuals harboring a germline mutation must be screened for the existence of other paragangliomas and pheochromocytomas (see "Genetic Conditions Associated with Pheochromocytomas and Paragangliomas," later).

Neuroblastomas, ganglioneuroblastomas, and ganglioneuromas are sympathetic nervous system tumors that are related to pheochromocytomas and likewise arise from embryonal sympathetic paragangliomas, usually occurring in infancy or early childhood. They arise from sympathetic tissue in the adrenal gland, neck, posterior mediastinum, retroperitoneum, or pelvis. These tumors differ in their degree of maturation and malignancy. Neuroblastoma tumors derive from immature neuroblasts, are generally aggressive, tend to occur in very young children, and display clinical heterogeneity. The prognosis for neuroblastoma depends on age at diagnosis, with infants under age 1 year having a high likelihood of cure with surgical excision. Similarly, children with a localized neuroblastoma may be cured surgically. Some tumors can regress spontaneously or differentiate into benign ganglioneuromas. However, older children with widespread hematogenous metastases have a very poor prognosis, as do those whose neuroblastoma harbors an amplification of the MYC proto-oncogene. Some neuroblastomas are more indolent, depending on the nature of their oncogene mutations.

Ganglioneuroblastomas are composed of a mixture of neuroblasts and more mature gangliocytes; these develop in older children and tend to run a more benign course. Ganglioneuromas are the most benign of these tumors and are composed of gangliocytes and mature stromal cells.

Despite catecholamine secretion, children with neuroblastomas tend to be more symptomatic from their primary tumor or metastases than from catecholamine secretion. Tumors tend to concentrate radiolabeled MIBG, making it a useful imaging and therapeutic agent. Treatment of malignant tumors consists of surgery, chemotherapy, external beam radiation to skeletal metastases, and high-dose 131I-MIBG therapy for patients with MIBG-avid tumors.

### Screening for Pheochromocytomas and Paragangliomas

Hypertension, defined as either a systolic or diastolic blood pressure over 140/90 mm Hg, is an extremely common condition, affecting about 20% of all American adults and over 50% of adults over 60 years of age. The incidence of pheochromocytoma is estimated to be less than 0.1% of the entire hypertensive population, but it is higher in certain subgroups whose hypertension is

Genetic Conditions Associated with Pheochromocytomas and Paragangliomas (Tables 11–8 through 11–11)

Most pheochromocytomas occur sporadically, although a substantial proportion of these tumors are found to have developed a somatic mutation similar to those germline mutations that give rise to familial syndromes. Based on family history, it was formerly thought that only about 10% of patients with these tumors developed it as part of a genetic syndrome. With genetic testing, it is now clear that about 26% of patients with pheochromocytomas or paragangliomas carry a germline mutation associated with a familial syndrome. About 19% of patients with an apparently sporadic single pheochromocytoma and no known family history of pheochromocytoma harbor a germline mutation. For example, about 9% of patients with a pheochromocytoma or paraganglioma have von Hippel-Lindau (VHL) mutations. Genetic testing is advisable for all patients with a pheochromocytoma or paraganglioma. Genetic testing is strongly recommended for patients with extra-adrenal paragangliomas or multifocal tumors; onset of symptoms before age 45 years; prior history of head-neck paraganglioma; family history of paraganglioma, pheochromocytoma, or other tumors associated with MEN 2 or VHL. Genetic screening is also performed for patients with other manifestations of genetic syndromes noted later. Genetic screening can be done for MEN 2 RET proto-oncogene mutations, VHL mutations, and SDH (SDHB, SDHD, and SDHC) gene mutations. Neurofibromatosis is usually diagnosed clinically without genetic testing, since the NF-1 gene is very large.

A. Multiple endocrine neoplasia type 2: RET proto-oncogene (10q11.2)

The first description of a pheochromocytoma was in a patient with MEN 2. In 1882, Felix Fränkel described pheochromocytomas in an 18-year-old woman with bilateral adrenal tumors; genetic testing of four living relatives has revealed a germline RET mutation. The prevalence of MEN 2 has been estimated at 1 in 30,000. MEN 2 is an autosomal dominant disorder that causes a predisposition to medullary thyroid carcinoma, pheochromocytoma, and other abnormalities described later. MEN 2 is caused by an activating mutation in the RET proto-oncogene on chromosome 10q11.2. RET consists of 21 exons that encode a transmembrane receptor tyrosine kinase that is expressed in neural crest tissues. The constitutive activation of RET causes hyperplasia in affected tissues, including the adrenal medulla. Additional mutation(s) are believed to be required for a pheochromocytoma to develop. The somatic loss of a tumor suppressor gene on chromosome 1p appears to be necessary for pheochromocytoma formation. Additionally, reduced expression of NF-1 has been reported in a minority of pheochromocytomas arising in patients with MEN 2 mutations.

TABLE 11–8 Surveillance protocol for individuals carrying a RET protooncogene mutation.

Twice yearly: physical examination with blood pressure and neck examination; plasma free metanephrine; serum calcium and albumin (serum PTH if RET codon 634 mutation); serum calcitonin (patients with intact thyroid or with medullary thyroid carcinoma); Prophylactic thyroidectomy: by age 5 years for MEN 2A and by 6 months for codon 918 mutations (MEN 2B); Yearly thyroid ultrasound for patients with an intact thyroid; For rising or elevated serum calcitonin levels after thyroidectomy; close surveillance for medullary thyroid carcinoma is required.¹⁸FDG-PET-CT fusion scans are particularly helpful; For suspicious symptoms and before major surgical procedures and pregnancy: biochemical screening for pheochromocytoma with plasma free metanephrine; For abnormal biochemical screening for pheochromocytoma: MRI or CT scan of the abdomen (nonionic contrast) with thin-section adrenal cuts;¹²³I-MIBG SPECT or¹⁸F-FDA PET scan to confirm the identity of small masses.
MEN 2 kindreds can be grouped into two distinct subtypes: MEN 2A (90%) and MEN 2B (10%). Patients with MEN 2A have various single amino acid missense mutations affecting the extracellular \textit{RET} domain that cause \textit{RET} homodimerization and constitutive activation of its tyrosine kinase. Patients with MEN 2B have a particular missense mutation (codon 918, exon 16) affecting the intracellular domain at the \textit{RET} tyrosine kinase's catalytic site, causing constitutive activation. In either subtype, pheochromocytomas usually develop in the adrenals (96%); extra-adrenal paragangliomas are rare (4%). About 42% of patients with pheochromocytoma in MEN 2 have hypertension, usually paroxysmal. Overall, only about 53% exhibit symptoms of pheochromocytoma. Each specific type of mutation in the \textit{RET} codon determines each kindred's idiosyncrasies, such as the age at onset and the aggressiveness of medullary thyroid carcinoma.

A limited number of \textit{RET} gene exons have been found to harbor mutations that are capable of causing constitutive activation of the tyrosine kinase. \textit{RET} exons 10, 11, 13, 14, 15, and 16 are usually involved. Therefore, routine genetic screening searches for mutations only in these exons. If no mutation is found in these exons, the remaining 15 exons can be sequenced in a research laboratory. When an affected kindred's \textit{RET} mutation is already known, an individual in the kindred is screened for that specific mutation.

Pheochromocytomas arise in the adrenals, and extra-adrenal paragangliomas are rare in MEN 2. In patients with MEN 2, only about 4% of pheochromocytomas are found to be metastatic, possibly because of earlier detection. When pheochromocytomas develop in patients with MEN 2, they are bilateral in about two-thirds of cases; however, with close surveillance of affected kindreds, pheochromocytomas are discovered earlier and are more likely to be unilateral. After a unilateral adrenalectomy for pheochromocytoma in a patient with MEN 2, a contralateral pheochromocytoma develops in about 50% of patients an average of 12 years after the first adrenalectomy. In patients with MEN 2, adrenal pheochromocytomas produce norepinephrine and epinephrine (with its metabolite metanephrine). When screening for small pheochromocytomas, plasma catecholamine concentrations may be normal but plasma metanephrine concentrations are usually elevated, making plasma free metanephrines the screening test of choice for these patients. However, some pheochromocytomas are detected only by a 24-hour urine determination for fractionated metanephrines, catecholamines, and creatinine.

1. MEN 2A (Sipple syndrome)—Patients with this genetic condition develop medullary thyroid carcinoma (95%-100%), hyperparathyroidism due to multiglandular hyperplasia (35%), and pheochromocytoma (50%; range 6%-100% depending on the kindred) or adrenal medullary hyperplasia. Patients with MEN 2A also have an increased incidence of cutaneous lichen amyloidosis and Hirschsprung disease. Pheochromocytomas tend to present in middle age, often without hypertension. The incidence of hyperparathyroidism has also varied, averaging 35%.

Individuals belonging to an MEN 2A kindred should have genetic testing for \textit{RET} proto-oncogene mutations by 5 years of age to determine if they carry the genetic mutation that will require prophylactic thyroidectomy and close surveillance for pheochromocytoma and hyperparathyroidism.

More than 85% of the mutations in MEN 2A families affect codon 634 in exon 11 of the \textit{RET} proto-oncogene. Individuals with mutations in \textit{RET} codon 630 also have a high incidence of pheochromocytoma. Pheochromocytomas also occur in most other kindreds with MEN 2A. Screening for pheochromocytoma should commence with the routine blood pressure measurements that are performed during examinations in childhood for medullary thyroid carcinoma and follow-up of hypothyroidism following thyroidectomy. At about age 15 years, affected individuals should commence yearly screening for pheochromocytoma with plasma free metanephrine determinations.

Certain \textit{RET} mutations (codons 609, 768, val804met, and 891) rarely produce pheochromocytomas. Less intense screening for pheochromocytomas is required in patients with these mutations.

2. MEN 2B—Over 90% of patients with MEN 2B have a single amino acid substitution of methionine to threonine on codon 918 in exon 16 that affects the intracellular domain of tyrosine kinase. About 50% of such mutations are familial while the rest arise de novo and are sporadic. Patients with this genetic condition are prone to develop mucosal neuromas, pheochromocytoma, adrenal medullary hyperplasia, and aggressive medullary thyroid carcinoma. About 50% of affected patients develop all three manifestations of the syndrome. Mucosal neuromas tend to develop first and occur in most patients. They appear as small bumps on the tongue, lips and buccal mucosa, eyelids, cornea, and conjunctivae. The lips and eyelids may become diffusely thickened. Intestinal ganglioneuromatosis occurs and alters intestinal motility, causing diarrhea or constipation and occasionally megacolon. Affected individuals have a marfanoid habitus with associated spinal scoliosis or kyphosis, pectus excavatum, a high-arched foot and talipes equino varus (club foot) deformities. In patients with MEN 2B, medullary thyroid carcinoma tends to be aggressive and occurs at an earlier age than in patients with MEN 2A. Members of kindred with MEN 2B should immediately have genetic testing for their family's \textit{RET} proto-oncogene mutation. If an individual is found to carry the family's \textit{RET} mutation, early prophylactic thyroidectomy is advisable. In kindreds with MEN 2B, infants are screened for the mutation at birth. For affected infants, prophylactic thyroidectomy is performed by 6 months of age. All individuals carrying a \textit{RET} proto-oncogene mutation must have close medical surveillance (see Table 11–8). See Chapter 22: Multiple Endocrine Neoplasia.

B. Von Hippel-Lindau disease: \textit{VHL} gene (3p25-26) VHL disease is inherited as an autosomal dominant trait that predisposes its carriers to develop tumors in multiple tissues. Although certain VHL kindreds are predisposed to develop pheochromocytomas, it is not the dominant tumor of this syndrome. Pheochromocytomas develop only in patients with type 2 VHL (see later), and these are different from sporadic pheochromocytomas in that they are less likely to be malignant, more likely to be bilateral, and more likely to present at an earlier age. Although most VHL-associated pheochromocytomas arise in the adrenal, extra-adrenal paragangliomas sometimes arise; these usually occur...
along the sympathetic chain, but head-neck parasympathetic paragangliomas have been described. The mean age of presentation for a pheochromocytoma in type 2 VHL is 28 years; the youngest reported patient was 5 years old.

The different types and subtypes of VHL are as follows:

1. **Type 1 VHL**—Affected members of families with type 1 VHL do not develop pheochromocytomas. They tend to have loss-of-function *VHL* gene mutations, particularly gene deletions, frameshifts, or truncations.

2. **Type 2 VHL**—Affected members of families with type 2 VHL mutations are prone to develop pheochromocytomas. These patients carry VHL missense mutations. Type 2 VHL may be divided into subtypes as follows:
   a. **Type 2A VHL**—Pheochromocytomas, hemangioblastomas, low risk of renal cell carcinoma.
   b. **Type 2B VHL**—Pheochromocytomas, hemangioblastomas, high risk of renal cell carcinoma.
   c. **Type 2C VHL**—Pheochromocytomas, no hemangioblastomas, no renal cell carcinomas.

The prevalence of VHL is about 1 in 30,000 persons. VHL disease carriers are predisposed to multicentric hemangioblastomas in the retina (retinal angiomas), cerebellum, and spinal cord. Renal cysts and renal clear-cell carcinoma commonly develop.

Multiple cysts and nonfunctional neuroendocrine tumors may develop in the pancreas. Endolympathic sac tumors may occur, resulting in hearing loss, vertigo, or ataxia. Adrenal cystadenomas of probable mesonephric origin (APMO) are found in many women with VHL. APMOs may develop in the ovary, broad ligament, vagina, uterine cervix, and vulva. Equivalent epididymal cystadenomas occur in men with VHL.

Genetic testing for VHL disease should be done in children born to a parent with known VHL disease. If VHL disease is suspected, but the family's VHL mutation is not known, the patient must be screened for point mutations by direct *VHL* gene sequencing of the entire coding region and splice junctions.

The clinical diagnosis of VHL disease is made when a patient with a known VHL gene mutation develops one tumor typical of VHL. In patients without a known family history of VHL, a presumptive diagnosis of VHL is made when they develop two or more hemangioblastomas or a hemangioblastoma in association with a pheochromocytoma or clear-cell renal carcinoma. Similarly, VHL disease should be suspected in patients with multiple VHL-associated tumors or one VHL-associated tumor that presents at a young age (<50 years for pheochromocytoma or hemangioblastoma; <30 years for clear-cell renal carcinoma). Such patients should have VHL gene sequencing.

The *VHL* gene is a tumor suppressor gene whose locus is 3p25/26. It encodes two different proteins (pVHL) of 213 and 160 amino acids. Both gene products have a role in the degradation of the hypoxia-inducible factors (HIF-1α and HIF-2α) as follows: The pVHL proteins have an α domain that binds with the protein elongin. The β domain of pVHL is open to bind HIF that has been hydroxylated, a reaction that requires oxygen. This complex then binds ubiquitin that targets HIF for intracellular destruction by proteases. In this manner, well-oxygenated cells destroy HIF. Conversely, cells that are either oxygen-deprived or that lack functional pVHL cause an intracellular accumulation of HIF. HIF is a transcription factor that induces the production of vascular endothelial growth factor (VEGF), erythropoietin, erythropoietin receptor, glucose transporter-1, and platelet-derived growth factor-B; these proteins allow an adaptation to hypoxia, but, in excess, they are believed to enhance tumorigenesis.

For a tumor to develop in a patient harboring a VHL germline mutation, an additional somatic mutation must develop in the patient's remaining wild-type VHL allele. This second-hit mutation must occur in a cell in susceptible somatic tissue (eg, vascular tissue) in order for the cell to grow into a VHL-associated tumor.

In patients with VHL disease, vascular tumors, particularly hemangioblastomas, renal cysts, and renal cell carcinomas, develop when there is a somatic second-hit on the wild-type allele in one cell; this can be caused by various spontaneous mutations (loss of heterozygosity) or promoter hypermethylation of the wild-type VHL allele. In these vascular tumors, a second-hit is usually necessary to cause sufficient accumulation of HIF to promote tumorigenesis. In contrast, pheochromocytomas that develop in patients with type 2 VHL typically have a normal wild-type VHL allele. However, most VHL-associated pheochromocytomas also demonstrate a somatic loss of chromosome 3 (94%) or chromosome 11 (86%).

A germline mutation in the VHL tumor suppressor gene has been identified in most families with VHL disease. About 60% of affected families have loss-of-function mutations (30% with truncated pVHL and 30% with large VHL gene deletions), resulting in type 1 VHL. About 40% have missense mutations, resulting in an amino acid substitution in pVHL, causing type 2 VHL.

In a French series of 36 patients with pheochromocytomas and VHL disease, pheochromocytomas were the presenting tumor in 53%. Pheochromocytomas tended to develop at an early age and were bilateral in 42%; concurrent paragangliomas were present in 11%. Three of the 36 patients had a malignant pheochromocytoma. In 18% of these patients with VHL disease, pheochromocytoma was the only known manifestation. Approximately 9% of patients with apparently sporadic, unilateral pheochromocytoma have been found to harbor a germline VHL mutation. In certain regions of Europe, the percentage is up to 20%, due to a founder effect for the Tyr98His back forest mutation that is more common in kindreds with German ancestry.

Phaeochromocytomas in VHL disease produce exclusively noradrenaline. Therefore, the metabolite of noradrenaline (normetanephrine) is also produced in these tumors. Plasma normetanephrine levels are usually elevated when patients with VHL disease develop a pheochromocytoma. Therefore, it is advisable for patients with a type 2 VHL gene missense mutation to be screened regularly with plasma normetanephrine levels.

In patients with VHL, a major risk to life is the development of a renal cell carcinoma. When an abdominal computed tomography (CT) scan detects a solid renal lesion, it must be removed. Even simple cystic renal lesions are considered premalignant, and their removal is advisable if renal function can be preserved. If renal cysts are observed, they must be followed every 6 months with dynamic thin-section CT scanning to search for characteristics of malignancy: growth, wall irregularity, or septation. Individuals carrying
TABLE 11-9  Surveillance protocol for individuals carrying a type 2 VHL mutation.

| Yearly: retinal examination; plasma free normetanephrine levels yearly from age 10 to 15 years |
| Twice yearly: physical examination with blood pressure beginning at age 5 years; plasma free normetanephrine levels beginning at age 15 years |
| Every 2 years: MRI scanning (with intravenous contrast) of the entire brain and spinal cord (VHL types 2A and 2B VHL); MRI scanning of the abdomen |
| For suspicious symptoms and before major surgical procedures and pregnancy: biochemical screening for pheochromocytoma with plasma free metanephrine |
| For abnormal biochemical screening: MRI or CT scan of the abdomen (nonionic contrast) with thin-section adrenal cuts; 
  123I-MIBG SPECT or 18F-FDA PET scan to confirm the identity of small masses |

C. Von Recklinghausen (type 1) neurofibromatosis: NF-1 gene (17q11.2) Pheochromocytomas are ultimately diagnosed in 0.1–5.7% of patients with von Recklinghausen neurofibromatosis type 1 (NF-1). Most of these pheochromocytomas are not diagnosed during life, since the autopsy incidence of pheochromocytoma in NF-1 patients is 3.3% to 13%. Pheochromocytomas that develop in patients with NF-1 are similar to sporadic pheochromocytomas: 84% have solitary adrenal tumors, 10% have bilateral adrenal tumors, 6% have extra-adrenal paragangiomas, and 12% have metastases or local invasion.

Pheochromocytomas are present in 20% to 50% of NF-1 patients with hypertension, and all NF-1 patients with hypertension must be screened for pheochromocytoma. It is prudent to screen all patients with NF-1 for pheochromocytoma yearly, with interval testing if hypertension or symptoms develop that are suggestive of pheochromocytoma (headache, perspiration, palpitations). Similarly, all patients with NF-1 should be screened for pheochromocytoma before major surgical procedures and pregnancy.

In patients with NF-1, pheochromocytomas can present anytime during life, from infancy to old age, with a mean age of 42 years at diagnosis. These pheochromocytomas can grow to large size. Although patients with pheochromocytomas may develop hypertension, many patients are surprisingly asymptomatic despite increased catecholamine secretion. Patients with NF-1 are prone to develop vascular anomalies such as coarctation of the aorta and renal artery dysplasia, which can produce hypertension and mimic a pheochromocytoma.

Von Recklinghausen disease is caused by a mutation in the NF-1 tumor suppressor gene mapped to chromosome 17q11.2. The NF-1 gene encodes a 2818 amino acid protein called neurofibromin, which inhibits Ras oncogene activity; loss of neurofibromin leads to Ras activation and tumor formation. It is a common autosomal dominant genetic disorder (although 50% of cases seem sporadic), with an approximate incidence of 300 to 400 cases per million population. Although genetic testing for NF-1 is available, the diagnosis is usually made clinically during childhood or adolescence.

Patients with NF-1 can present in childhood with optic gliomas that impair vision or in adolescence with plexiform neurofibromas. Patients develop visible subcutaneous neurofibromas and schwannomas of cranial and vertebral nerve roots. Skeletal abnormalities are common. Hypothalamic hamartomas may occur and cause precocious puberty. Iris hamartomas may occur and are known as Lisch nodules. NF-1 patients have an increased risk of developing other tumors, especially malignant peripheral nerve sheath tumors and leukemia (particularly juvenile chronic myelogenous leukemia). Patients may also have freckles in their axillae and skin folds. Multiple cutaneous pigmented café au lait spots develop and grow in size and number with age; most patients ultimately develop more than six spots (smooth bordered) measuring more than 1.5 cm in diameter. Individuals carrying an NF-1 mutation must have close medical surveillance. A surveillance protocol is recommended in Table 11-10.

D. Familial paragangioma/pheochromocytoma syndromes: succinate dehydrogenase gene mutations Certain kindreds have a proclivity to develop multicentric head-neck paragangliomas, sympathetic paragangliomas, and adrenal pheochromocytomas. These autosomal dominant syndromes were originally called familial paraganglioma syndromes, although some patients develop adrenal pheochromocytomas. The paraganglioma syndromes are caused by mutations in three of the four genes encoding mitochondrial complex II: SDH subunit B (SDHB, PGL 4), SDH subunit C (SDHC, PGL 3), and SDH subunit D (SDHD, PGL 1). (Note that PGL 2 is not caused by an SDH mutation.) SDHB encodes a catalytic subunit, while SDHD and SDHC encode membrane-anchoring subunits involved in electron transport. SDHC and SDHD (paternal) have an autosomal dominant proclivity to develop paragangliomas; those with SDHB and SDHD mutations can also develop adrenal pheochromocytomas. Individuals with SDHD mutations develop paragangliomas only if the mutated gene is inherited from the father (see later). Overall, about 12% of patients with paragangliomas and

TABLE 11-10  Surveillance protocol for individuals carrying a NF-1 gene mutation.

| Twice yearly: physical and neurologic examination and blood pressure, and a careful examination of the skin for development or growth of neurofibromas |
| Yearly: CBC with WBC differential; plasma-fractionated free metanephrines; complete eye examination with visual fields |
| Before major surgical procedures and pregnancy: plasma-fractionated free metanephrines to screen for pheochromocytoma |
| For abnormal biochemical screening: MRI or CT scan of the abdomen (nonionic contrast); 123I-MIBG SPECT or 18F-FDA PET scan |
pheochromocytomas have been found to have germline SDH gene mutations.

Head-neck paragangliomas occur with an incidence of 10 to 33 cases per million persons. In one series of 34 patients with head-neck paragangliomas, 41% were found to have SDH germline mutations. Of those patients with germline mutations, 79% had SDHD mutations, and 21% had SDHB mutations.

These syndromes are caused by mutations in nuclear genes that encode three of the four subunits that comprise mitochondrial complex II (SDH) that oxidizes succinate to fumarate (Krebs cycle). The four subunits of the tetracemic SDH consist of a 70-kDa flavoprotein (SDHA), a 30-kDa iron-sulfur protein (SDHB), a 15-kDa subunit of cytochrome b (SDHC), and a 12-kDa subunit of cytochrome b (SDHD). SDHC and SDHD components of cytochrome b are integral mitochondrial membrane subunits anchoring the catalytic subunits SDHA and SDHB that are involved with the electron transport chain, transferring an electron to coenzyme Q (ubiquinone). SDH is essential for aerobic energy production and the tricarboxylic acid cycle. Genetic defects cause mitochondrial dysfunction making the cells functionally hypoxic. This leads to increased secretion of VEGF that is necessary for tumor growth. (SDHA germline mutations do not cause paragangliomas but rather cause Leigh syndrome, a fatal early-onset mitochondrial neurodegenerative disease.)

All patients with paragangliomas and pheochromocytomas ideally should be tested for germline mutations in SDH; such testing is highly recommended for patients with neck paragangliomas (>15% have germline mutations), other paragangliomas (particularly multifocal paragangliomas or pheochromocytomas), a family history of paraganglioma or pheochromocytoma, and paragangliomas arising in patients with Dutch ancestry.

Carney-Stratakis syndrome: Some patients with loss-of-function mutations in SDHB, SDHC, or SDHD can develop the dyad of paragangliomas and gastric stromal sarcomas, which is known as Carney-Stratakis syndrome. Tumors present relatively early, with an average age of 24 years at diagnosis. Women and men are affected equally. The paragangliomas that develop in this syndrome are usually functional and develop in the abdomen, rather than head-neck region. In this syndrome, the condition is familial and affected kindreds do not develop pulmonary chondromas, factors that distinguish it from Carney triad.

1. **SDHB gene mutations**—The SDHB gene has been mapped to chromosome 1p36. This has also been described as familial paraganglioma syndrome type 4 or PGL 4. Affected individuals are prone to develop paragangliomas all along the sympathetic chains, from the neck to the pelvis, and can develop pheochromocytomas as well; they are less prone to glomus tumors of the neck than individuals with SDHD mutations. Paragangliomas that arise in patients with SDHB germline mutations are much more likely to be metastatic (35%) at the time of diagnosis than tumors seen in patients with SDHD germline mutations. In one kindred with a large SDHB exon 1 deletion, the phenotypic penetrance of paraganglioma was 35% by age 40. There have been no clear genotype-phenotype correlations with different SDHB mutations. However, certain kindreds have a distinctly higher penetrance. Also, some point SDHB mutations may be relatively benign genetic polymorphisms rather than pathological mutations. Due to the rarity of these tumors, the precise penetrance for each SDHB mutation has not been fully determined. Other malignancies may possibly be more common in patients with SDHB mutations. In one series of 53 patients, renal cell carcinoma was detected in two patients. Pediatric neuroblastoma has been described in a child with an SDHB exon deletion.

2. **SDHC gene mutations**—The SDHC gene has been mapped to chromosome 11q2. Affected individuals are prone to develop parasympathetic head-neck paragangliomas, but not pheochromocytomas. This is the least common SDH mutation. About 4% of patients with head-neck paragangliomas harbor an SDHC germline mutation.

3. **SDHD gene mutations**—The SDHD gene has been mapped to chromosome 11q23. Only patients with paternally inherited SDHD gene mutations are predisposed to develop paragangliomas and pheochromocytomas. Affected individuals are particularly prone to develop parasympathetic head-neck paragangliomas that do not typically secrete catecholamines. About 15% of patients with head-neck paragangliomas harbor this germline mutation.

In kindreds with SDHD gene mutations, only paternal transmission of the mutated gene causes the susceptibility to paragangliomas and pheochromocytomas; this phenomenon is known as maternal genomic imprinting, meaning that the maternally inherited mutant gene does not cause the syndrome in the mother’s offspring. A male who inherits an SDHD mutation from his mother does not express the phenotype (ie, no paragangliomas) but can pass on the gene to his children, who can express the phenotype (paragangliomas). A female who inherits an SDHD mutation from her father develops paragangliomas, but her children who inherit the SDHD mutation are not affected.

**Head-neck paragangliomas**: Individuals with SDHD germline mutations are particularly prone to develop head-neck paragangliomas that arise from parasympathetic ganglia that are embryologically related to sympathetic paraganglia. These tumors do not usually secrete catecholamines and are known as nonchromaffin paragangliomas. Carotid body tumors are also known as chemodectomas and arise near the carotid bifurcation. They usually present as a painless neck mass but can injure the vagus or hypoglossal nerves. Glomus tympanicum paragangliomas arise in the middle ear and cause tinnitus and hearing loss. The tumor may be seen as a reddish mass behind an intact tympanic membrane. Glomus jugulare paragangliomas arise in the jugular foramen that often causes tinnitus and hearing loss as well as compression of cranial nerves, resulting in dysphagia. Vagal paragangliomas are rare, usually presenting as a painless mass in the neck that may cause hoarseness or dysphagia. Head-neck paragangliomas can also arise in the larynx, nasal cavity, nasal sinuses, and thyroid gland. Multicentric tumors have been reported in about 74% of paraganglioma patients with SDHD mutations. About 50% of patients with seemingly isolated pheochromocytomas and a germline SDHD mutation harbor a hidden paraganglioma. Sympathetic paragangliomas and adrenal pheochromocytomas (8%) also occur in affected individuals. A founder SDHD mutation has been noted in families of Italian descent: Q109X. Three SDHD founder mutations have
been discovered in families of Dutch ancestry: Lcn975Pro, Asp92Tyr, and Asp92Tyr. An investigation of 243 family members with a paternally inherited Asp92Tyr mutation in SDHD reported the following. The risk of developing a paraganglioma or pheochromocytoma was 54% by age 40 years, 68% by 60 years, and 87% by 70 years. Most patients had head-neck paragangliomas, while some had sympathetic paragangliomas and 8% had pheochromocytomas. Multiple tumors were found in 65%.

Malignancy appears to be uncommon in patients with SDHD-associated paragangliomas. However, cervical paragangliomas can be indolent, and metastases to neck nodes, lungs, and bones may not be clinically evident for many years. Therefore, lifelong surveillance is necessary (Table 12-11).

### E. Other genetic syndromes associated with pheochromocytoma or paraganglioma

1. **Carney triad**—Multicentric paragangliomas occur in patients with Carney triad. While this is not a familial syndrome, it is believed to be genetic in origin. The underlying genetic defect is not known. Affected individuals can develop indolent gastric leiomyosarcomas, pulmonary chondromas, and paragangliomas (or adrenal pheochromocytomas). Only one-third of reported cases have had all three tumors, while most patients have had two of the three tumors, usually gastric sarcomas and pulmonary chondromas. Other tumors can develop in this syndrome, including adenocortical adenomas (12%) and esophageal leiomyomas. Women account for 86% of the cases. Tumors tend to develop early in life, with an average age of 21 years at diagnosis.

2. **Beckwith-Wiedemann syndrome**—Pheochromocytomas have been reported in patients with Beckwith-Wiedemann syndrome and may be bilateral. Affected individuals also have other abnormalities, particularly neonatal hypoglycemia, omphalocele, umbilical hernia, macroglossia, and gigantism, and they are prone to develop malignancies.

3. **Prolyl hydroxylase domain 2 (PHD2) gene mutations**—PHD proteins regulate HIF. Germline mutations in PHD2 cause congenital erythrocytosis. An additional mutation of the wild-type PHD2 allele in paraganglia can give rise to a sympathetic paraganglioma. This gene mutation is different from VHL gene mutations, although both gene mutations cause an increase in HIF as a probable mechanism for paraganglioma tumor production.

4. **KIF1B gene mutations**—KIF1B is a gene that is believed to be a proapoptotic factor for sympathetic cell precursors. The gene is located on 1p36, where gene deletions have been noted in neural crest tumors. Mutations in KIF1B have been associated with pheochromocytomas, paragangliomas, and neuroblastomas, as well as other tumors that are not of neural crest origin. These tumors are transcriptionally related to NF-1 and RET tumors.

5. **Familial paraganglioma syndrome type 2**—One known kindred has a familial paraganglioma syndrome that has been labeled PGL2, but which is not due to an SDH mutation. This kindred harbors a mutation in the succinate dehydrogenase assembly factor 2 (SDHAF2) gene at 11q13.1.

### Physiology of Pheochromocytoma and Paraganglioma

Pheochromocytomas are tumors that arise from the adrenal medulla, whereas paragangliomas arise from sympathetic nerve ganglia. Although some pheochromocytomas do not secrete catecholamines, most synthesize catecholamines at increased rates that may be up to 27 times the synthetic rate of the normal adrenal medulla (Figure 11-9). The persistent hypersecretion of catecholamines by most pheochromocytomas is probably due to lack of feedback inhibition at the level of tyrosine hydroxylase. Catecholamines are produced in quantities that greatly exceed the vesicular storage capacity and accumulate in the cytoplasm. Catecholamines that are in the cytoplasm are subject to intracellular metabolism to metanephrines; excess catecholamines and their metabolites diffuse out of the pheochromocytoma cell into the circulation.

In contrast to the normal adrenal medulla, most adrenal pheochromocytomas produce more norepinephrine than epinephrine, while many produce both hormones. Some pheochromocytomas produce epinephrine almost exclusively. Most paragangliomas produce mostly norepinephrine with some dopamine and no epinephrine. Paragangliomas that produce large amounts of dopamine tend to be metastatic. Some paragangliomas secrete no catecholamines or metanephrines.

Serum levels of catecholamines correlate only modestly with tumor size. On average, large tumors secrete more catecholamines than smaller tumors. However, large tumors are much more variable in their secretion of tumor markers. This may be due to the fact that larger tumors tend to develop hemorrhagic necrosis and cysts that are not functional. Additionally, about 20% of large, malignant paragangliomas are less differentiated and are nonsecretory.

Severe hypertensive episodes occur in most patients with pheochromocytomas. Exocytosis of catecholamines from the pheochromocytoma can play a role in such paroxysms, but most pheochromocytomas have minor sympathetic innervation. Instead, hypertensive crises are often caused by spontaneous hemorrhages within the tumor or by pressure on the tumor causing the release of blood from venous sinusoids that are rich in catecholamines.
Thus, catecholamines can be released by physical stimuli such as bending or twisting or by micturition in patients with bladder paragangliomas. Of course, surgical manipulation of such tumors releases catecholamines and can cause life-threatening hypertensive crises.

Chronically high circulating levels of catecholamines may cause normal sympathetic axons to become saturated with catecholamines due to active catecholamine neuronal uptake. This may account for the paroxysms of hypertension that are triggered by pain, emotional upset, intubation, anesthesia, or surgical skin incisions. Adrenergic catecholamine saturation may also explain the elevations in plasma and urine catecholamines that can occur for 10 days or longer after a successful surgical resection of a pheochromocytoma.

**TABLE 11–12** Other proteins and peptides that may be secreted by pheochromocytomas, in addition to catecholamines and metanephrines.

| Adrenocorticotropic hormone | Adrenomedullin | Atrial natriuretic factor | Beta-endorphin | Calbindin | Calcitonin | Cholecystokinin | Chromogranin A | Cytokines | Enkephalins | Erythropoietin | Galanin | Gonadotropin-releasing hormone | Growth hormone | Interleukin-6 | Motilin | Neuron-specific enolase | Neuropeptide Y | Neurotensin | Parathyroid hormone-related peptide | Peptide histidine-isoleucine | Renin | Serotonin | Somatostatin | Substance P | Vasoactive intestinal polypeptide |
|-----------------------------|----------------|--------------------------|---------------|-----------|------------|----------------|-----------------|------------|-------------|----------------|---------|-----------------------------|----------------|----------------|--------|-------------------------|---------------|----------------|--------------------------|-----------------------------|-------|-----------|-----------|-------------|-----------|-------------------------|

Although pheochromocytomas secrete mainly catecholamines and their metabolites, they also secrete many other peptide hormones, many of which contribute to a patient's clinical symptoms. Secretion of parathyroid hormone–related peptide (PTHrP) can cause hypercalcemia. Ectopic ACTH production can cause Cushing syndrome. Erythropoietin secretion can cause erythrocytosis. Leukocytosis is frequently seen in patients with pheochromocytoma, probably caused by cytokine release from the tumor.

**Secretion of Other Peptides by Pheochromocytomas and Paragangliomas (Table 11–12)**

Although pheochromocytomas secrete mainly catecholamines and their metabolites, they also secrete many other peptide hormones, many of which contribute to a patient's clinical symptoms. Secretion of parathyroid hormone–related peptide (PTHrP) can cause hypercalcemia. Ectopic ACTH production can cause Cushing syndrome. Erythropoietin secretion can cause erythrocytosis. Leukocytosis is frequently seen in patients with pheochromocytoma, probably caused by cytokine release from the tumor.
Interleukin-6 secretion can cause fevers and acute respiratory distress syndrome (ARDS).

**Chromogranin A (CgA):** Chromogranins are acidic single-chain glycoproteins that are found in neurosecretory granules. They have been categorized into three classes: chromogranins A (CgA), CgB (secretogranin I), and CgC (secretogranin II). In humans, the gene for CgA is on chromosome 14 and encodes a molecule with 431 to 445 amino acids. CgA molecules aggregate with low pH or high calcium concentrations and promote the formation of secretory vesicles and the concentration of hormones within these vesicles.

CgA also acts as a prohormone. It is cleaved by endopeptidases into smaller peptides. CgA is the prohormone for the amino terminal fragments vasostatin I (CgA 1–76) and vasostatin II (CgA 1–115), which appear to inhibit vasoinhibition. CgA is also the prohormone for cestatin (CgA 352–372), which blocks acetylcholine receptors and thus inhibits adrenosympathetic activity.

Most pheochromocytomas secrete CgA, and serum CgA levels may be assayed as a tumor marker for pheochromocytoma. However, CgA is not unique to the adrenal medulla. It is produced in neuroendocrine cells outside the adrenal medulla that secrete peptide hormones. CgA is found in the pituitary gland, parathyroid gland, central nervous system, and pancreatic islet cells.

**Neuropeptide Y (NPY):** Many pheochromocytomas secrete significant amounts of NPY. The molecule is a 36 amino acid peptide (see primary sequence later) that is found in neurosecretory granules and is secreted along with catecholamines. It is a very potent nonadrenergic vasocostricr that contributes to hypertension in some patients with pheochromocytoma.

\[
\text{NPY: } \text{Tyr-Pro-Ser-Lys-Pro-Asp-Asn-Pro-Gly-Glu-Asp-Ala-Asp-Met-Ala-Arg-Tyr-Tyr-Ser-Ala-LeuArg-His-Tyr-Ile-Asn-Leu-Ile-Thr-Arg-Gln-Arg-Tyr-NH}_2
\]

NPY acts on G protein–coupled receptors, which belong to the pancreatic polypeptide family of cell-surface receptors called peptide YY (PYY). Six subtypes of these receptors have been identified (Y1R–Y6R). NPY has particular affinity for the Y1R, Y2R, Y3R, and Y5R receptors. Some PYY receptors are found in vascular smooth muscle and mediate NPY-induced vasoconstriction. Other PYY receptors are found on the pheochromocytomas themselves and mediate NPY’s autocrine effects: NPY appears to inhibit catecholamine synthesis via Y2R, a receptor which blocks L-type Ca²⁺ channels. It inhibits catecholamine release via Y1R, a receptor which blocks N-type Ca²⁺ channels.

NPY also has paracrine effects, stimulating endothelial cell proliferation and angiogenesis that may foster tumor growth. Patients with essential hypertension have normal levels of NPY. However, in a series of eight patients with pheochromocytomas, NPY levels were elevated 2- to 465-fold above the normal reference range. In another series, 59% of adrenal pheochromocytomas were found to secrete NPY during surgical resection; high serum levels of NPY were observed to correlate with vascular resistance, independent of norepinephrine. NPY appears to contribute to hypertension and left ventricular hypertrophy in most patients with pheochromocytoma. In contrast, few paragangliomas secrete NPY.

**Adrenomedullin (AM):** It was originally isolated from a pheochromocytoma, thus its misleading name. Although AM is produced by the adrenal medulla, it is also produced in the adrenal cortex (zona glomerulosa). It is produced by so many other tissues that the adrenal gland is actually a minor source for circulating AM.

AM is a 52 amino acid peptide cleavage product of a prohormone, preproadrenomedullin, encoded on chromosome 11. AM has some homology with calcitonin gene–related peptide (CGRP), and exerts its effects as a ligand for CGRP1 receptors and specific AM receptors. Ligand binding to the G protein–coupled receptors causes adenylate cyclase activation and an elevation of cellular cAMP levels.

AM is a pluripotent hormone. In the adrenal, AM appears to suppress aldosterone secretion. It is also secreted by the heart, lung, kidney, and brain as well as vascular endothelium, where it causes vasodilation. AM is also a natriuretic peptide and is secreted by the heart in congestive heart failure. AM is expressed in pheochromocytomas and a variety of other tumors, where it appears to stimulate tumor growth, reduce apoptosis, and suppress the immune response to the tumor.

**Neuron-specific enolase (NSE):** It is a neuroendocrine glycolytic enzyme. Serum levels of NSE have been reported to be normal in patients with benign pheochromocytoma but are elevated in about half of patients with malignant pheochromocytomas. Therefore, an elevated serum level of NSE increases the likelihood that a given pheochromocytoma is malignant.

### Manifestations of Pheochromocytoma and Paraganglioma (Table 11–13)

More than one-third of pheochromocytomas cause death prior to diagnosis. Death usually results from a fatal cardiac arrhythmia, myocardial infarction, or stroke. Adult patients with a pheochromocytoma usually have paroxysmal symptoms, which may last minutes or hours; symptoms usually begin abruptly and subside slowly. The particular constellation of symptoms varies considerably among patients. One cause for the differences in symptoms is the variable production of epinephrine and norepinephrine by these tumors. Pheochromocytomas that produce epinephrine tend to cause paroxysmal β-adrenergic manifestations, particularly anxiety, tremor, diaphoresis, tachycardia, palpitations, and hyperglycemia. Epinephrine and cytokine secretion can cause pulmonary edema and ARDS. Paragangliomas do not secrete epinephrine but most secrete norepinephrine that causes hypertension. Paragangliomas are more likely to metastasize.

Manifestations and their approximate incidence include hypertension (90%), headaches (80%), diaphoresis (70%), and palpitations or tachycardia (60%). Other common symptoms include episodic anxiety (60%), tremor (40%), abdominal or chest pain (35%), pallor (30%), and nausea or vomiting (30%). Hyperglycemia occurs in about 30% but is usually asymptomatic; diabetic ketoacidosis has been reported but is very rare. Patients may also experience fever (28%), fatigue (25%), flushing (18%), and dyspnea (15%).
Change in bowel habits occurs frequently with either constipation (13%) or diarrhea (6%). Visual changes occur in 12% with either transient blurring or field loss during attacks; metastases to the orbit or skull base may directly impinge on the optic nerve. See Table 11–13.

Triggers for paroxysms: Episodic paroxysms may not recur for months or may recur many times daily. Each patient tends to have a different pattern of symptoms, with the frequency or severity of episodes usually increasing over time. Attacks can occur spontaneously or may occur with bladder catheterization, anesthesia, and surgery. Acute attacks may also be triggered by eating foods containing tyramine (the precursor to catecholamines): aged cheeses, meats, fish, beer, wine, chocolate, or bananas. Hypertensive crises can also be triggered by certain drugs: ionic radiocontrast media, MAO inhibitors, tricyclic antidepressants, sympathomimetics, decongestants, glucagon, chemotherapy, prednisone, ACTH, opiates, methyldopa, metoclopramide, nicotine, and cocaine. Phenothiazines have been reported to cause shock and pulmonary edema in patients with pheochromocytoma.

Paroxysms can be induced by seemingly benign activities such as bending, rolling over in bed, exertion, abdominal palpation, or micturition (with bladder paragangliomas). There is an amazing individual variability in the manifestations of pheochromocytomas. Most patients have dramatic symptoms, but other patients with incidentally discovered secretory pheochromocytomas are completely asymptomatic. Patients who develop pheochromocytomas as part of MEN 2 or VHL disease are especially prone to be normotensive and asymptomatic.

**Blood pressure:** Hypertensive crisis is the quintessential manifestation of pheochromocytoma. Blood pressure that exceeds 200/120 mm Hg is an immediate threat to life, being associated with encephalopathy or stroke, cardiac ischemia or infarction, pulmonary edema, aortic dissection, rhabdomyolysis, lactic acidosis, and renal insufficiency.

**Definition of hypertension:** In adults, hypertension is considered to be present when blood pressure exceeds 140 mm Hg systolic or 90 mm Hg diastolic. In children, blood pressure increases with age, such that maximal normal ranges are age dependent; hypertension is considered to be present when blood pressure measurements exceed the following: younger than 6 months, 110/60 mm Hg; 3 years, 112/80 mm Hg; 5 years, 115/84 mm Hg; 10 years, 130/90 mm Hg; and 15 years, 138/90 mm Hg.

**Presentation of hypertension:** Hypertension is present in 90% of patients in whom a pheochromocytoma is diagnosed. Hypertension occurs primarily from the secretion of norepinephrine. Epinephrine secretion variably increases blood pressure. Also, pheochromocytomas

</table>
often secrete neuropeptide Y that is a potent vasoconstrictor. Some tumors may grow so large that they impinge upon the renal artery, causing increased renin production and secondary renovascular hypertension. Blood pressure patterns vary among patients with pheochromocytomas. Adults most commonly have sustained but variable hypertension, with severe hypertension during symptomatic episodes. Paroxysms of severe hypertension occur in about 50% of adults and in about 8% of children with pheochromocytoma. Other patients may be completely normotensive, may be normotensive between paroxysms, or may have stable sustained hypertension.

Hypertension can be mild or severe and resistant to treatment. Severe hypertension may be noted during induction of anesthesia for unrelated surgeries. Although hypertension usually accompanies pheochromocytomas and may be elicited by the above activities, this is not always the case.

Orthostasis: Patients with sustained hypertension frequently exhibit orthostatic changes in blood pressure, often with orthostatic tachycardia. Patients may complain of orthostatic faintness. Blood pressure may drop, even to hypotensive levels, after the patient arises from a supine position and stands for 3 minutes; such orthostasis, especially when accompanied by a rise in heart rate, is suggestive of pheochromocytoma. Epinephrine secretion from a pheochromocytoma may cause episodic hypotension and even syncope.

Hypotension and shock: Although hypertension is usually the key symptom in pheochromocytoma patients, hypotension and shock can occur. Some pheochromocytomas produce purely epinephrine that can produce mild hypertension from alpha stimulation but can also produce hypotension from predominantly beta-stimulated vasodilation. After a especially intense and prolonged attack of hypertension, shock may ultimately occur. This may be due to loss of vascular tone, low plasma volume, arhythmias, or cardiac damage. Spontaneous necrosis within a pheochromocytoma can lead to severe hypotension when norepinephrine levels suddenly drop. Similarly, surgical resection of a pheochromocytoma often precipitates sudden and severe intraoperative hypotension, particularly in the presence of alpha blockade and other antihypertensives. Cardiogenic shock can occur as a result of cardiac ischemia or infarction as well as catecholamine cardiomyopathy. (See "Cardiac Manifestations," later.)

Peripheral vasospasm and gangrene: Vasoconstriction is responsible for the pallor and mottled cyanosis that can occur with paroxysms of hypertension. Raynaud phenomenon can occur. Peripheral pulses may become thready or even nonpalpable during paroxysms. Catheters inserted into the radial artery and connected to continuous blood pressure monitoring transducers can give misleadingly low-pressure readings during paroxysms of vasospasm, a condition known as pseudoshock. Prolonged severe peripheral vasospasm has rarely caused gangrene of the skin, fingers, or toes. Reflex vasodilation usually follows an attack and can cause facial flushing.

Multisystem crisis: Massive release of catecholamines can occur spontaneously during tumor necrosis or can be triggered by any of the factors noted earlier. This can cause multisystem crisis that can be the presenting manifestation of pheochromocytoma, with hypertension or hypotension, high fever, encephalopathy, renal failure, ARDS, and death. Multisystem crisis resembles septic shock, so the diagnosis of pheochromocytoma may be missed entirely.

Cardiac manifestations: The heart is affected in most patients with pheochromocytoma, either directly from excessive catecholamines or indirectly from hypertension. Palpitation is one of the most frequent complaints.

Dysrhythmias: Tachycardia or dysrhythmias occur in about 60% of patients with pheochromocytoma. Patients may note palpitations, described variably as episodes of excessive heart pounding at rest or a fluttering sensation, during which they may become lightheaded. Supraventricular tachycardia is common, particularly in patients with epinephrine-secreting pheochromocytomas. The heart rate will often increase when standing. There can be an initial tachycardia during a paroxysm, followed by a reflex bradycardia. Atrial fibrillation may occur. Other dysrhythmias described with pheochromocytoma include nodal tachycardia, torsades de pointes, sick sinus syndrome, and Wolff-Parkinson-White (WPW) syndrome. Atrioventricular dissociation can occur and right bundle branch block has been reported. Ventricular tachycardia or ventricular fibrillation can occur suddenly and is a common cause of death.

Acute coronary syndrome (ACS): During a paroxysm, severe coronary vasospasm can cause myocardial ischemia or infarction, even in the absence of coronary atherosclerosis. This typically occurs simultaneously with increased myocardial oxygen demand caused by catecholamine-induced increases in heart rate and contractility. Patients may experience crushing chest pain or pressure with referred pain, usually to the jaw or the left shoulder or arm. Acute heart failure may occur along with severe hypotension or shock.

It can be difficult to distinguish ACS due to coronary stenosis/thrombosis from ACS due to a pheochromocytoma. Changes in the electrocardiogram and serum levels of troponin and creatine kinase-MB (CK-MB) are the same for both conditions. Patients with coronary disease can have tachycardia, cardiomyopathy, hypertension, dysrhythmias, diaphoresis, anxiety, and increased plasma catecholamine levels. However, patients with pheochromocytoma usually do not have critical coronary artery stenosis on coronary angiogram and usually have severe hypertension, headache, and other paroxysmal symptoms.

Cardiomyopathy: Left ventricular hypertrophy and hypertensive cardiomyopathy can occur in patients with chronic hypertension from pheochromocytoma. High levels of catecholamines can also directly cause myocarditis and a dilated cardiomyopathy. This is known as catecholamine cardiomyopathy. Takotsubo cardiomyopathy is the term used to describe asymmetric cardiac contractility with apical and midventricular akinesis or dyskinesis with hyperkinesis at the base. Other patterns of cardiac hypokinesis can occur. Most patients with catecholamine cardiomyopathy develop pulmonary edema and die. However, full recovery from cardiomyopathy may occur after treatment and surgical resection of a pheochromocytoma. In some patients, myocardial scarring and fibrosis lead to irreversible cardiomyopathy and heart failure. Fatal Takotsubo cardiomyopathy has been reported after dobutamine stress echocardiography.
There can be multiple causes of cardiomyopathy in patients with pheochromocytoma: hypertensive, ischemic, and catecholamine. The underlying pathophysiology of catecholamine cardiomyopathy appears to involve high levels of intracellular calcium in cardiac myocytes. Postmortem histopathology typically reveals intracardiac hemorrhages, edema, and concentrations of lymphocytes and leukocytes in cardiac muscle with areas of myocardial fibrosis.

Cardiac paragangliomas: These are rare tumors that arise at the base of the heart near the trunks of the aortic and pulmonary arteries and may be asymptomatic or cause hypertension and palpitations. They typically involve the left atrium or interatrial groove and often protrude into the atrium, resembling an atrial myxoma. Cardiac paragangliomas often have an invasive intramural component, making tumor resection difficult.

Diaphoresis and fever: During a paroxysm, sweating usually occurs initially from apocrine glands, affecting the palms, axillae, head, and shoulders. Reflex thermoregulatory eccrine sweating occurs later in an attack, dissipating the heat that was acquired during the prolonged vasoconstriction that occurred during the paroxysm. This can cause drenching sweats, usually as a paroxysm subsides. Patients with pheochromocytoma commonly develop fevers that may be mild or severe, even as high as 41°C. Up to 70% of patients have unexplained low-grade elevations in temperature of 0.5°C or more. Such fevers have been attributed to the secretion of interleukin-6 and respond to NSAID therapy.

Gastrointestinal manifestations: Many patients with pheochromocytoma exhibit gastrointestinal symptoms such as abdominal pain, nausea, and vomiting. Most patients lose some weight, even if appetite is preserved. More severe weight loss (>10% of basal weight) occurs in about 15% of patients overall and in 41% of those with sustained and prolonged hypertension. Abdominal pain may be due to splanchic vasoconstriction (intestinal angina) and prolonged vasoospasm can cause ischemic enterocolitis. Vasoospasm can rarely cause ischemic gangrene of the bowel. Pain may also be caused by the growth of a large intra-abdominal tumor. Intestinal motility disorders are also common. Catecholamines relax gastrointestinal smooth muscle while increasing contraction of the pyloric and ileocecal sphincters. Constipation is common, and abdominal distention and even toxic megacolon can occur. Other abdominal emergencies can be seen with pheochromocytoma, including the rupture of an aortic aneurysm, acute cholecystitis, and acute pancreatitis.

Neurologic manifestations: Headache is a common manifestation during an acute paroxysm. Patients frequently complain of paresthesia, numbness, or dizziness. Affected patients have an increase risk of experiencing a cerebrovascular accident (CVA) or transient ischemic attack (TIA). Hemiplegia can occur, sometimes with homonymous hemianopsia, and may be transient or permanent. Although most CVAs are ischemic in origin, hemorrhagic stroke can also occur during hypertensive paroxysms. Rupture of the internal carotid artery into the cavernous sinus can occur, causing a third nerve palsy. Some patients develop confusion or even psychosis during paroxysms. Paresthesias can occur.

Pulmonary manifestations: Patients may complain of dyspnea during a paroxysm. Patients with catecholamine cardiomyopathy may also present with dyspnea. Some patients develop ARDS, which can develop acutely or over several days. This is a life-threatening condition but may be self-limited during an attack. Isolated adrenal pheochromocytomas can produce ARDS. Patients with large hepatic metastases may be more prone to develop this complication. It may be mistaken for pneumonia, pulmonary edema, pulmonary emboli, or congestive heart failure. It is hypothesized that ARDS is caused by interleukin-6 produced by the tumor. Congestive heart failure may also cause pulmonary edema and can be distinguished from ARDS by echocardiogram.

Renal manifestations: Some degree of renal insufficiency is common in patients with pheochromocytoma. Hypertensive nephrosclerosis occurs in patients with a long history of severe hypertension. Nephrotic syndrome may occur with significant proteinuria, possibly due to secretion of interleukin-6 by the tumor. Malignant nephrosclerosis can occur with severe hypertension damaging renal arterioles, resulting in rapidly progressive renal failure. Large pheochromocytomas and perirenal paragangliomas can impinge upon the renal artery, causing increased renin production and a Goldblatt kidney, resulting in renovascular hypertension that is additive to norepinephrine-induced hypertension. The tumor may directly invade the renal vein and extend into the inferior vena cava, causing pulmonary emboli and an increased risk of lower extremity deep vein thrombosis. Severe hypertensive paroxysms can cause muscle ischemic damage and rhabdomyolysis with release of myoglobin that causes myoglobinuric renal failure. Acute tubular necrosis can occur after a severe hypertensive episode.

Ectopic hormone production: Pheochromocytomas can rarely produce ACTH that stimulates the adrenal cortex to produce excessive cortisol, resulting in Cushing syndrome. Tumors can also produce VIP that can cause watery diarrhea, hypokalemia, and achlorhydria, the WHDA (Verner-Morrison) syndrome. Some tumors produce PTHrP that causes hypercalcemia. Although pheochromocytomas can secrete renin directly, elevated plasma renin levels are usually derived from the juxtaglomerular apparatus, whose β₁ receptors are stimulated by both epinephrine and norepinephrine.

Manifestations in children: The symptoms of pheochromocytomas in children are different from those in adults. Over 80% of children exhibit hypertension that is usually sustained and less frequently (10%) paroxysmal. Children are more prone to diaphoresis and visual changes. Children are more likely to have paroxysms of nausea, vomiting, and headache, which often occur after exertion. They are also prone to weight loss, polydipsia, polyuria, and convulsions. Affected children may also exhibit reddish-blue mottled skin along with edematous and cyanotic-appearing hands, a symptom rarely seen in adults. Children are more likely to have multiple tumors and extra-adrenal paragangliomas. In one series, 39% of affected children had bilateral adrenal pheochromocytomas, an adrenal pheochromocytoma plus a paraganglioma, or multiple paragangliomas; a single paraganglioma occurred in an additional 14% of children. Affected children often have genetic conditions associated with pheochromocytomas and paragon-
Adrenergic desensitization is caused by adrenergic receptors.

**Manifestations in women:** There are sex differences in pheochromocytoma symptomatology, with women tending to be more symptomatic than men. Women report significantly more headache (80% vs 52%), weight change (88% vs 43%), numbness (57% vs 24%), dizziness (83% vs 39%), tremor (64% vs 33%), anxiety (85% vs 50%), and changes in energy level (89% vs 64%).

**Manifestations in pregnancy:** A pheochromocytoma during pregnancy can cause sustained hypertension or paroxysmal hypertension that is typically mistaken for eclampsia. Hypertensive paroxysms tend to occur more frequently as the uterus enlarges, triggered by direct pressure upon the tumor by shifts in position or movement of the fetus. Hypertensive crisis typically occurs at the time of vaginal delivery and is commonly associated with cardiac arrhythmia, ARDS, and death. Postpartum women may develop shock or fever that can mimic uterine rupture, amniotic fluid embolus, or infection (puerperal sepsis). A tumor that is unrecognized carries a grave prognosis, with a reported 40% maternal mortality and a 56% fetal mortality. If the diagnosis of pheochromocytoma is made before delivery, the maternal mortality rate drops to about 10%. (See “Pregnancy and Pheochromocytoma,” later in the chapter.)

**Manifestations of malignancy:** Metastases occur in about 10% of pheochromocytomas and 30% of non–head-neck sympathetic paragangliomas. Since histopathology cannot distinguish whether a given pheochromocytoma is malignant, the term malignant is dependent upon whether metastases are detectable at presentation (50%) or months to years later (50%). Metastases are usually (80%) functional and can cause recurrent hypertension and symptoms many months or years after an operation that had been thought to be curative. (See “Metastatic Pheochromocytoma and Paraganglioma” discussed later.)

**Normotension despite high plasma levels of norepinephrine** Interestingly, about 14% of patients with pheochromocytomas and paragangliomas have no hypertension despite having chronically elevated serum norepinephrine levels. This phenomenon has been variably called desensitization, tolerance, or tachyphylaxis.

Patients can be genetically prone to adrenergic desensitization. Adrenergic desensitization is caused by adrenergic receptors undergoing sequestration, downregulation, or phosphorylation. Adrenergic desensitization appears to be one cause of the cardiovascular collapse that can occur abruptly following the removal of a pheochromocytoma in some patients.

Desensitization does not account for all patients who are normotensive in the face of elevated serum levels of norepinephrine, because some such patients can still have hypertensive responses to norepinephrine. Secretion of epinephrine can have a hypotensive effect and may account, at least in part, for this phenomenon. Some patients are homozygous for certain polymorphisms of β2-adrenergic receptors that allow continued β2-adrenergic-mediated vasodilation, thus counteracting the pressor effects of circulating epinephrine and norepinephrine caused by stimulation of vascular α1-adrenergic receptors.

Cosecretion of DOPA may reduce blood pressure through a central nervous system action. Similarly, cosecretion of dopamine may directly dilate mesenteric and renal vessels and thus modulate the effects of norepinephrine.

**Biochemical Testing for Pheochromocytoma**

No single test is absolutely sensitive and specific for pheochromocytoma. Plasma-fractionated free metanephrines or urinary 24-hour metanephrines have a sensitivity of about 97%. Sensitivities of other tests are somewhat lower: urinary norepinephrine 93%, plasma norepinephrine 92%, urinary VMA 90%, plasma epinephrine 67%, urinary epinephrine 64%, and plasma dopamine 63%. However, some malignant tumors secrete only dopamine and no catecholamines and no metanephrines at all. Also, the determination of plasma catecholamines-metanephrine ratios can be of value in discriminating false-positive from true-positive results (see later). Therefore, assays for plasma catecholamines, dopamine, and serum chromogranin A are often warranted.

Pheochromocytomas are deadly tumors and missing the diagnosis can be disastrous, so screening tests must be very sensitive. The secretion of catecholamines can be paroxysmal, with low secretion rates between paroxysms. In contrast, the secretion of metanephrine or normetanephrine metabolites is relatively high and constant. Tumors secrete metanephrines in their unconjugated (free) form. Thus, plasma-fractionated free metanephrines is the single most sensitive screening tests for these tumors. Urinary 24-hour fractionated metanephrines has a similar sensitivity but is less convenient. Some rare tumors (usually malignant) have a defect in the conversion of dopamine to norepinephrine by DBH, such that serum dopamine levels are very high while catecholamines are normal or mildly elevated and metanephrines are totally normal. Additionally, some paragangliomas secrete no catecholamines or metanephrines but do secrete chromogranin A.

The establishment of normal reference ranges is problematic for catecholamines and metanephrines, since levels vary with sex, age, and medical conditions:

1. **Sex**—Women have lower plasma epinephrine and metanephrine levels than men; their urinary excretion of catecholamines and metanephrines is also lower.
2. **Age**—Children, especially boys, have somewhat higher levels of plasma epinephrine and metanephrine than do adults. Conversely, children's average 24-hour urine epinephrine and norepinephrine excretion rates are lower than those of adults and increase through childhood as weight increases. Therefore, children's 24-hour urine tests are best assessed by using ratios of catecholamines to creatinine and metanephrines to creatinine.
3. **Medical conditions**—On average, hospitalized patients and those with essential hypertension have higher levels of catecholamines and metanephrines (plasma and urine) than do
matched nonhospitalized and normotensive individuals. Therefore, many laboratories have separate reference ranges for hypertensives and nonhypertensives.

Patients with illness, trauma, or sleep apnea have increased excretion of both catecholamines and metanephrines. Patients with renal failure on dialysis have elevated levels of plasma catecholamines (58%), plasma free metanephrines (25%), and plasma total (deconjugated) metanephrines (100%). Patients with partial renal insufficiency also have misleadingly elevated levels of plasma catecholamines (32%), plasma free metanephrines (26%), and plasma total metanephrines (50%). Thus, in patients with renal failure, the best screening test is plasma free metanephrines, but the test still lacks specificity when elevated. Serum chromogranin A levels are also elevated in renal insufficiency.

Misleading elevations of at least one metanephrine or catecholamine determination occur in 10% to 20% of tested individuals without pheochromocytoma. These elevations are typically less than 50% above the upper limit of normal and often normalize on retesting. Patients with pheochromocytomas usually have elevations of metanephrines or catecholamines that are more than three times normal. In one large series, a false-positive elevation in at least one test occurred in 22% and marked elevations in at least one test occurred in 3.5% of patients with no pheochromocytoma. False-positive test results were judged to have occurred from physiologic variation (33%), laboratory errors (29%), or drug interference (21%).

Plasma normetanephrines reflect disease activity in patients with secretory paragangliomas or metastases. Normal ranges for plasma metanephrines in children are different from those of adults and have been reported by Weise et al, 2002. Plasma normetanephrine levels typically increase with age; about 16% of older patients being evaluated for pheochromocytoma have levels above the published normal range for young adults (false positives); only 3% of young adults have false-positive plasma normetanephrine concentrations. Plasma concentrations of norepinephrine do not correlate with blood pressure. Stimulation tests are not recommended (see later).

A. Metanephrines and catecholamines

**Plasma-fractionated free metanephrines.** The most sensitive test for pheochromocytoma is an assay for plasma-fractionated (metanephrine and normetanephrine) free metanephrines. This assay is particularly useful when screening for a small pheochromocytoma in patients with established MEN 2 (metanephrine) or VHL disease (normetanephrine). For younger children, plasma testing is preferred to urine testing due to the relative ease of collection.

Normal references ranges for plasma-fractionated metanephrines vary by sex (children), age, and laboratory. For boys ages 5 to 17 years, the upper limit of normal (ULN) for plasma free metanephrine is ≤0.52 nmol/L and the ULN for plasma free normetanephrine is ≤0.53 nmol/L. For girls ages 5 to 17 years, the ULN for plasma free metanephrine is ≤0.37 nmol/L and the ULN for plasma free normetanephrine is ≤0.42 pmol/L. For adults, the reported ULN for plasma free metanephrine has ranged from 0.30 to 0.47 nmol/L and the reported ULN for plasma free normetanephrine has ranged from 0.60 to 1.1 nmol/L. In conventional units, the adult ULN reported by Quest Diagnostics Laboratory is ≤57 pg/mL for plasma free metanephrine and ≤148 pg/mL for plasma free normetanephrine.

In the United States, most reference laboratories assays for metanephrines use high-pressure liquid chromatography (HPLC) with tandem mass spectrometry (MS/MS). This test is 97% sensitive and about 87% specific for pheochromocytoma in a referred patient population. MS/MS reduces drug interference that can be a problem with assays that employ HPLC with electrochemical detection (ECD). Metanephrine assays are more sensitive and specific for pheochromocytoma than plasma or urinary catecholamine determinations.

The 3% of affected patients with normal plasma-fractionated free metanephrines usually have very small tumors, nonsecreting tumors, or dopamine-secreting tumors such that they are not hypertensive. Since the test’s specificity is much lower than its sensitivity, most patients with levels above the reference range do not harbor a tumor. This is particularly true when plasma levels are less than three times higher than the upper limit of the reference range. Conversely, it is extremely likely that a patient harbors a pheochromocytoma when the plasma metanephrine is above 236 pg/mL (1200 nmol/mL) or the plasma normetanephrine is above 400 pg/mL (2200 nmol/mL).

Normally, about 90% of circulating metanephrine and about 50% of circulating normetanephrine originate directly from the adrenal medulla. The term **total metanephrines** refers to both normetanephrine and metanephrine. There are two circulating forms of normetanephrine and metanephrines: free and sulfate-conjugated metanephrines. The free metanephrines produced in the adrenal medulla and paraganglia are sulfate conjugated by intestinal tissue; the sulfated form represents 97% of circulating metanephrines. Only 3% of total circulating metanephrine is free. Plasma metanephrine levels are sometimes measured after a deconjugation step, such that both free and conjugated metanephrines are measured; this assay is termed **deconjugated metanephrines** and reflects mostly the sulfate-conjugated species. The plasma free metanephrines assay is superior to the total (deconjugated) metanephrine assay.

In the United States, when plasma metanephrines are requested, most reference laboratories test for free (nondeconjugated) metanephrines. Most reference laboratories assay metanephrines using MS/MS, which avoids interference by drugs and foods. Blood specimens for plasma-fractionated free metanephrines can be collected at any time, but are best drawn after an overnight fast while the patient is seated and relaxed.

The sensitivity of the plasma free metanephrines is due to the tumor’s continuous secretion of metanephrines. Catecholamines in secretory vesicles exist in a dynamic equilibrium with the surrounding cytoplasm, with catecholamine uptake into the vesicles being balanced by their leakage into the cytoplasm. In the cytoplasm, the enzyme COMT converts epinephrine to metanephrine and converts norepinephrine to normetanephrine. The catecholamine metabolites then leak out of the cell continuously to
become free metanephrines. While catecholamines are secreted in bursts associated with exocytosis of neurosecretory vesicles, free metanephrines are produced continuously. This eliminates the need to catch a paroxysmal hypertensive event. Plasma free metanephrine levels are within the reference range in 75% of patients on dialysis and 74% of patients with renal insufficiency. In contrast, plasma deconjugated metanephrines are within the reference range in 0% of patients on dialysis and in 50% of patients with renal insufficiency.

**Factors causing misleading plasma free metanephrine levels.** Smoking can elevate plasma free metanephrine assays. The patient must not smoke for at least 4 hours before collection. Epinephrine-like drugs should be discontinued for at least 7 days before the test. Other drugs that can interfere with the plasma free metanephrine assay include local anesthetics, cocaine, lidocaine, halothane anesthesia, MAO inhibitors, and acetaminophen. Drug withdrawal and severe stress can also increase plasma free metanephrine levels. Misleading elevations in plasma free metanephrines occur in children (especially boys), renal failure, and stressful illness. Physical exercise raises plasma free metanephrine and normetanephrine by over 80%. Assumption of a supine resting position reduces plasma metanephrine by an average of 34% and reduces normetanephrine by 19%, compared to standing at rest. Coffee increases plasma normetanephrine by 20% and food increases plasma normetanephrine by 8%; but they have no effect upon metanephrine levels. Blood samples should ideally be drawn from an indwelling heparin-locked intravenous line while the patient is fasting and resting supine. Blood should be centrifuged immediately and stored at 4°C to improve stability.

In patients with adrenal pheochromocytoma, over 90% of circulating metanephrine originates from the tumor, while variable percentages of circulating normetanephrine originate from the tumor. Patients with elevated plasma metanephrine are likely to have an adrenal pheochromocytoma, since paragangliomas do not secrete epinephrine or metanephrine. Metastases from epinephrine-secreting pheochromocytomas may sometime continue to secrete epinephrine and metanephrine.

**24-Hour urine-fractionated metanephrines.** This assay, which measures the sum of both conjugated and free urinary metanephrines, rivals plasma free metanephrines in sensitivity. In the United States, most reference laboratories employ tandem mass spectrometry (MS/MS), which eliminates interference by drugs and foods. Urinary metanephrines are rather stable compounds, so it is not necessary to collect the specimen with acid preservative. Conversely, acid preservative (used for collection of urinary catecholamines) does not adversely affect metanephrines. The disadvantages of 24-hour urine collections include: (1) the inconvenience to the patient; (2) the likelihood that there will be an error in the patient's collection or in the laboratory's handling of the specimen; (3) the inaccuracy for patients with renal failure. (See Appendix for normal reference ranges for 24-hour metanephrines.)

Like plasma-fractionated metanephrines, urinary metanephrines are much more sensitive than they are specific. Most patients with elevated levels of fractionated metanephrines do not harbor a pheochromocytoma if their levels are less than three times the upper limit of the reference range. Conversely, patients are very likely to have a pheochromocytoma if the 24-hour urine metanephrine excretion is above 600 µg/d (3.0 µmol/d) or normetanephrine excretion is above 1500 µg/d (8.2 µmol/d).

As with plasma metanephrines, patients with elevated urinary metanephrine are likely to harbor an adrenal pheochromocytoma, since paragangliomas do not secrete epinephrine or metanephrine.

**Plasma-fractionated catecholamines.** Misleading elevations in plasma catecholamines commonly occur from the stress of having the phlebotomy. Normal plasma levels of catecholamines are listed in the Appendix. Although plasma metanephrines are more sensitive than plasma catecholamines for detecting a pheochromocytoma, plasma catecholamines are of value in helping distinguish true-positive from false-positive results. In normal individuals, about 100% of circulating epinephrine originates from the adrenals medulla, while over 90% of circulating norepinephrine originates from peripheral sympathetic synapses. In both normals and those with pheochromocytomas, plasma norepinephrine levels fluctuate with the degree of peripheral sympathetic activation and both epinephrine and norepinephrine levels can increase during pheochromocytoma paroxysms. In patients with pheochromocytomas, the tumor's production of metanephrine metabolites is rather constant and relatively unrelated to peripheral sympathetic activity or a tumor's paroxysmal catecholamine secretion. Patients with false-positive test results due to sympathetic activation tend to have the following pattern: a higher percentage increase of plasma norepinephrine above the upper limit of the reference range compared to plasma normetanephrine; a higher percentage increase of plasma epinephrine above the upper limit of the reference range compared to plasma metanephrine.

Plasma catecholamines are of limited value in patients on dialysis and in those with renal insufficiency. About 58% of dialysis patients have plasma catecholamines above the normal reference range; about 32% of renal insufficiency patients have catecholamines above the normal reference range.

Most assays for plasma catecholamines currently employ HPLC with ECD; assays using tandem mass spectrometry (MS/MS) have not become generally available.

**Urine-fractionated catecholamines and dopamine.** Adult normal maximal urinary concentrations for catecholamines and their metabolites are listed in the Appendix. A single 24-hour urine specimen is collected for fractionated catecholamines, fractionated metanephrines, dopamine, and creatinine. The container is acidified with 10 to 25 mL of 6 N HCl for preservation of the catecholamines; the acid does not interfere with metanephrine and creatinine assays. The acid preservative may be omitted for children for safety reasons, in which case the specimen should be kept cold and processed immediately. The laboratory requisition form should request that assays for fractionated catecholamines, fractionated metanephrines, and creatinine be performed on the same specimen.
A single-void urine specimen may be collected on first morning void or following a paroxysm. No acid preservative is used on single-void specimens, because it dilutes the specimen and is not required. For single-void collections, patients are instructed to void and discard the urine immediately at the onset of a paroxysm and then collect the next voided urine. The laboratory requisition should request spot urine for total metanephrine (by HPLC and ECD) and creatinine concentrations. It is prudent to contact the laboratory technician and explain that the specimen is meant to be a single-void urine and not a 24-hour specimen or else the specimen may be rejected. Patients with pheochromocytomas generally excrete over 2.2 μg total metanephrine/mg creatinine.

Urinary dopamine determination is not a sensitive test for pheochromocytomas. However, in patients with established pheochromocytomas, a normal urine dopamine is fairly predictive of benignity, whereas elevated urine dopamine excretion is seen in both benign and malignant pheochromocytomas.

B. Serum chromogranin A Some tumors (mostly paragangliomas) fail to secrete catecholamines or metanephrines. Serum chromogranin A (CgA) is a useful test to diagnose and monitor such nonsecretory tumors. CgA may be determined by immuno-radiometric assays. The serum CgA assay has become useful for the diagnosis of pheochromocytoma. However, CgA undergoes extensive tumor-specific cleavages so that only certain serum assays are useful for clinical diagnosis.

Serum CgA levels have a circadian rhythm in normal individuals, with lowest levels found at 8 AM and higher levels in the afternoon and at 11 PM. CgA levels are not elevated in essential hypertension. CgA is also secreted from extra-adrenal sympathetic nerves. Serum CgA levels are elevated in the great majority of patients with pheochromocytomas. The serum levels of CgA correlate with tumor mass, making CgA a useful tumor marker. However, smaller tumors may not be diagnosed. Serum CgA levels tend to be particularly elevated in patients with metastatic pheochromocytoma.

Serum CgA can be elevated even in patients with biochemically silent tumors. In patients with normal renal function, serum CgA has a sensitivity of 83% to 90% and a specificity of 96% for diagnosis of these tumors. However, the usefulness of serum CgA levels is negated by any degree of renal failure because of its excretion by the kidneys; even mild azotemia causes serum levels to be elevated. However, in patients with normal renal function, a high serum level of CgA along with high urine or plasma catecholamines or metanephrines is virtually diagnostic of pheochromocytoma.

Since CgA is also cosecreted with gastrin, serum CgA levels are also elevated in conditions with elevated serum gastrin: atrophic gastritis, pernicious anemia, postvagotomy, gastrinoma, gastric carcinoma, carcinoid tumor, and small cell lung carcinoma. CgA levels are elevated in about 60% of patients taking proton pump inhibitors (PPIs), but not H₂ blockers. Serum CgA levels rise variably after meals, so blood for CgA should be drawn after an overnight fast or repeated fasting if a nonfasting level is elevated. False-positive testing has also occurred in patients with inflammatory bowel disease, liver disease, hepatocellular carcinoma, prostate cancer, pituitary tumors, rheumatoid arthritis, and stress. False-positives have been reported to be due to heterophile antibody interference with the assay. Serum CgA levels can also be elevated without any discernable cause.

C. Suppression and stimulation testing Glucagon stimulation testing is no longer used since it can cause dangerous hypertension.

Clonidine suppression test: This test may help distinguish patients with pheochromocytoma from normals with elevated normetanephrine levels. Clonidine is a central 2-adrenergic blocker that suppresses the release of norepinephrine at sympathetic nerve synapses, thereby reducing circulating levels of norepinephrine and its metabolite, normetanephrine. In contrast, in patients with pheochromocytoma, most circulating normetanephrine is derived from continuous leakage from the tumor, such that clonidine is less able to suppress it. This test is most accurate when free normetanephrine is assayed, rather than norepinephrine.

To perform the clonidine suppression test, the patient must be fasting overnight and avoid smoking or interfering medications such as phenoxybenzamine, b-blockers, tricyclics and diuretics for at least 48 hours. An indwelling venous catheter is inserted, and the patient should remain recumbent. Thirty minutes later, blood is drawn for baseline plasma free normetanephrine. Clonidine is then given orally in a dose of 0.3 mg/kg; 3 hours afterward, blood is again drawn for plasma free normetanephrine. In 1 study of 49 normals without pheochromocytoma, clonidine suppressed plasma normetanephrine levels more than 40% or to below 112 pg/mL in 100%. However, clonidine failed to suppress normetanephrine in 46 of 48 patients with pheochromocytoma. Despite the potential helpfulness of the clonidine suppression test, it cannot be completely relied upon. Unnecessary surgeries have been performed on the basis of misleading clonidine suppression testing.

D. Other laboratory tests

1. Urine VMA—Urinary VMA determinations have an overall diagnostic sensitivity for pheochromocytoma of only about 63% and do not improve the sensitivity or specificity of other tests for the diagnosis of pheochromocytoma. However, some centers have traditionally used a combination of 24-hour urinary VMA, metanephrine, and creatinine determinations with good results. VMA is stable for 5 days at room temperature; 6 N HCl is used to preserve urine specimens that are stored for longer than 5 days before analysis. Before urine collections for VMA testing, patients must avoid salticyles, caffeine, phenothiazines, and antihypertensive drugs for 72 hours. Coffee, tea, chocolate, bananas, and vanilla must also be avoided. Normal ranges for VMA vary by age (see Appendix).

2. Plasma renin activity—Levels of plasma renin activity are not typically suppressed in patients with pheochromocytomas because catecholamines stimulate renin release, and some tumors may secrete renin ectopically.

3. Other tests—Patients with pheochromocytoma are frequently found to have an increased white blood count with a high absolute neutrophil count. Counts as high as 23,600/μL.

¹Note that assays for metanephrine employing tandem mass spectroscopy (MS/MS) are not prone to interference from drugs or foods, except those that increase catecholamine excretion. Reproduced, with permission, from McPhee SJ, Papadakis MA, ed. Current Medical Diagnosis & Treatment 2010. McGraw Hill; 2010.

²May cause confounding peaks on HPLC chromatograms.

³Increases catecholamine excretion.

⁴Decreases catecholamine excretion.

⁵May decrease urine metanephrine excretion.

⁶Increases plasma and urinary normetanephrine and metanephrine.

have been reported. Marked eosinophilia may sometimes occur. Hyperglycemia is noted in about 35% of patients with pheochromocytoma, but frank diabetes mellitus is uncommon. The erythrocyte sedimentation rate is elevated in some patients. Hypercalcemia is common and may be caused by bone metastases or tumoral secretion of PTHrP. Hypocalcemia occurs rarely. Erythrocytosis sometimes occurs, usually due to volume contraction and rarely due to ectopic secretion of erythropoietin.

Factors That May Cause Misleading Biochemical Testing for Pheochromocytoma

Several different methods may be employed for assay of urine and plasma catecholamines and metanephrines. Each assay uses different methods and internal standards. Most assays for catecholamines now employ HPLC with ECD. Such assays can be affected by interference from a diverse range of drugs and foods. These substances cause unusual shapes in the peaks on the chromatogram. Not all of these assays are the same, and the potential for interference depends on the particular method employed. Therefore, it is best to check with the reference laboratory that runs the test or provides the test kit.

A. Drugs (see Table 11-14) Certain radiopaque contrast media, including those that contain meglumine acetrizoate or meglumine diatrizoate (eg, Renografin, Hypaque-M, Renovist, Cardiografin, Urografin, and Conray), can falsely lower urinary metanephrine determinations in some assays for up to 12 hours following administration. However, diatrizoate sodium is an intravenous contrast agent that does not cause such interference and should be requested if a CT scan must be performed prior to testing for metanephrines. Many other drugs cause interference in the older fluorometric assays for VMA and metanephrines. Tandem mass spectrometry for metanephrines virtually eliminates direct drug interference in the assay.

B. Foods Even while using HPLC-ECD assay techniques, certain foods can cause misleading results in assays for catecholamines and metanephrines (see Table 11-16). Coffee (even if decaffeinated) contains substances that can be converted into a catechol metabolite (dihydrocaffeic acid) that may cause confusing peaks on HPLC. Caffeine inhibits the action of adenosine; one action of adenosine is to inhibit the release of catecholamines. Heavy caffeine consumption causes a persistent elevation in norepinephrine production and raises blood pressure an average of 4 mm Hg systolic. Bananas contain considerable amounts of tyrosine, which can be converted to dopamine by the central nervous system; dopamine is then converted to epinephrine and norepinephrine. Dietary peppers contain 3-methoxy-4-hydroxybenzylamine (MHBA), a compound that can interfere with the internal standard used in some assays for metanephrines.

C. Diseases Any severe stress can elicit increased production of catecholamines and metanephrines. Urinary excretion of catecholamines and metanephrines is reduced in renal failure.

Differential Diagnosis of Pheochromocytoma (Table 11-15)

Pheochromocytomas have such protean manifestations that many conditions enter into the differential diagnosis. Essential hypertension is extremely common, and it is not practical to screen for pheochromocytoma in all patients with elevated blood pressure. However, pheochromocytoma should enter the differential diagnosis for any hypertensive patient having blood pressures above 180 mm Hg systolic and for any hypertensive patient who has one of the following symptoms: headaches, palpitations, sweating episodes, or unexplained bouts of abdominal or chest pains.

Anxiety (panic) attacks begin abruptly and can be associated with tachycardia, tachypnea, and chest discomfort, symptoms that

are commonly seen with pheochromocytomas. However, patients with panic attacks are more likely to have a precipitating social situation, tend to be exhausted for more than 2 hours following an attack, live in dread of the next attack, and often change their activities to avoid situations that might trigger anxiety.

Renal artery stenosis and renal parenchymal disease can cause increased secretion of renin resulting in severe hypertension. However, a detectable serum renin level does not exclude pheochromocytoma, because catecholamines can stimulate renin secretion and pheochromocytomas can secrete renin ectopically. Furthermore, large pheochromocytomas and paragangliomas arising near the renal hilum can occlude the renal artery, causing concomitant renovascular hypertension.

Hypogonadism can cause vasomotor instability in both women and men; attacks of flushing, sweating, and palpitations can mimic symptoms seen with pheochromocytoma. Factitious symptoms may be caused by surreptitious self-administration of various drugs such as epinephrine. Hyperthyroidism can cause heat intolerance, sweating, palpitations, and systolic hypertension with a widened pulse pressure. Carcinoid syndrome causes flushing during attacks but usually without pallor, hypertension, palpitations, or diaphoresis.

Obstructive sleep apnea can cause systemic hypertension; recurrent nocturnal hypoxia in repeated episodes of stressful arousal that cause bursts of secretion of catecholamines, particularly epinephrine. Sleep apnea has been reported to cause misleading increases in the urinary excretion of catecholamines.

Patients with erythromelalgia can have episodic hypertension, but it is associated with flushing of the face and legs during the attack; patients with pheochromocytoma typically have facial pallor during attacks. With erythromelalgia, patients have painful erythema and swelling in the legs that is relieved by application of ice; such symptoms are not characteristic of pheochromocytoma.

Patients who have intermittent bizarre symptoms may have their blood pressure and pulse checked during a symptomatic episode with a home blood pressure meter or an ambulatory blood pressure monitor. Those who are normotensive during an attack are not likely to harbor a pheochromocytoma.

Pheochromocytomas often present with abdominal pain and vomiting. Such symptoms are similar to those of an intra-abdominal emergency, particularly in the presence of leukocytosis and fever, which can also be seen with pheochromocytomas. Abdominal pain usually prompts a CT scan of the abdomen, which generally shows the pheochromocytoma or paraganglioma. Even after detection on CT scan, pheochromocytomas and juxtaglomerular paragangliomas may be mistaken for renal carcinoma. Large left-sided pheochromocytomas are often mistaken for carcinoma of the tail of the pancreas.

Neuroblastoma is the most common extra-cranial solid malignancy of childhood. It is also the most common malignancy in infants under 18 months old. Neuroblastomas are derived from the embryonic neural crest of the peripheral sympathetic nervous system. They most often arise in the adrenal gland, but can also develop in sympathetic nerve ganglia near the cervical or thoracic vertebrae or in the pelvis. They metastasize to bones, lymph nodes, liver, and skin. Symptoms depend upon the age of the patient, site of origin, degree of metastatic involvement, and the systemic response to the tumor. Infants usually present with localized disease (Stage 1 or 2) or with a special disseminated pattern of disease (Stage 4S—infants with metastatic disease to liver and/or skin) associated with a favorable outcome. In contrast, most children over 1 year of age present with advanced disease (Stage 3 or 4). Unfavorable biologic features include amplification of myeloma­
tosis viral-related oncogene, neuroblastoma (MYCN), deletion or loss of heterozygosity of chromosome 1p or 11q and gains at 17q. Favorable biologic features include hyperdiploidy and overexpression of the gene encoding the nerve growth factor receptor, tyrosine kinase A (TrkA). About 85% of affected children secrete excessive catecholamines—but rarely in sufficient amounts to cause symptomatic hypertension or the paroxysms typical of pheochromocytomas. Most neuroblastomas concentrate 123I-MIBG but they can be distinguished from pheochromocytomas and paragangliomas by clinical and histologic criteria.

Localisation Studies for Pheochromocytoma

There are several available imaging modalities for pheochromocytoma and paraganglioma, each having unique sensitivity and specificity. There is no single imaging study that is 100% sensitive and specific. Generally, when a pheochromocytoma or paraganglioma is suspected, the initial diagnosis is best made biochemically. The initial localization scan is with CT or MRI of the abdomen and pelvis, which will detect about 95% of these tumors. However, since paragangliomas can arise in the chest, further scanning of the chest may be required. Diagnostic confirmation that
the tumor is a pheochromocytoma or paraganglioma may be done with either ¹²³I-MIBG or ¹⁸F-FDA positron emission tomography (PET) scanning; unfortunately, these scans are only 78% sensitive for these tumors. Scanning with ¹⁸F-FDG or ¹⁸F-FDA PET is more sensitive for detecting metastases than is ¹²³I-MIBG.

A. Computed tomography (Figure 11-10) After a pheochromocytoma has been diagnosed by clinical and biochemical criteria, hypertension must first be controlled (see later), because intravenous ionic contrast can precipitate a hypertensive crisis. The pheochromocytoma must then be localized. It is useful to perform an initial nonenhanced (without intravenous contrast) CT of the adrenals because the density of an adrenal tumor can be better approximated without intravenous contrast. An adrenal mass with a density of less than 10 Hounsfield units (HU) is unlikely to be a pheochromocytoma. CT scanning of the entire abdomen (from the diaphragm through the pelvis) is obtained with intravenous contrast-enhanced and delayed contrast-enhanced imaging. Thin-section (2-5 mm) cuts should be obtained through the adrenals with an adrenal protocol that specifically looks for a vascular tumor blush and determines rate of contrast washout. Pheochromocytomas tend to have a tumor blush and slower contrast washout than adrenocortical adenomas. Hypertensive crises have been provoked in pheochromocytoma patients receiving ionic intravenous contrast agents; this has prompted the tradition of initiating an alpha-blocking agent before the CT scan. However, nonionic intravenous contrast poses much less of threat. No increases in blood pressure or plasma catecholamines were noted in a series of 10 pheochromocytoma patients who received iohexol intravenous nonionic contrast. Glucagon should not be used during a CT because it may provoke a hypertensive crisis.

If no mass is discovered, ¹²³I-MIBG imaging may be obtained or the CT scan may be extended into the chest in search of a paraganglioma—or both procedures may be employed. The great majority of pheochromocytomas are over 2 cm in diameter, well within the resolution capacity of the CT scan.

The overall sensitivity of CT scanning for an adrenal pheochromocytoma is about 90%—and over 95% for pheochromocytomas that are over 0.5 cm in diameter. However, CT scanning is less sensitive for the detection of small adrenal pheochromocytomas or adrenal medullary hyperplasia; this becomes an important issue in patients with MEN 2 or VHL disease. CT is also less sensitive for detecting extra-adrenal paragangliomas and early recurrent tumors in the adrenal surgical bed. CT will not detect small metastases or some metastases that strictly involve the bone marrow without osteoclastic activity. Metal surgical clips pose problem for CT scanning, causing distortion artifact and reducing the resolution of the scan.

B. Magnetic resonance imaging MRI is useful in the diagnosis of adrenal pheochromocytomas, paragangliomas, and metastatic disease. It may be used with or without gadolinium contrast. Intravenous gadolinium contrast does not cause hypertensive crisis. MRI scanning with intravenous gadolinium contrast is also useful for patients with a known allergy to intravenous iodinated CT contrast agents. MRI is the scanning technique of choice in children and during pregnancy, because it involves no radiation exposure. Since MRI scanning delivers no radiation, it is preferred for serially scanning patients known to harbor a gene mutation predisposing them to PHEO/PGL.

MRI can help determine whether an adrenal mass is a pheochromocytoma when biochemical studies are inconclusive. On MRI T1-weighted images, pheochromocytomas have a dull signal (due to lack of fat cells), similar to kidney and muscle, distinguishing it from adrenal cortical adenomas, which contain fat and therefore have an intensely bright signal on T1-weighted images. The hypervascularity of pheochromocytomas makes them appear bright on MRI T2-weighted images, without signal loss on opposed phase imaging. However, other adrenal
malignancies, adrenal adenomas, and hemorrhages can also appear bright on MRI T2-weighted images. Therefore, MRI scanning cannot definitively identify an adrenal mass as a pheochromocytoma. MRI of the abdomen has a sensitivity of about 95% for adrenal pheochromocytomas over 0.5 cm in diameter. Like CT scanning, MRI is less sensitive for the detection of extra-adrenal paragangliomas, metastatic disease, and recurrent small tumors in the adrenal surgical bed. MRI is helpful in visualizing paragangliomas that are intracardiac, juxtacardiac, or juxtavascular; MRI is particularly important for patients with paragangliomas adjacent to the vena cava or renal vein to detect vascular invasion. MRI is superior to CT in visualizing paragangliomas of the bladder wall. MRI can visualize some metastases to bone suspected on 123I-MIBG imaging or PET scanning. Another advantage of MRI scanning is that retained internal metallic surgical clips do not cause the distorting reflection artifacts that occur with CT scanning.

The disadvantages of MRI scanning include expense and its inability to crisply image lungs (due to movement artifact). Also, morbidly obese patients may not be able to fit into a standard helical MRI scanner; open MRI scanners can be used but are generally less sensitive. Claustrophobic patients require a sedative before the scan or an open MRI. Patients with internal pacemakers or defibrillators may not have MRI scans; nor may patients with implanted neural stimulators, cochlear implants, Swan-Ganz catheters, insulin pumps, cerebral aneurysm clips, ocular metallic foreign bodies, or retained metal shrapnel or bullets. Patients with retained surgical clips, artificial heart valves and joints may have MRI imaging; the spine may be imaged in patients with spinal hardware, but the imaging can be distorted.

C. Metaiodobenzylguanidine scanning (Figure 11-11 and Table 11-16) MIBG is a guanidine derivative that resembles norepinephrine and is actively transported into adrenal medullary cells via the norepinephrine transporter system, selectively accumulating in neurosecretory granules. Unlike norepinephrine, MIBG has low affinity for catecholamine receptors and is not metabolized.

Scintigraphy using 123I-MIBG or 131I-MIBG is useful for determining whether an adrenal mass is a pheochromocytoma, for imaging occult paragangliomas, and for confirming whether a certain extra-adrenal mass is a paraganglioma or neuroblastoma. MIBG scanning is also useful for screening patients for metastases. MIBG uptake can often be seen in apparently nonfunctioning pheochromocytomas.

The isotope that is preferable for precise imaging is 123I-MIBG, because 123I emits γ radiation at lower energy (159 keV) than does 131I (364 keV). The lower-energy γ emissions allows crisper images with 123I-MIBG scanning as well as single photon emission computed tomography (SPECT). 123I-MIBG SPECT scanning is more sensitive than 123I-MIBG planar imaging for detecting small metastases and has the advantage of being able to do the scanning on the day following injection of the isotope. SPECT scanning with 123I-MIBG can be combined with CT to produce a three-dimensional fusion scan; the resultant combined images can help distinguish whether a given mass has 123I-MIBG uptake.

123I-MIBG is administered intravenously in doses of 3 mCi (children) to 10 mCi (adults), whereas 131I-MIBG is administered intravenously in doses of 0.5 to 1 mCi. 123I emits lower energy γ radiation and less heavy particle radiation over a shorter period than 131I, so 123I-MIBG scanning results in a somewhat lower absorbed radiation dose than 131I-MIBG scanning. However, most centers still use 123I-MIBG due to its longer half-life, lower expense, and better commercial availability.
MIBG scanning has an overall sensitivity of 82% and a specificity of 82% for pheochromocytomas and paragangliomas combined. The sensitivity of 123I-MIBG scanning is 88% for primary adrenal pheochromocytomas and 67% for paragangliomas, with an overall sensitivity of 78% for primary PHEO/PGL tumors. The sensitivity of 123I-MIBG scanning for metastases is lower at only 57%. Scanning with 123I-MIBG is more sensitive for pheochromocytomas that are benign, unilateral, adrenal, capsule-invasive, and sporadic. Scanning with 123I-MIBG is less sensitive for bilateral, malignant, extra-adrenal, noninvasive, and MEN 2-related or VHL-related pheochromocytomas.

To block the thyroid's uptake of free radioiodine, saturated solution of potassium iodide, five drops orally three times daily, is given before the injection and daily for 4 days after 123I-MIBG and for 7 days after 131I-MIBG. Scanning is performed 24 to 48 hours after 123I-MIBG infusion and 48 to 72 hours after 131I-MIBG infusion.

False-negative MIBG scans are seen in about 15% of cases of either benign or malignant pheochromocytoma. False-negative scans can occur in patients who have taken certain drugs (eg, tricyclic antidepressants or cyclobenzaprine) within 6 weeks. Other drugs that can cause false-negative scans when taken within 2 weeks include amphetamines, phenylpropanolamine, haloperidol, phenothiazines, thiothixene, reserpine, nasal decongestants, cocaine, and diet pills. Labetalol reduces MIBG uptake, but the scan can still be done, albeit with suboptimal sensitivity (Table 11-16). When plasma norepinephrine levels are over 500 pg/mL (3 nmol/L), cardiac visualization is reduced on 18F-dopamine PET scanning. This phenomenon is believed due to competitive inhibition of uptake-1 by high levels of circulating norepinephrine. Therefore, it is likely that very high endogenous norepinephrine levels may reduce the sensitivity of 123I-MIBG scanning as well as PET scanning that employs 18F-DA or 19F-DOPA because these compounds are transported into pheochromocytomas, paragangliomas, and their metastases by the same uptake mechanism.

False-positive MIBG scans occur infrequently. Following 123I-MIBG, some uptake in a normal adrenal medulla is seen in 32% to 75% of patients at 24 hours. Following 131I-MIBG, uptake in a normal adrenal medulla is seen in 16% of normals at 48 hours. Adrenal uptake is often asymmetric and can be misinterpreted as showing a tumor. MIBG has renal excretion, so the renal pelvis and bladder are usually visualized on scanning and must be distinguished from tumor. If a patient is being evaluated for a bladder mass (ie, to exclude a paraganglioma), a bladder catheter may be inserted and the bladder flushed with saline to distinguish tumor from renal excretion of isotope. Urine contamination with 123I-MIBG can also cause a false-positive scan. False-positive results have been reported with adrenal carcinomas and infections such as actinomycosis. The salivary glands are typically visualized since they are richly innervated. The heart, liver, and spleen normally take up some 123I-MIBG. Some isotope is excreted in the stool, and intracolonic collections can be mistaken for tumor. When there is doubt about whether an area of uptake is a tumor, scanning can be repeated the next day, preceded by a laxative if required.

D. Positron emission tomography (Figure 11-12) PET scanning can be performed shortly after the intravenous infusion of short-lived isotopes that are tagged to a compound that is preferentially absorbed by tumor tissue. These isotopes emit positrons (anti-matter) during their decay, causing positron-electron collisions that emit γ photons traveling in precisely opposite directions (180 degrees out of phase). In the PET scanner, sensitive gamma detectors surround the patient; simultaneous activation of two gamma detectors indicates that the source is located directly between them. Multiple such detections of this nature allow three-dimensional imaging of tumors and can accurately determine their location. Advanced scanners can perform PET and CT scanning simultaneously to produce particularly sensitive and accurate three-dimensional anatomic imaging.

PET scanning has certain advantages over MIBG scanning. PET scanning can be done almost immediately. This gives it some advantage over MIBG scanning, which must be delayed for 24 to 48 hours after the injection to allow dissipation of background radiation. PET scanning does not require pretreatment with iodine to protect the thyroid, as is necessary with MIBG scanning. However, PET scanning is very expensive. The isotope 18F has a
half-life of just 2 hours and must be produced in a cyclotron, so \(^{18}\text{F-FDG}\) or \(^{18}\text{F-FDA}\) PET scanning is practical only at medical centers that have a cyclotron nearby.

1. **PET scanning with \(^{18}\text{F-FDG}\).** Deoxyglucose (DG) is absorbed by tissues with active metabolism, including tumors. For PET scanning, DG is tagged with \(^{18}\text{F}\) to produce florodeoxyglucose, or \(^{18}\text{F-FDG}\). This scan is widely available as a fusion scan with CT, \(^{18}\text{F-FDG}\) PET/CT. This scan's sensitivity is 88% for nonmetastatic pheochromocytoma/paraganglioma and 76% for metastatic pheochromocytoma/paraganglioma. The sensitivity of \(^{18}\text{F-FDG}\)-PET/CT is lower for indolent tumors and for patients who are diabetic or who are not fasting before the scan. \(^{18}\text{F-FDG}\)-PET localizes in other tissues with a high metabolic rate, including areas of inflammation, brown fat, shivering muscles, but such areas of PET uptake can be distinguished from tumors by the lack of a CT correlate. However, \(^{18}\text{F-FDG}\)-PET/CT detects other tumors besides pheochromocytoma/paraganglioma and is, therefore, less specific for pheochromocytoma/paraganglioma than is \(^{18}\text{F-FDA}\)-PET or \(^{123}\text{I-MIBG}\) scanning.

2. **PET scanning with \(^{18}\text{F-FDA}\).** PET scanning may also be performed using radioisotope-tagged dopamine: \(^{6-}[^{18}\text{F}]\text{fluorodopamine (^{18}\text{F-FDA-PET})}\). This scan is more specific for paraganglioma and metastatic pheochromocytoma than is \(^{18}\text{F-FDG}\)-PET/CT, because dopamine is a substrate for the norepinephrine transporter in tumor tissue. The sensitivity of \(^{18}\text{F-FDA}\)-PET is 78% for nonmetastatic pheochromocytoma/paraganglioma and 76% for metastatic pheochromocytoma/paraganglioma. It is widely available and is generally more sensitive than \(^{123}\text{I-MIBG}\) scanning, particularly in patients who harbor VHL or MEN 2 germline mutations.

3. **PET scanning with \(^{18}\text{F-DOPA}\).** PET scanning may be performed using radioisotope-tagged DOPA: \(^{6-}[^{18}\text{F}]\text{fluoro-L-dihydroxyphenylalanine (^{18}\text{F-DOPA})}\). The sensitivity of \(^{18}\text{F-DOPA}\)-PET is about 81% for nonmetastatic PHEO/PGL and 45% for metastatic pheochromocytoma/paraganglioma. For SDHB-associated metastatic paraganglioma, its sensitivity is only 20%. This scan is not widely available and is not recommended because of its lack of sensitivity for metastatic pheochromocytoma or paraganglioma.

E. **Somatostatin receptor imaging with \(^{111}\text{In-octreotide}\).** Somatostatin receptors are cell surface, transmembrane, and G protein–coupled receptors, and there are five subtypes. About 70% of pheochromocytomas express somatostatin receptors, particularly types 2 and 4. Octreotide is a stable 8 amino acid analog of somatostatin with a high affinity for type 2 receptors. For imaging, octreotide is coupled with \(^{111}\text{In-diaminetriramine-pentacetate (DTPA)}\). \(^{111}\text{In}\) has a half-life of 2.8 days and \(\gamma\) emissions of 173 keV and 247 keV. Scanning with \(^{111}\text{In-octreotide}\), known as somatostatin receptor imaging (SRI), has a sensitivity of only 25% for adrenal pheochromocytomas and juxtaglomerular paragangliomas. This low sensitivity is due to high uptake of \(^{111}\text{In-octreotide}\) by the kidneys as well as renal excretion. However, SRI detects 87% of pheochromocytoma metastases and is also a sensitive technique for detecting paragangliomas of the head and neck (chemodectomas). SRI also detects some metastases not visible on MIBG scanning, and vice versa. SRI has been reported to detect a cardiac paraganglioma that was not visible on MIBG scanning. When paragangliomas or metastases are suspected, SRI may be useful, particularly when MIBG scanning is negative. \(^{111}\text{In-octreotide}\) has physiologic uptake in the kidneys, thyroid, pituitary, salivary glands, gallbladder, bowels, spleen, liver, and mammary glands. Infection and recent surgery sites can also have misleading uptake of \(^{111}\text{In-octreotide}\).

F. **Ultrasound imaging** On transabdominal ultrasound, an adrenal pheochromocytoma typically appears as a well-defined mass. Large pheochromocytomas tend to develop internal hemorrhagic necrotic cysts, making the tumor appear heterogeneous. Transabdominal ultrasound is most sensitive in slender individuals, in whom 85% of adrenal pheochromocytomas can be visualized. However, ultrasound lacks specificity, such that a pheochromocytoma is not distinguishable from an adrenal adenoma or a mass in the superior pole of a kidney. Likewise, a left adrenal pheochromocytoma may be mistaken for a pancreatic tail tumor, and a right adrenal pheochromocytoma may be mistaken for a hepatic mass. Ultrasound may be used for initial imaging for pheochromocytomas in pregnant women, infants, and young children, although MRI is superior. Ultrasound is also useful for imaging and surveillance of neck paragangliomas. Ultrasound examinations have also been performed endoscopically, from the stomach and duodenum, with a longitudinal sector array, yielding sensitive detection of small adrenal pheochromocytomas, lymphangitic metastases, and local recurrences. For pelvic and bladder paragangliomas, pelvic transvaginal ultrasound is very helpful for tumor localization and surveillance.

G. **Venous sampling for catecholamines (see Figure 11–9)** Selective venous sampling for catecholamines is dangerous, since the required venography can provoke a pheochromocytoma crisis. Venous sampling can help distinguish whether a mass is a secretory pheochromocytoma or paraganglioma. However, venous sampling is rarely required and seldom indicated.

**INCIDENTALLY DISCOVERED ADRENAL MASSES**

Clinically inapparent adrenal nodules are commonly discovered incidentally on abdominal CT or MRI scans that are performed for unrelated reasons. (See “Computed Tomography,” earlier.) Such nodules are known as *adrenal incidentalomas*. The incidence of adrenal nodules is about 3% in middle-aged, rising to 10% in the elderly. Most such nodules are small, benign adrenal adenomas, with densities below 10 HU on noncontrast CT. However, pheochromocytomas can produce nonspecific symptoms of abdominal pain, nausea, and weight loss, for which CT scans may be performed. Pheochromocytomas account for about 4% of incidentally discovered adrenal masses. In the United States nearly half of the pheochromocytomas diagnosed during life are detected incidentally on an abdominal or chest CT scan performed for other reasons. Therefore, all patients with adrenal
nodules, even normotensive, should be screened for pheochromocytoma with plasma-fractionated free metanephrines. A problem arises with metanephrines that are marginally elevated. Such patients with metanephrines that are one to two times higher than the reference range’s ULN have about a 30% chance of harboring a pheochromocytoma. Those with metanephrines more than twice the ULN have a very high risk of having a pheochromocytoma. For apparently nonfunctioning adrenal nodules, it is generally reasonable to observe those that are under 3 cm in maximum diameter. Nonfunctioning nodules that are 3 to 5 cm in maximum diameter require especially close surveillance. Adrenal nodules that are over 5 cm in diameter are generally resected, except for obvious myelolipomas. When pheochromocytoma has been ruled out, patients with an adrenal nodule should be screened for hyperaldosteronism and Cushing syndrome.

**Adrenal Percutaneous Fine-Needle Aspiration Biopsy**

Most pheochromocytomas can be readily diagnosed on the basis of their clinical, biochemical, and radiologic presentation. Fine-needle aspiration biopsy (FNAB) is not usually required for the diagnosis of a pheochromocytoma. However, some pheochromocytomas are discovered incidentally on abdominal CT or ultrasound and may be clinically or biochemically silent. Although there may be a temptation to biopsy such masses, patients with a suspicious adrenal or retroperitoneal mass require resting for pheochromocytoma before any biopsy. There is a 70% risk of complications after percutaneous FNAB of pheochromocytomas and paragangliomas. Such complications include: increased difficulty in the tumor’s resection (41%), severe hypertension (15%), hematoma (30%), severe pain (25%), and incorrect or inadequate biopsy (25%). FNAB cytology can be misinterpreted as a different primary malignancy or a metastasis from another malignancy; this potential for confusion is due to the fact that pheochromocytomas are rare tumors and have pleomorphic and hyperchromatic nuclei. Large left-sided pheochromocytomas have been misdiagnosed as carcinoma of the tail of the pancreas based on CT scanning and biopsy. Percutaneous biopsy can also disrupt the pheochromocytoma capsule and cause seeding of the tumor within the peritoneum.

**Medical Management of Pheochromocytoma and Paraganglioma**

Patients need to be treated with oral antihypertensives and stabilized hemodynamically prior to surgery. Patients receiving increasing doses of antihypertensive medications should have daily measurements of blood pressure and pulse rate in the lying, sitting, and standing positions. Additionally, patients are taught to determine their own blood pressure and pulse rate during any paroxysmal symptoms. Most clinicians gradually increase antihypertensive medications over 2 or more weeks. However, prolonged preoperative preparation has not proven more effective for preventing intraoperative hypertension than are shorter preparation periods. Some hypertensive patients have been admitted emergently for hypertension control and hydration, stabilized, and operated on successfully with intravenous infusion of a vasodilator drug (eg, nicardipine, nitroprusside, nitroglycerin; see discussed later). Ideally, the blood pressure should be reduced to an average of 130/85 mm Hg or less prior to surgery, while avoiding symptomatic orthostasis.

**A. Alpha-adrenergic blockers**

Alpha-adrenergic blockers have historically been used for most patients with pheochromocytoma in preparation for surgical resection. Patients who are normotensive are also usually treated (carefully) preoperatively. Phenoxybenzamine (10-mg capsules) is an oral nonselective alpha blocker that is the most commonly used alpha-blocking agent. It has a long half-life of about 24 hours. Patients with mild hypertension may be given phenoxybenzamine at a starting dosage of 10 mg once daily, while those with more severe hypertension may receive a starting dosage of 10 mg twice daily. The dose of phenoxybenzamine may be increased by 10 mg every 2 days until the blood pressure falls to an average of 130/85 mm Hg sitting or until symptomatic orthostatic hypotension occurs. Patients who have been normotensive between paroxysms are particularly prone to develop hypotension with phenoxybenzamine. Phenoxybenzamine does not block the synthesis of catecholamines; in fact, the synthesis of catecholamines and metanephrines tends to increase during alpha blockade. Therapy with phenoxybenzamine increases the heart rate but decreases the frequency of ventricular arrhythmias. Patients are encouraged to hydrate themselves well. Patients must be monitored daily for symptomatic orthostatic hypotension. Certain adverse effects are common, including dry mouth, headache, diplopia, inhibition of ejaculation, and nasal congestion. Nasal decongestants should not be used if urinary catecholamine determinations or \(^{123}\)I-MIBG scanning is planned, but antihistamines are acceptable. Phenoxybenzamine is not well tolerated as chronic therapy for hypertension in patients with unresctable or metastatic pheochromocytoma, and such patients are better treated with calcium channel blockers (see later), sometimes together with low-dose phenoxybenzamine.

Phenoxybenzamine crosses the placenta and accumulates to levels that are 60% higher in the fetus than in the maternal circulation; this can cause hypotension and respiratory depression in the newborn for several days following birth. Most patients require 30 to 60 mg/d, but the dosage is sometimes escalated to as high as 140 mg/d. Excessive alpha blockade with phenoxybenzamine is undesirable because it worsens postoperative hypotension. Furthermore, excessive alpha blockade may deny a critical surgical indicator (ie, a drop in blood pressure after complete resection of the tumor and aggravation of hypertension during palpation of the abdomen in case of multiple tumors or metastases).

Doxazosin is another alpha blocker with a half-life of about 22 hours. It is effective in the medical management of pheochromocytomas when given orally in doses of 2 to 16 mg daily. In one series, there was no difference in hemodynamic instability during surgery in patients pretreated with doxazosin versus
phenoxymenzamine. Alternatively, prazosin is a short-acting selective alpha blocker with a half-life of about 3 hours. It appears to cause less reflex tachycardia and less postoperative hypotension. With chronic use, it has been reported to cause less ejaculatory disturbance in men, compared to phenoxymenzamine. The starting dose of prazosin is 0.5 mg/d, increasing up to 10 mg twice or three times daily, if necessary.

B. Calcium channel blockers Calcium channel blockers are excellent antihypertensive agents for patients with pheochromocytomas. Patients tend to tolerate calcium channel blockers better than alpha blockers. Patients who are normotensive between paroxysms are less likely to become hypertensive with calcium channel blockers compared to alpha blockers. Patients with angina from coronary vasospasm are also best treated with calcium channel blockers. Perioperative fluid requirements have been lower among patients who were pretreated with calcium channel blockers instead of alpha blockers. In a French series, 70 patients with pheochromocytomas were successfully prepared for surgery using oral calcium channel blockers (usually nicardipine). Nicardipine may be given in doses of 20 to 40 mg orally every 8 hours; nicardipine is also available as a sustained-release preparation that may be given in doses of 30 to 60 mg orally every 12 hours.

Nifedipine is a calcium channel blocker that is administered as a slow-release preparation in doses of 30 to 60 mg orally once or twice daily. For hypertensive paroxysms, nifedipine 10 mg (chewed pierced capsule) is usually a fast and effective treatment. Chewed nifedipine is generally safe for use by patients with pheochromocytoma, who may self-administer the drug at home during paroxysms but only with close blood pressure monitoring. In one small study, nifedipine therapy appeared to improve the uptake of MIBG into pheochromocytomas in four of eight patients at scanning doses. It is possible that nifedipine might reduce the growth of pheochromocytomas and metastases, because in vitro nifedipine added to cultured pheochromocytoma cells reduces their mitotic index and proliferation. The effect of nifedipine on pheochromocytoma tumor growth in vivo has not been studied. Amlodipine may also be used for patients with pheochromocytoma in doses of 10 to 20 mg daily.

Other calcium channel blockers are reported to be less effective for patients with pheochromocytoma. Verapamil has been used in a sustained-release preparation, but has been reported to be associated with postoperative pulmonary edema after pheochromocytoma resection. Diltiazem has been reported to provide inadequate intraoperative blood pressure control.

Intravenous calcium channel blockers are useful for hypertensive crisis, particularly during surgery. Nicardipine and clevidipine are both available as intravenous preparations. (See “Surgical Management of Pheochromocytoma and Paraganglioma” later.)

C. Angiotensin-converting enzyme inhibitors ACE inhibitors have successfully treated hypertension in patients with pheochromocytomas but not as the sole agent. Angiotensin receptor blockers have also been successfully added to multidrug antihypertensive therapy. Catecholamines stimulate renin production. In turn, renin stimulates the production of angiotensin I, which is converted by ACE to angiotensin II; this can be blocked by ACE inhibitors. Furthermore, pheochromocytomas have been demonstrated to have angiotensin II-binding sites. ACE inhibitors are contraindicated in pregnancy, because their use in the second and third trimesters has been associated with fetal malformations, including skull hypoplasia, renal failure, limb and craniofacial deformation, lung hypoplasia, intrauterine growth retardation, patent ductus arteriosus, and death.

D. Beta-adrenergic blockers These agents are generally not prescribed for patients with pheochromocytomas until treatment has been started with antihypertensive medications such as α-adrenergic blockers or calcium channel blockers. Beta-adrenergic blockade should then be used for treatment of β-adrenergic symptoms such as flushing, pounding heart, or tachycardia. It is important to institute alpha blockade first, because blocking vasodilating β receptors without also blocking vasoconstricting α receptors can lead to hypertensive crisis if serum norepinephrine levels are high.

Nonselective beta blockers block both β1- and β2-adrenergic receptors. The inhibition of vasodilating arterial β1 receptors causes unopposed vasoconstrictive α-adrenergic stimulation that aggravates hypertension. Therefore, nonselective beta blockers should ordinarily not be administered to patients with pheochromocytoma or paraganglioma. Nonselective beta blockers include: nadolol, pindolol, propranolol, and timolol. Labelol and carvedilol are different nonselective β blockers that additionally block α1 receptors. Labetalol has been used to treat patients with pheochromocytoma; however, it can initially aggravate hypertension, produce false elevations of catecholamines in some assays, and reduce MIBG uptake.

Selective beta blockers specifically block β1-adrenergic receptors at low doses. This leads to a rather selective reduction in heart rate without unopposed alpha receptor dependent hypertension. However, at higher doses, these beta blockers also block β2-adrenergic receptors and can cause a paradoxical worsening of hypertension. Selective beta blockers include: atenolol, betaxolol, bisoprolol, nebivolol, esmolol, and metoprolol. Atenolol has a half-life of only 6 hours, so it does not produce satisfactory 24-hour blockade. Nebivolol has vasodilating activity through enhancement of nitric oxide release. Esmolol is the preferred intravenous preparation. Extended-release metoprolol (metoprolol ER) is the preferred oral preparation.

E. Metyrosine (α-methylparatyrosine) Metyrosine inhibits the enzyme tyrosine hydroxylase, which catalyzes the first reaction in catecholamine biosynthesis. Because of its potential side effects, it is usually used only to treat hypertension in patients with metastatic pheochromocytoma. Metyrosine is administered orally as 250-mg capsules, beginning with one every 6 hours; the dose is titrated upward every 3 to 4 days according to blood pressure response and side effects. Most patients can tolerate 2 g/d, but higher doses usually cause side effects. The maximum dosage is 4 g/d. Catecholamine excretion is usually reduced by 35% to 80%.
Preoperative treatment with metyrosine tends to reduce intraoperative hypertension and arrhythmias; however, postoperative hypotension is likely to be more severe for several days. Side effects of metyrosine include sedation, psychiatric disturbance, extrapyramidal symptoms, and potentiation of sedatives and phenothiazines. Crystalluria and urolithiasis can occur, so adequate hydration is mandatory. Metyrosine does not inhibit MIBG uptake by the tumor, allowing concurrent $^{123}$I-MIBG scanning or treatment with high-dose $^{131}$I-MIBG.

**F. Octreotide** Octreotide has not been formally studied or approved for use in patients with pheochromocytoma. However, octreotide (100 μg subcutaneously three times daily), has been reported to reduce hypertensive episodes and catecholamine excretion in a man with pheochromocytoma whose hypertensive paroxysms were uncontrolled using other means. Octreotide therapy has been observed to reduce bone pain in a woman with a malignant paraganglioma whose skeletal metastases were avid for $^{111}$In-labeled octreotide. Octreotide therapy is usually begun at a dose of 50 to 100 μg injected subcutaneously every 8 hours. Side effects are common and may include nausea, vomiting, abdominal pain, and dizziness. If the drug is tolerated, the dose can be titrated upward to a maximum of 1500 μg daily. Octreotide LAR can be given as subcutaneous injections in doses of 10 to 30 mg every 4 weeks.

**G. Activities to avoid** Vigorous exercise, particularly involving bending or heavy lifting, can aggravate hypertension in some individuals with pheochromocytoma, so mild exertion or rest is best during preparation for surgery. Emotional stress can provoke hypertensive attacks, so arguments and stressful situations are best avoided.

**H. Foods to avoid** Tyramine is a precursor to catecholamines and intravenous tyramine causes hypertension in most patients with pheochromocytoma. While dietary tyramine has not been studied in patients with pheochromocytoma, it is known that dietary tyramine can provoke hypertensive crisis in patients taking MAO inhibitor antidepressants. Therefore, although strict dietary precautions are not required, it is reasonable for patients with a known pheochromocytoma to avoid consuming large amounts of foods with high tyramine content during preparation for surgery such as red wine, tap beers, aged dairy products, aged meats, fermented or pickled fish, liver, protein extracts, overripe fruit, soybeans, tofu, fava bean pods, bean pastes, brewer's yeast pills, marmite, and vegemite.

**Surgical Management of Pheochromocytoma and Paraganglioma**

**A. Perioperative preparation** Prior to surgery, patients should be reasonably normotensive on medication, with an average blood pressure of 130/85 mm Hg or less, without symptomatic orthostasis (see earlier). They should also be well hydrated. It is ideal for patients to be admitted for administration of intravenous fluids at least 1 day prior to surgery. Patients may predominate blood for autologous transfusion. The transfusion of two units of blood within 12 hours before surgery reduces the risk of postoperative hypotension. Blood pressure must be monitored continuously during surgery. This requires placement of an arterial line, preferably in a large artery that is not prone to spasm (eg, femoral artery). A central venous pressure line helps determine the volume of fluid replacement. For certain high-risk patients with congestive heart failure or coronary artery disease, a pulmonary artery (Swan-Ganz) line may be inserted preoperatively to further optimize fluid replacement. Constant electrocardiographic monitoring is mandatory. Severe hypertension can occur—even in fully blocked patients—during bladder catheterization, intubation, or surgical incision. During laparoscopic surgery, catecholamine release is typically stimulated by pneumoperitoneum and by tumor manipulation. However, laparoscopic procedures cause less fluctuation of catecholamine levels and blood pressure than do open surgeries. All antihypertensive medications (see later) that might be required should be available and should be in the operating room well in advance.

Arterial embolization of the tumor can be performed immediately prior to surgery. This may be beneficial to the surgeon, particularly for the open resection of very large paragangliomas that tend to be extremely vascular and difficult to resect, due to blood loss and venous oozing. Embolization of neck paragangliomas is an established intervention. Secretory paragangliomas can also be embolized preoperatively. An experienced interventional radiologist must perform such embolizations with full monitoring and an anesthesia team in attendance.

The major problem during surgery for pheochromocytoma is hemodynamic instability. Serious blood pressure variations are more common in patients whose blood pressure has not been adequately pretreated. Intraoperative hemodynamic instability is also more common in patients with higher plasma norepinephrine levels and larger tumor size.

**B. Antihypertensive and antiarrhythmic drugs**

1. Calcium channel blockers—These are effective therapies for intraoperative hypertension. They can cause reflex tachycardia that can be controlled with intravenous beta blockers (eg, esmolol). Nicardipine is administered as an intravenous infusion, starting at a dose of 5 mg/h and increasing by 2.5 mg/h every 5 to 15 minutes up to 15 mg/h. Nicardipine was successfully used as the sole intraoperative vasodilating agent in one French series of 70 patients and in another series of 19 patients. Its half-life is 9 hours. Clevidipine has a shorter half-life of 1 to 15 minutes. It is available for intravenous infusion at a dose of 1 to 2 mg/h, doubling the dose after 90 seconds, then increasing in smaller increments at longer intervals (5-10 minutes) up to 4 to 6 mg/h or a maximum of 16 mg/h.

2. Phentolamine—It is a parenteral α-adrenergic blocker that has a short half-life of 19 minutes. It can be given intravenously in bolus doses, starting with 5 mg (children, 1-3 mg) and repeating in doses of 5 to 15 mg as needed for blood pressure control. Phentolamine may also be given by intravenous infusion at a rate of 0.5 to 1 mg/min. Side effects include
hypotension, tachycardia, cardiac arrhythmias, nasal stuffiness, nausea, and vomiting.

3. **Nitroprusside**—It is given by intravenous infusion and is an effective drug for managing hypertensive episodes; advantages include widespread familiarity with its use and its short half-life of 2 minutes. Nitroprusside is initiated at 0.25 to 0.3 μg/kg/min and titrated for the desired effect. The maximum infusion rate is 10 μg/kg/min for 10 minutes. High infusion rates should not be given for prolonged periods; long-duration (over 6 hours) nitroprusside infusion rates above 2 μg/kg/min cause cyanide accumulation and toxicity. Cyanide toxicity causes metabolic acidosis and an increase in venous oxygen saturation (>90%) in severe cases. If cyanide toxicity is suspected, the nitroprusside infusion must be stopped or slowed. In the United States, there are two different cyanide antidote kits available. (1) The conventional kit contains amyl nitrite, sodium nitrite, and thiosulfate. Administer an amyl nitrite crushed ampule at the end of the endotracheal tube or under the patient’s nose and give 10 mL 3% sodium nitrite intravenously. Also administer 25% sodium thiosulfate solution (50 mL) intravenously. (2) Additionally, hydroxocobalamin (Cyanokit) is available for intravenous administration at a dose of 5 g (children, 70 mg/kg). Coadministration of sodium thiosulfate (1 g/100 mg nitroprusside) prevents cyanide accumulation. Nitroprusside must be administered cautiously, since it can cause precipitous and profound hypotension, resulting in irreversible ischemic injuries.

4. **Nitroglycerin**—It is given by intravenous infusion and is effective therapy for perioperative hypertension. Nitroglycerin infusions are initiated at 5 μg/min and increased by 5 μg/min every 3 to 5 minutes until target blood pressure is achieved or a dose of 20 μg/min is reached; if the response has been insufficient, the dose can be increased by 10 to 20 μg/min every 5 minutes to a maximum of 100 μg/min. Because nitroglycerin adheres to polyvinyl chloride tubing, non-PVC infusion sets must be used. Nitroglycerin infusions can cause headache and hypotension. Methemoglobinemia has occurred during prolonged high-dose infusions and is manifested by cyanosis in the presence of a normal arterial pO2. The therapy for methemoglobinemia consists of immediately stopping the nitroglycerin and giving methylene blue, 1 to 2 mg/kg intravenously.

5. **Magnesium sulfate**—It is given intravenously in a bolus of 4 g over 15 minutes and has been reported to be effective in managing hypertension during resection of a pheochromocytoma during pregnancy.

6. **Lidocaine**—It may be used to treat cardiac ventricular arrhythmias. In adults, lidocaine is administered with a loading dose of 150 to 200 mg over about 15 minutes, or as a series of smaller boluses. This is followed by a maintenance infusion of 2 to 4 mg/min in order to achieve a therapeutic plasma level of 2 to 6 μg/mL.

7. **Beta blockers**—Atrial tachyarrhythmias may be treated with intravenous esmolol in 1-mg boluses or by constant intravenous infusion of esmolol, a short-acting beta blocker. Esmolol is given as an initial dose of 500 μg/kg intravenously over 1 minute, then continued at 50 μg/kg/min. If required, the infusion rate may be increased by 50 μg/kg/min every 4 minutes.

8. **Drugs to avoid**—Atropine should not be used as preoperative medication for patients with pheochromocytomas because it can precipitate arrhythmias and severe hypertension. Metoclopramide and glucagon can also precipitate a hypertensive crisis. MAO inhibitor antidepressants can provoke hypertensive crisis by blocking the metabolism of catecholamines. Other medications that can elicit hypertensive crisis include decongestants (eg, pseudoephedrine), epinephrine, amphetamines and amphetamine derivatives, and cocaine.

**Labetalol** is not recommended for preoperative or intraoperative management of pheochromocytomas because it aggravates postresection hypotension as a consequence of its long half-life. It can also paradoxically initially aggravate hypertension, because its beta-blocking effect may occur initially, allowing a brief period of unopposed α-receptor stimulation. Labetalol also inhibits MIBG uptake and causes misleading elevations in catecholamine determinations in certain assays. **Diazoxide** is ineffective against hypertension caused by pheochromocytoma.

C. **Anesthesia** Anesthetic agents such as intravenous propofol, enflurane, isoflurane, sufentanil, alfentanil, and nitrous oxide appear to be safe and effective. Atropine should not be used. Muscle relaxants with the least hypertensive effect should be employed (eg, vecuronium). Intraoperative hypertension can be managed by increasing the depth of anesthesia and by intravenous vasodilators for blood pressures over 160/90 mm Hg. Serum catecholamine levels drop sharply after adrenal vein ligation and profound hypotension can occur suddenly after resection of a pheochromocytoma. Therefore, it is prudent to stop the vasodilator infusion just prior to adrenal vein ligation.

D. **Operative management** Perioperative mortality is about 2.4% overall, but morbidity rates of up to 24% have been reported. Surgical complications do occur and include splenectomy, which is more common with open abdominal exploration than with laparoscopic surgery. Reported surgical complication rates have been higher in patients with severe hypertension and in patients having reoperations. Surgical morbidity and mortality risks can be minimized by adequate preoperative preparation, accurate tumor localization, and meticulous intraoperative care.

1. **Laparoscopy**—Most pheochromocytomas can be resected laparoscopically, which has become the procedure of choice for removing most adrenal neoplasms that are under 6 cm in diameter. Adrenal laparoscopic surgery is usually performed through 4 subcostal ports of 10 to 12 mm. Laparoscopic surgery is widely used now that preoperative localization of the tumor is possible. However, tumors that are invasive or over 6 cm in diameter are more difficult to resect laparoscopically and may require open surgery. For larger pheochromocytomas, a lateral laparoscopic approach can be used, because it affords greater opportunity to explore the abdomen and inspect the liver for metastases. For patients with small adrenal pheochromocytomas and for those who have had prior abdominal surgery, a posterior laparoscopic approach may be preferred.

The laparoscope allows unsurpassed magnified views of the pheochromocytoma and its vasculature. Pheochromocytomas are bagged to reduce the risk of fragmentation and spread of tumor cells within the peritoneum or at the port site. Larger tumors can be removed through laparoscopic incisions that can be widened for the surgeon’s
hand (laparoscopic-assisted adrenalectomy). With laparoscopic surgery, hypotensive episodes are less frequent and less severe. Laparoscopic adrenalectomy has other advantages also compared with open adrenalectomy: less postoperative pain, faster return to oral foods, and shorter hospital stays (median 3 days vs 7 days for the open approach). This approach is the least invasive for the patient, who can usually begin eating and ambulating the next day. The laparoscopic approach may be used during pregnancy. The technique has also been used successfully for certain extra-adrenal paragangliomas. Surgical mortality is under 3% at referral centers.

2. Needlescopic adrenalectomy—This procedure uses three subcostal ports of 3 mm, with a larger umbilical port for tumor removal. In one series of 15 patients, this technique reduced surgical times and recovery time compared with the standard laparoscopic approach. However, more extensive experience with this technique is required.

3. Adrenal cortex-sparing surgery—All patients undergoing bilateral total adrenalectomies require life-long glucocorticoid and mineralocorticoid hormone replacement. To avoid adrenal insufficiency, patients with benign familial or bilateral pheochromocytomas have had successful selective laparoscopic resection of small pheochromocytomas, sparing the adrenal cortex. Such adrenal-sparing surgery has unfortunately resulted in a pheochromocytoma recurrence rate of about 24%.

4. Open laparotomy—Open laparotomy is indicated for patients with particularly large pheochromocytomas or paragangliomas, or for those with intra-abdominal metastases that require debulking. Large vascular paragangliomas can be considered for preoperative arterial embolization, but its efficacy is uncertain. An open anterior midline or subcostal approach usually yields adequate exposure. For patients with paragangliomas of the urinary bladder, a partial cystectomy can sometimes be curative. Other patients with larger bladder paragangliomas require a total cystectomy and construction of a diverting uroenterostomy if the tumor has not been fully resected. For patients with a curative total cystectomy, construction of a new ileal neobladder is possible.

E. Therapy for shock occurring after pheochromocytoma resection—Severe shock and cardiovascular collapse can occur immediately following ligation of the adrenal vein during resection of a pheochromocytoma, particularly in patients having norepinephrine-secreting tumors. Such hypotension may be due to desensitization of α,-adrenergic receptors, persistence of antihypertensives, and low plasma volume. Preoperative preparation with calcium channel blockers or alpha blockade plus intravenous hydration or blood transfusions reduces the risk of shock. Intravenous antihypertensives are held just prior to ligation of the adrenal vein. Treatment of shock consists of large volumes of intravenous saline or colloid. Intravenous norepinephrine is sometimes required in very high doses.

F. Intravenous dextrose—Immediately following removal of a pheochromocytoma, intravenous 5% dextrose should be infused at a constant rate of about 100 mL/h to prevent the postoperative hypoglycemia that is otherwise frequently encountered.

Pregnancy and Pheochromocytoma

Pheochromocytomas occur in about 1 in every 50,000 pregnancies and are unrecognized antepartum in about 50% of cases. Such unsuspected pheochromocytomas result in a maternal mortality of 40% and a fetal mortality of 56%. However, if the diagnosis is made antepartum, the mortality is much lower. Hypertension is often misdiagnosed as eclampsia. Hypertensive crisis usually occurs during labor and can be associated with cardiac arrhythmias or pulmonary edema. Although maternal catecholamines do not cross the placenta, maternal hypertensive crisis is very dangerous for the fetus, causing uteroplacental insufficiency and fetal death.

Pregnant hypertensive patients are often treated with methyldopa that can cause false-positive testing for catecholamines by older fluorometric methodologies, but not by HPLC. Methyldopa does not cause interference with plasma or urine metanephrine measurements performed with tandem mass spectrometry. The localization of a pheochromocytoma in pregnancy is best done with MRI.

As soon as a pheochromocytoma is diagnosed, alpha blockade is commenced. Phenoxybenzamine is usually used. However, phenoxybenzamine crosses the placenta and accumulates in the fetus. After 26 days of maternal phenoxybenzamine therapy, cord blood levels in the newborn are 60% higher than the mother’s serum levels. Therefore, some perinatal depression and hypotension may occur in newborns of mothers receiving phenoxybenzamine. For maternal treatment near term, a short-acting selective alpha blocker (eg, prazosin) would have an obvious theoretical advantage over long-acting alpha blockers; chronic use increases the risk of fetal demise. The starting dose of prazosin is 0.5 mg/d orally, increasing up to 10 mg orally twice daily if necessary.

There has been little experience with the use of calcium channel blockers to treat hypertension in pregnant women with pheochromocytoma. However, calcium channel blockers can be safely used during pregnancy and are not teratogenic in the first trimester. Therefore, nifedipine or nicardipine may be used to supplement or replace alpha blockade as needed.

If possible, beta blockade should not be used at all during pregnancy. Propranolol crosses the placenta and can cause intrauterine growth restriction. Newborns of mothers taking propranolol at delivery exhibit bradycardia, respiratory depression, and hypoglycemia. Therefore, during cesarean delivery, serious atrial tachyarrhythmias should be controlled by a short infusion of esmolol, a beta blocker with a very short half-life.

During the first 6 months of pregnancy, it is often possible to treat a woman with alpha blockade, followed by laparoscopic resection of the tumor. Although the fetus usually survives, spontaneous abortion is common despite a successful resection of the tumor. If a pheochromocytoma is not discovered until the last trimester, treatment consists of alpha blockade followed by elective cesarean delivery as early as feasible. Intravenous magnesium sulfate is a useful antihypertensive during surgery. Intravenous calcium channel blockers may be used to treat patients with hypertensive crisis caused by pheochromocytoma in pregnancy. The tumor is resected after the cesarean delivery. In the presence of an active pheochromocytoma, vaginal delivery...
Pathology of Pheochromocytoma and Paraganglioma

On histopathology, pheochromocytomas are extremely vascular tumors with neurosecretory granules. Central necrosis is often present. The cells may be arranged in nests (zellballen pattern), anastomosing cords (trabecular pattern), or a combination of both. Cells vary in size with pleomorphic and eccentric nuclei that are often large and bizarre in appearance. The cells exhibit immunofluorescence staining for CgA and synaptophysin.

No single characteristic of pheochromocytoma or paraganglioma can determine whether a given tumor is malignant. Therefore, the definition of malignancy is based upon whether metastases are present. Metastases must be distinguished from additional paragangliomas by their location (liver, lung, bone) where sympathetic paraganglia are rare. Metastases must also be distinguished from intraportal seeding, a phenomenon known as pheochromocytomatosis. Metastases can vary in virulence from relatively indolent to extremely aggressive (see discussion on malignant pheochromocytoma later).

Overall, about 26% of these tumors arise in patients with identifiable germline mutations. Individuals with no known family history of these tumors have about a 17% risk of harboring a known germline mutation. About 18% of cases develop in children. The earlier a tumor presents, the more likely that individual harbors a germline mutation. (See discussion on genetics of pheochromocytoma and paraganglioma, earlier.)

Adrenal pheochromocytomas and paragangliomas appear very similar on microscopy. Paragangliomas are often large and arise near the adrenal, making the distinction particularly difficult based upon preoperative localization scans. But it is important to distinguish these two tumors because paragangliomas are more likely to metastasize. One way to distinguish these tumors preoperatively is to evaluate their secretions. Tumors that secrete epinephrine (or its metabolite, metanephrine) are predictably adrenal pheochromocytoma. However, tumors that secrete strictly norepinephrine (or its metabolite normetanephrine) may be either pheochromocytoma or paraganglioma. Intraoperatively, the surgeon may be able to identify the adrenal gland as separate from the tumor. On pathology, it is often possible to visualize the adrenal cortex lying in close proximity to the pheochromocytoma or even arising out of the adrenal medulla. An intact adrenal gland may be included in the surgical specimen, indicating that the tumor was a juxta-adrenal paraganglioma. On microscopy, paragangliomas may have visible nerve ganglia.

Composite pheochromocytomas are rare tumors that exhibit histopathologic features of both pheochromocytoma and neuroblastoma. Such tumors have generally not recurred and have not exhibited N-myc amplification, which distinguishes them from typical neuroblastomas. Therefore, composite pheochromocytomas are considered to be a histological variant of pheochromocytomas.

Metastatic Pheochromocytoma and Paraganglioma (Table 11–17)

No pheochromocytoma or paraganglioma should be labeled benign. Histopathology cannot reliably determine whether a given tumor has metastasized. Such metastases can be microscopic and indolent, eluding detection with the most sensitive scanning and biochemical screening. Therefore, it is best to think of these tumors as either having detectable metastases (metastatic pheochromocytoma) or having no detectable metastases.

It is conceivable that all pheochromocytomas and paragangliomas metastasize single cells but that such cells will only grow if certain genes are downregulated and other genes upregulated. This concept is supported by genome-wide expression profiling of pheochromocytomas. These profiles have identified candidate genes that are differentially expressed in tumors with detectable metastases versus those with no detectable metastases. Gene expression arrays of pheochromocytomas with detectable metastases have demonstrated that five genes are differentially upregulated in these tumors.

Research in malignant pheochromocytoma has been hampered by the absence of a viable human cell line. However, a highly malignant mouse pheochromocytoma model has been developed in which a gene expression array has demonstrated the upregulation of 8 genes and the downregulation of 38 genes.

The risk for detectable metastases is higher under the following circumstances: extra-adrenal location (paraganglioma) or extensive local invasion. One surgical observation is that tumors that are stickier and more difficult to dissect from adjacent tissue are more likely to recur or metastasize. Tumors are also more likely to metastasize if they contain high levels of Ki-67, a protein expressed in proliferating cells that can be detected by the monoclonal antibody MIB-1 and quantified as a high MIB-1 score. Metastatic pheochromocytomas also have increased activity of telomerase. Tumors with high c-Myc gene expression are more likely to be malignant. In one series, 50% of patients with malignant pheochromocytoma were found to have high serum levels of NSE, but in none of 13 patients in another series with benign pheochromocytomas.

Metastases are evident at the time of diagnosis in about 10% of patients with an adrenal pheochromocytoma. Another 5% to 10% are found to have metastatic disease or local recurrence within 20 years. In genetic syndromes, pheochromocytomas have been found to be metastatic or locally invasive at the time of diagnosis as follows: MEN 2A, 4%; VHL, 8%; and NF-1, 12%. Extra-adrenal paragangliomas commonly metastasize. In a Mayo Clinic series of paragangliomas, 15% had local invasion and 21% had detectable distant metastases at the time of initial surgery, with an overall 36% risk of local or distant metastasis.

Malignancy is determined only by the presence of metastases. CT or MRI scanning may not detect small metastases within their field and will certainly not visualize metastases outside their field. Therefore, following the resection of an apparently benign PHEO or PGL, long-term surveillance is required because metastases may not become clinically apparent for years or decades. Such surveillance includes regular lifetime clinical assessment and biochemical
testing as indicated. Plasma-fractionated metanephrines is the most sensitive test to detect early recurrence or metastases. However, screening for metastases from nonsecretory paragangliomas should include serum CgA determinations. Plasma metanephrines and serum CgA usually fall into the normal range by 2 weeks following successful resection of a single benign pheochromocytoma. However, sensitive test to detect early recurrence or metastases. However, serum CgA usually fall into the normal range by 2 weeks following surgery. Plasma metanephrines and CgA are occasionally involved. Patients with metastases and an SDHB mutation have a higher prevalence of metastases involving long bones compared to those without the mutation. PHEO/PGL metastases have a proclivity for the skull where they may form a dumbbell-type lesion, sometimes being palpable as a soft cyst-like bump; they also may grow inside the skull to impinge upon the brain. Prevertebral paragangliomas may destroy adjacent vertebrae, and spinal cord compression may occur. Most bone metastases affect the cortical bone; they may be indolent, but are often osteolytic and cause progressive bone destruction. Other bone metastases primarily involve trabecular bone and marrow; such metastases are usually visible on MRI but may be invisible on CT. Metastases to lymph nodes outside the abdomen are most frequent in the supraclavicular and inguinal regions. Metastases to muscle are usually indolent. These tumors have not been reported to metastasize to brain, although metastases to the cranium and skull base may impinge upon the brain, pituitary, and cranial nerves.

**Sites of metastasis (see Table 11-17):** Metastases from pheochromocytomas or paragangliomas typically involve bones (82%), liver (30%), lungs (36%), lymph nodes, the contralateral adrenal, and sometimes muscle. The bones most frequently involved include vertebrae, pelvis and ischium, clavicles, cranium, and proximal femurs and humeri. Tibia, radius, and ulna are occasionally involved. Patients with metastases and an SDHB mutation have a higher prevalence of metastases involving long bones compared to those without the mutation. PHEO/PGL metastases have a proclivity for the skull where they may form a dumbbell-type lesion, sometimes being palpable as a soft cyst-like bump; they also may grow inside the skull to impinge upon the brain. Prevertebral paragangliomas may destroy adjacent vertebrae, and spinal cord compression may occur. Most bone metastases affect the cortical bone; they may be indolent, but are often osteolytic and cause progressive bone destruction. Other bone metastases primarily involve trabecular bone and marrow; such metastases are usually visible on MRI but may be invisible on CT. Metastases to lymph nodes outside the abdomen are most frequent in the supraclavicular and inguinal regions. Metastases to muscle are usually indolent. These tumors have not been reported to metastasize to brain, although metastases to the cranium and skull base may impinge upon the brain, pituitary, and cranial nerves.

**Metastases usually secrete norepinephrine and normetanephrine.** Some metastases secrete predominantly dopamine. Metastases rarely secrete epinephrine or metanephrine, with the exception of some metastases from epinephrine-secreting adrenal pheochromocytomas. About 20% of primary paragangliomas and their metastases do not secrete catecholamines or metanephrines, but most continue to secrete CgA, which becomes a valuable tumor marker.

**Assessing the growth rate of PHEO/PGL metastases:**

Treatment can be tailored to the tumor's rate of growth. Knowledge of the growth rate of a patient's metastases may be obtained through close biochemical surveillance and serial volumetric imaging with CT or MRI. Patients who are asymptomatic with a few indolent osseous metastases may elect to receive bisphosphonate therapy and delay life-threatening chemotherapy or radioisotope therapy, as long as they remain under close surveillance. Even patients with a symptomatic osteolytic metastasis may elect to receive targeted therapy rather than systemic treatment if their overall tumor burden is low.

**Surveillance:** A series of 110 Swedish patients with PHEO/PGL, treated surgically, found an unexpectedly high relative risk for developing non-PHEO/PGL malignancies (RR ≥ 2.0). Therefore, additional tumors should not be presumed to be metastases unless they have uptake on MIBG scanning or 18F-FDG-PET scanning. Suspicious lesions without such uptake should be considered for biopsy. Patients with hereditary forms of PHEO or PGL can present with bilateral disease or develop second primaries, distinct from metastatic disease.

**Biochemical surveillance:** Such screening is best done with plasma-fractionated metanephrines and catecholamines (with dopamine), along with serum CgA. While this is sensitive for secretory metastases, false-positive testing occurs commonly. Adrenal PHEOs usually secrete both norepinephrine and epinephrine; metastases from adrenal PHEOs may sometimes continue to produce epinephrine, but more commonly produce norepinephrine and its metabolite normetanephrine. Extra-adrenal PGLs ordinarily produce only norepinephrine and normetanephrine and sometimes only CgA; their metastases do likewise.

**Scan surveillance:** CT or MRI scanning is the most sensitive for recurrence; however, they will not detect metastases that are outside their field and obtaining full-body CT or MRI scanning is logistically difficult. Radionuclide scanning is advantageous in that the entire body may be included in the scan. However, no radionuclide scan is 100% sensitive. PHEO/PGL metastases have variable avidity for MIBG. Even when the primary tumor is avid for MIBG, some or all of the metastases may not be visible on MIBG scanning. Some metastases are deficient in norepinephrine transporter (NET) expression and are invisible on 123I-MIBG scanning, such that the scan's sensitivity for metastasis is only 57%. In a given individual, some metastases may be avid for MIBG, while others show virtually no uptake. When patients have a recurrence or progression of metastases after 131I-MIBG therapy, metastases with less MIBG-avid are usually the ones that emerge or progress in size. When such imaging is negative, metastases may be detected with MRI or CT scanning. Metabolically active metastases are usually visible with 18F-FDG-PET scanning.

Note: One case of abdominal recurrence was peritoneal seeding (pheochromocytomatosis).
which has the additional advantage of being a whole-body scan with a sensitivity of about 76% for metastases. 18F-FDA-PET has a sensitivity of about 78% for metastases. Octreoscan will often detect metastases that are not visible with other scans.

**A. Surgery** It is usually best to resect the primary tumor as well as large metastases. This is especially true of secretory tumors that are causing hypertension and other symptoms that can be a threat to life. Even lung metastases may be resected. However, the decision about whether to resect metastases is a difficult one and must be based upon very thorough staging of the patient's tumor. Of course, when resecting secretory metastases, preoperative preparation is mandatory and hypertension must be adequately controlled.

**B. Chemotherapy** Due to the rarity of pheochromocytoma and paraganglioma, there have been no large-scale series comparing available chemotherapies. However, there have been small series of patients and case reports from which to derive recommendations.

In vitro studies have found that cultured pheochromocytoma cells are protected from cytotoxic insult by amitriptyline and fluoxetine, possibly through upregulation of superoxide dismutase. Therefore, patients being treated for metastatic pheochromocytoma or paraganglioma should probably not take tricyclic antidepressants or selective serotonin reuptake inhibitors, although there have been no in vivo studies of their effect on survival.

Cyclophosphamide, vincristine, dacarbazine (CVD): In one series, 8 of 14 patients responded to this regimen, with a median remission of 21 months. CVD was delivered over 2 days and the cycles repeated every 3 to 4 weeks, indefinitely. After controlling symptoms of catecholamine excess, cycles of CVD were administered as follows: cyclophosphamide 750 mg/m², vincristine 1.4 mg/m², and dacarbazine 600 mg/m² on day 1, followed by dacarbazine 600 mg/m² on day 2. Metastases progressed in 9 of the 14 patients, and there were 6 deaths with short-term follow-up. About one-third of patients appear to have a sustained remission or stable disease, as long as CVD is continued. When chemotherapy is stopped, the tumors usually recur. Many patients cannot tolerate such a long-term regimen, due to fatigue, cytopenias, neuropathy, and other adverse reactions. However, some patients tolerate it reasonably well and may experience a complete biochemical remission. Once in remission, CVD cycles are continued at gradually increasing intervals. If complete biochemical remission is achieved, chemotherapy may be stopped, while the patient is kept under close surveillance for progressive disease.

**Sunitinib:** Partial remissions in metastatic pheochromocytoma have been reported with sunitinib, a tyrosine kinase inhibitor. Sunitinib is administered orally, usually in a dose of 50 mg daily in cycles of 4 weeks on, then 2 weeks off. The dosage may be adjusted in 12.5-mg increments according to response and toxicity. Sunitinib is metabolized in the liver by CYP3A4, so dose adjustments should be made for patients taking the wide variety of drugs that are inhibitors or inducers of CYP3A4. Sunitinib can cause serious adverse reactions, including heart failure, cardiac arrhythmias, marrow suppression, pancreatitis, hypo- or hyperthyroidism, nephrotic syndrome, and rhabdomyolysis with acute renal failure. Patients treated with sunitinib also commonly experience nausea, vomiting, diarrhea, hypertension, skin discoloration, mucositis, asthenia, dyspnea, myalgias, and arthralgias. The use of sunitinib has been limited by its expense.

**C. Bisphosphonates** No controlled clinical trials have assessed the efficacy of bisphosphonates against osteolytic bone metastases from paragangliomas and pheochromocytomas. However, bisphosphonates have demonstrated effectiveness in other osteolytic solid tumors to reduce skeletal-related adverse events. Zoledronic acid is usually administered every 1 to 2 months as an intravenous infusion to patients with osteolytic bone metastases. Patients unable to tolerate zoledronic acid may tolerate intravenous pamidronate.

**D. Radiation therapy** When administered to patients with symptomatic spinal or cranial metastases, radiation therapy can reduce pain and produce neurologic improvement. Although conventional radiation therapy is usually administered, Gamma Knife can be given to smaller symptomatic bone metastases. Conventional radiation therapy to large primary tumors or intra-abdominal metastases is not advisable, because it is usually ineffective and causes morbidity such as radiation enteritis and a proclivity to later surgical complications such as wound dehiscence, infections, and fistulas. However, small recurrent tumors can be treated with CyberKnife stereotactic radiosurgery. Radiation therapy to tumors reduces their uptake of 131I-MIBG. Surgical debulking of large abdominal or thoracic tumors (or other therapies) is usually preferable to radiation therapy.

**E. Arterial embolization and radiofrequency ablation** Before arterial embolization or radiofrequency ablation, patients with secretory pheochromocytomas or paragangliomas must be fully prepared such that their blood pressure is near normal as described earlier. Pretreatment includes alpha blockade and/or other measures such as beta blockade, calcium channel blockers, or metyrosine. Patients are monitored with arterial blood pressure transducers and given a central line before endotracheal general anesthesia. Anesthesia standby is necessary in case severe hypotension occurs, and it becomes necessary to administer intravenous antihypertensive drugs.

Arterial embolization has been used on rare occasions to reduce blood flow to paragangliomas and pheochromocytomas, either in preparation for surgery or for inoperable cases. These tumors are usually very vascular and preoperative embolization may reduce intraoperative hemorrhage. Also, embolizing the tumor's blood supply may slow its growth. However, there have been no controlled clinical trials as to its effectiveness. A major potential risk of embolization is that of pheochromocytoma crisis. However, embolization has been used successfully on secretory tumors where the patient has been fully prepared with alpha blockade and/or other measures. Localization arteriograms should use non-ionic contrast.
Radiofrequency (RF) thermal ablation has been used successfully for patients with metastatic PHEO/PGL, particularly for liver and bone metastases. Most reported RF ablations of bone metastases have targeted rib or ischial/pelvic lesions. Before RF ablations, the RF electrode(s) is guided into the tumor with ultrasound and CT guidance. Single electrodes may be used for small lesions, while metastases over 2.5 cm diameter usually require triple parallel cluster needle electrodes.

F. \(^{131}\text{I-MIBG therapy (Figure 11-13)}\) \(^{131}\text{I-MIBG is a treatment option for patients with metastatic or unresectable pheochromocytoma or paraganglioma whose tumors are avid for the isotope.}^{131}\text{I-MIBG therapy was developed at the University of Michigan and first administered to patients with metastatic pheochromocytomas in 1983. Subsequently, many other patients have been treated with}^{131}\text{I-MIBG. Treatment protocols have employed repeated doses of 100 to 200 mCi (3.7-7.4 GBq) or larger single doses of 500 to 1000 mCi (18.5-37 GBq). Uptake occurs in many nonfunctioning pheochromocytomas and metastases, and such treatment can be effective for these tumors as long as scanning demonstrates that they are avid for MIBG. Following therapy with}^{131}\text{I-MIBG, once background radiation has dissipated, a posttreatment whole-body scan is obtained.}^{131}\text{I-MIBG therapy, patients are premedicated with potassium iodide to reduce the risk of thyroid damage that could be caused by any free}^{131}\text{I generated through metabolism of}^{131}\text{I-MIBG. Patients are pretreated with nonphenothiazine antiemetics; they remain hospitalized in lead-shielded rooms until the emitted gamma radiation declines to acceptable levels, which usually requires about 5 to 7 days. Complete or partial remissions, defined by strict RECIST (Response Evaluation Criteria in Solid Tumors), occur in about 22% of patients treated with}^{131}\text{I-MIBG, while an additional 35% have minor responses and 8% have stable disease. However, 35% of patients experience progressive disease within a year after therapy. High-dose}^{131}\text{I-MIBG appears to improve 5-year survival. It predictably causes some degree of bone marrow suppression that commences about 2.5 weeks after therapy. Other adverse reactions include nausea, occasional sialadenitis, and transient hair, hypogonadism, infertility, and an increased lifetime risk of second malignancies, particularly myelodysplasia and leukemia. ARDS and bronchiolitis obliterans organizing pneumonia (BOOP) are rare complications of treatment with}^{131}\text{I-MIBG that have rarely occurred in patients treated with doses over 800 mCi. Repeated treatments may be required. About 30% to 40% of patients with metastatic PHEO or PGL have insufficient uptake of MIBG for treatment to be effective. Also, there can be variable MIBG uptake into metastases in a given patient. So, theoretically, therapy with}^{131}\text{I-MIBG could be
made more effective if the tumor’s uptake of MIBG could be increased. Pretreatment with nifedipine increased MIBG retention in four of eight patients in one report. Some patients with good uptake of MIBG on diagnostic scanning have disappointingly poor uptake of large therapeutic doses of $^{131}$I-MIBG, possibly caused by competitive inhibition by large amounts of nonradioactive $^{127}$I-MIBG that are present in most formulations of $^{131}$I-MIBG.

**Prognosis**

The mortality rate for patients undergoing pheochromocytoma resection has dropped to under 3% due to improved medical preparation and surgical technique. Laparoscopic resections have reduced perioperative morbidity and shortened the length of hospitalization. However, even after complete resection of the pheochromocytoma, hypertension persists or recurs in 25% of patients. Recurrent hypertension is an indication for reevaluation for pheochromocytoma.

Following surgical resection of a benign pheochromocytoma, patients have a 5-year survival rate of 96%. Risk factors for death from pheochromocytoma include tumor size over 5 cm, metastatic disease, and local tumor invasion. However, the long-term mortality rate is much higher than expected. In a Swedish long-term outcome study of 121 patients with pheochromocytoma, there was no perioperative mortality, but 50% of patients remained hypertensive postoperatively. Of the 121 patients, 42 died during an observation period averaging 15 years, versus an expected 24 deaths in an age-matched control population. Thus, their relative risk of mortality was increased 78% (1.78). Of the 42 patients who died, 20 deaths were due to cardiovascular disease, 6 from associated neuroectodermal tumors, 5 from other malignancies, 7 from unrelated causes, and 4 from malignant pheochromocytoma.

Patients with pheochromocytoma or paraganglioma metastases have an average 5-year survival of about 50% from the time that metastases are detected. However, for patients in whom close surveillance and scanning find presymptomatic metastases, the average 5-year survival is probably longer, simply because the metastases are diagnosed at an earlier stage. Also, metastases are variably aggressive, between patients and within a given patient. Some metastases are quite indolent and may present clinically one or two decades after resection of the primary tumor. However, other metastases are exceptionally aggressive. Asymptomatic patients with only a few bone metastases tend to have the best prognosis, while those with a heavy burden of liver and lung metastases tend to have the most malignant disease.

Additionally, patients should be tested for familial genetic syndromes and appropriately screened for associated malignancies (see “Genetic Conditions Associated with Pheochromocytomas and Paragangliomas,” Tables 11-8 through 11-11). Persistent symptoms or hypertension can signify recurrence at the surgical site, seeding of the peritoneum, a contralateral pheochromocytoma, a paraganglioma, or possibly metastatic disease. About 10% of pheochromocytomas have metastasized at the time of diagnosis or soon postoperatively. However, occult metastatic disease is detected up to 20 years later in another 5%. Other patients develop multiple recurrent intra-abdominal tumors (pheochromocytomatosis) probably caused by tumor seeding that may occur spontaneously from the original tumor or during surgery.

Patients with secretory tumors are usually followed with plasma-fractionated free metanephrine determinations. Plasma-fractionated catecholamines and dopamine may also be obtained if they were predominantly secreted by the primary tumor. The first determination of postoperative plasma-fractionated free metanephrines is obtained at least 2 weeks after surgery, because catecholamine excretion often remains high for up to 10 days after successful surgery. Testing is obtained quarterly during the first year following surgery, then annually or semiannually for at least 5 years. Serum CgA is a useful tumor marker for patients with pheochromocytomas whose primary tumor secreted CgA and whose renal function is normal; elevated and rising levels of CgA usually indicate tumor recurrence or metastases. (See Chromogranin A, earlier.) Rarely, nonfunctioning tumors may later develop functioning metastases. Lifetime medical follow-up is required. Patients should continue to have annual physical examinations for life. Long-term biochemical follow-up is tailored to the individual patient.

For hypertensive patients, weekly home blood pressure monitoring is recommended for the first year postoperatively and monthly afterward. A rising blood pressure or recurrence of symptoms should trigger a full work-up for recurrent or metastatic pheochromocytoma.

A postoperative $^{123}$I-MIBG scan or PET scan is recommended for all patients—but especially for those in whom there is any doubt about complete resection of the pheochromocytoma and for any patients with paraganglioma or multiple tumors. The postoperative scan is usually obtained several months after surgery. PET scanning is particularly useful for patients with metastatic PHEO/PGL or nonsecreting paragangliomas.

CHAPTER 11 Adrenal Medulla and Paraganglia 393
The testes contain two major components that are structurally separate and serve different functions. The **Leydig cells**, or interstitial cells, comprise the major endocrine component. The primary secretory product of these cells, testosterone, is responsible either directly or indirectly for embryonic differentiation along male lines of the external and internal genitalia, male secondary sexual development at puberty, and maintenance of libido and potency in the adult male. The **seminiferous tubules** comprise the bulk of the testes and are responsible for the production of approximately 30 million spermatozoa per day during male reproductive life (puberty to death).

Both of these testicular components are interrelated, and both require an intact hypothalamic-pituitary axis for initiation and maintenance of their function. In addition, several accessory genital structures are required for the functional maturation and transport of spermatozoa. Thus, disorders of the testes, hypothalamus, pituitary, or accessory structures may result in abnormalities of androgen or gamete production, infertility, or a combination of these problems.

**ANATOMY AND STRUCTURE-FUNCTION RELATIONSHIPS**

**TESTES**

The adult testis is a prolate spheroid with a mean volume of 18.6 ± 4.8 mL. The average length is 4.6 cm (range, 3.6-5.5 cm), and the average width is 2.6 cm (range, 2.1-3.2 cm). The testes are located within the scrotum, which not only serves as a protective envelope but also helps to maintain the testicular temperature approximately 2°C (35.6°F) below abdominal temperature. Three layers of membranes—visceral tunica vaginalis, tunica albuginea, and tunica vasculosa—comprise the testicular capsule. Extensions of the tunica albuginea into the testicle as fibrous septa result in the formation of approximately 250 to 300 pyramidal lobules, each of which contains coiled seminiferous tubules. Within each testis there are over 400 meters of seminiferous tubules, and these structures account for about half of the testicular mass. The approximately 200 million androgen-producing Leydig cells, as well as the blood and lymphatic vessels, nerves, and fibroblasts, are interspersed between the seminiferous tubules.

The blood supply to the testes is derived chiefly from the testicular arteries, which are branches of the internal spermatic arteries. After traversing a complicated capillary network, blood enters multiple testicular veins that form an anastomotic network, the pampiniform plexus. The pampiniform plexuses coalesce to form the internal spermatic veins. The right spermatic vein drains directly into the vena cava; the left enters the renal vein.

The seminiferous tubules in the adult average 165 μm in diameter and are composed of Sertoli cells and germinal cells. The Sertoli cells line the basement membrane and form tight junctions with other Sertoli cells. These tight junctions prevent the passage of proteins from the interstitial space into the lumens of the seminiferous tubules, thus establishing a **blood-testis barrier**. Through extension of cytoplasmic processes, the Sertoli cells surround developing germ cells and provide an environment essential for germ cell differentiation. In addition, these cells have been shown to be responsible for the movement of germ cells from the

base of the tubule toward the lumen and for the release of mature sperm into the lumen. These cells also actively phagocytose damaged germ cells and residual bodies, which are portions of the germ cell cytoplasm not used in the formation of spermatozoa. Finally, in response to follicle-stimulating hormone (FSH) or testosterone, the Sertoli cells secrete androgen-binding protein, a molecule with high affinity for androgens. This substance, which enters the tubular lumen, provides a high concentration of testosterone to the developing germinal cells during the process of spermatogenesis.

More than a dozen different types of germ cells have been described in males. Broadly, they can be classified as spermatogonia, primary spermatocytes, secondary spermatocytes, spermatids, and spermatozoa. Spermatogenesis occurs in an orderly fashion, with the spermatocytes being derived from the spermatogonia via mitotic division. Through meiotic (or reduction) division, the spermatids are formed; they contain a haploid number of chromosomes (23). The interval from the beginning of spermatogenesis to release of mature spermatozoa into the tubular lumen is approximately 64 days. Although there is little variation in the duration of the spermatogenic cycle, a cross-section of a seminiferous tubule demonstrates several stages of germ cell development.

ACCESSORY STRUCTURES

The seminiferous tubules empty into a highly convoluted anastomotic network of ducts called the rete testis. Spermatozoa are then transported through efferent ductules and into a single duct, the epididymis, by testicular fluid pressure, ciliary motion, and contraction of the efferent ductules. During the approximately 12 to 14 days required for transit through the epididymis, spermatozoa undergo morphologic and functional changes essential to confer on the gametes the capacity for fertilizing an ovum. The epididymis also serves as a reservoir for sperm. Spermatozoa stored in the epididymis enter the vas deferens, a muscular duct 35 to 50 cm long that propels its contents by peristaltic motion into the ejaculatory duct.

In addition to the spermatozoa and the secretory products of the testes, retia testis, and epididymides, the ejaculatory ducts receive fluid from the seminal vesicles. These paired structures, 4.5 to 5.5 cm long, are composed of alveolar glands, connective tissue, and muscle. They are the source of seminal plasma fructose, which provides nourishment to the spermatozoa. In addition, the seminal vesicles secrete seminogelin I, phosphorylcholine, ergothioneine, and spermatozoa. During the approximately 12 to 5.5 cm long, are composed of alveolar glands, connective tissue, and muscle. They are the source of seminal plasma fructose, which provides nourishment to the spermatozoa. In addition, the seminal vesicles secrete seminogelin I, phosphorylcholine, ergothioneine, and spermatozoa. Fluid is also added to the seminal plasma by the bulbourethral (Cowper) glands and urethral (Litre) glands during its transit through the penile urethra.

PHYSIOLOGY OF THE MALE REPRODUCTIVE SYSTEM

GONADAL STEROIDS (FIGURE 12–2)

The three steroids of primary importance in male reproductive function are testosterone, dihydrotestosterone, and estradiol. From a quantitative standpoint, the most important androgen is testosterone. Over 95% of the testosterone is secreted by the testicular Leydig cells. In addition to testosterone, the testes secrete small amounts of the potent androgen dihydrotestosterone and the weak androgens dehydroepiandrosterone (DHEA) and androstenedione. The Leydig cells also secrete small quantities of estradiol, estrone, pregnenolone, progesterone, 17α-hydroxyprogrenolone, and 17α-hydroxyprogesterone. The steps in testicular androgen biosynthesis are illustrated in Figure 12–2.

Dihydrotestosterone and estradiol are derived not only by direct secretion from the testes but also by conversion in peripheral tissues of androgen and estrogen precursors secreted by both the testes and the adrenals. Thus, about 80% of the circulating concentration of these two steroids is derived from such peripheral conversion. Table 12–1 summarizes the approximate contributions of the testes, adrenals, and peripheral tissues to the circulating levels of several sex steroid hormones in men.

In the blood, androgens and estrogens exist in either a free (unbound) state or as bound to serum proteins. Although about 38% of testosterone is weakly bound to albumin, the major binding protein is sex hormone–binding globulin (SHBG), a high affinity, low capacity binding protein, which binds 60% of the testosterone. This glycosylated dimeric protein is homologous to, yet distinct from, the androgen-binding protein secreted by the Sertoli cells. SHBG is synthesized in the liver, with the gene located on the short arm of chromosome 17. The serum concentrations of this protein are increased by estrogen, tamoxifen, phenytoin, or thyroid hormone administration and by hyperthyroidism and cirtosis and are decreased by exogenous androgens, glucocorticoids, or growth hormone and by hypothyroidism, acromegaly, obesity, and hyperinsulinemic states. About 2% of the circulating testosterone is not bound to serum proteins and is able to enter cells and exert its metabolic effects. In addition, some of the albumin–bound testosterone may dissociate from the protein and enter target tissues; thus, the amount of bioavailable testosterone may be greater than just the amount of non–protein-bound testosterone.

As noted later, testosterone may be converted to dihydrotestosterone within specific androgen target tissues. Most circulating testosterone is converted primarily by the liver into various metabolites such as androstanediol and etiocholanolone, which, after conjugation with glucuronic or sulfuric acid, are excreted in the urine as 17-ketosteroids. However, it should be noted that only 20% to 30% of the urinary 17-ketosteroids are derived from testosterone metabolism. The majority of the 17-ketosteroids are
formed from the metabolism of adrenal steroids. Therefore, 17-ketosteroid determinations do not reliably reflect testicular steroid secretion.

Testosterone leaves the circulation and rapidly traverses the cell membrane (Figure 12–3). In most androgen target cells, testosterone is enzymatically converted to the more potent androgen dihydrotestosterone by the microsomal isoenzyme 5α-reductase-2, which has a pH optimum of 5.5. Another isoenzyme, 5α-reductase-1, has a pH optimum near 8.0 and may involve androgen action in the skin, but it is not active in the urogenital tract. Dihydrotestosterone as well as testosterone then binds to the same specific intracellular receptor protein (R, in Figure 12–3) that is distinct from both androgen-binding protein and SHBG. The genes that encode for this protein are located on the X chromosome. The androgen receptor is a member of the steroid-hormone nuclear superfamily. It is synthesized in the cytoplasm and is associated with several heat shock proteins and immunophilins. When testosterone or dihydrotestosterone binds to the receptor, it dissociates from the multiprotein complex, and conformational changes take place that allow it to form a homodimer with another hormone-androgen receptor molecule and to be translocated into the nucleus through binding to
importins (Rn in Figure 12–3). In the nucleus, the androgen–
androgen receptor complex binds to androgen response elements in
DNA through the DNA-binding domain of the receptor and inter-
acts with protein coactivators, which allows the polymorphic trans-
activating domain of the receptor to initiate transcriptional activity. 
This results in the synthesis of messenger RNA (mRNA), which is 
eventually transported to the cytoplasm, where it directs new pro-
tein synthesis and other changes that together constitute androgen 
action. In addition to this classical genomic pathway of androgen 
action, which brings about action in hours to days, androgens may 
exhibit a rapid effect through nonclassical signaling pathways 
involving cell surface actions that alter cellular calcium influx.

A variety of biologic effects of androgens have been defined in 
males. As discussed in Chapter 14, they are essential for appropriate
differentiation of the internal and external male genital system dur-
ding fetal development. During puberty, androgen-mediated growth 
of the scrotum, epididymis, vas deferens, seminal vesicles, prostate, 
and penis occurs. The functional integrity of these organs requires 
androgens. Androgens stimulate skeletal muscle growth and growth of 
the larynx, which results in deepening of the voice, and of the 
epiphyseal cartilaginous plates, which results in the pubertal growth 
spurt. Both ambisexual (pubic and axillary) hair growth and sexual 
(beard, mustache, chest, abdomen, and back) hair growth are 
stimulated, as is sebaceous gland activity. Other effects include stimulation of erythropoiesis and social behavioral changes.

**CONTROL OF TESTICULAR FUNCTION**

**Hypothalamic-Pituitary-Leydig Cell Axis (Figure 12–4)**

The hypothalamus synthesizes a decapetide, gonadotropin-
releasing hormone (GnRH), and secretes it in pulses every 30 to 
120 minutes into the hypotalahomohypophysial portal blood. After

**FIGURE 12–3** Mechanisms of androgen action (DHT, dihydrotes-
tosterone; mRNA, messenger RNA; Rn, inactive receptor; Rn, activated

hormone; LH, luteinizing hormone; T, testosterone; +, positive influ-
ence; −, negative influence).
reaching the anterior pituitary, GnRH binds to the gonadotrophs and stimulates the release of both luteinizing hormone (LH) and, to a lesser extent, FSH into the general circulation. LH is taken up by the Leydig cells, where it binds to specific membrane receptors. The LH receptor is a G protein–coupled receptor containing seven transmembrane domains with a serine- and threonine-rich cytoplasmic region containing a phosphorylation site and a 350- to 400 amino acid extracellular hormone-binding domain. The binding of LH to the receptor leads to activation of adenylyl cyclase and generation of cAMP and other messengers. It also stimulates the synthesis of a steroidogenic acute regulatory protein. This enhances the transfer of cholesterol into the inner mitochondrial membrane, leading to the synthesis and secretion of androgens. In turn, the elevation of androgens inhibits the secretion of LH from the anterior pituitary through a direct action on the pituitary and an inhibitory effect at the hypothalamic level. Both the hypothalamus and the pituitary have androgen and estrogen receptors. Experimentally, pure androgens such as dihydrotestosterone (DHT) reduce LH pulse frequency, whereas estradiol reduces LH pulse amplitude. However, the major inhibitory effect of androgen on the hypothalamus appears to be mediated principally by estradiol, which may be derived locally through the aromatization of testosterone. Leydig cells also secrete small quantities of cytokines and other peptides, which may be important for paracrine regulation of testicular function.

**Hypothalamic-Pituitary-Seminiferous Tubular Axis (See Figure 12–4)**

After stimulation by GnRH, the gonadotrophs secrete FSH into the systemic circulation. This glycoprotein hormone binds to specific receptors in the Sertoli cells and stimulates the production of androgen-binding protein. FSH is necessary for the initiation of spermatogenesis. However, full maturation of the spermatooza appears to require not only an FSH effect but also testosterone. Indeed, the major action of FSH on spermatogenesis may be via the stimulation of androgen-binding protein production, which allows a high intratubular concentration of testosterone to be maintained.

In addition to androgen-binding protein, the Sertoli cell secretes several other substances, including insulin-like growth factor-I, transferrin, Müllerian duct inhibitory factor, and inhibin. At least three genes have been found to direct inhibin synthesis. Although two forms of inhibin have been identified, only inhibin B has been found in males. This 32-kDa protein, which is composed of an alpha and a beta subunit, selectively inhibits FSH release from the pituitary without affecting LH release. FSH directly stimulates the Sertoli cells to secrete inhibin B. Serum inhibin B concentrations reflect Sertoli cell number and sperm production. They correlate with testicular size. There is a reciprocal relationship between serum inhibin B and FSH levels, and inhibin B is therefore probably a physiologic regulator of pituitary FSH secretion, possibly together with the gonadal steroids. Inhibin levels decline with advancing age.

Two additional inhibin-related proteins that have been identified in porcine follicular fluid may also be present in the testes. These factors, designated follicle regulatory protein and activin, are composed of inhibin beta subunit dimers and can selectively stimulate pituitary FSH secretion in vitro. They are structurally similar to transforming growth factor β (TGFβ), which can also stimulate pituitary FSH release. The physiologic role, if any, that follicle regulatory protein, activin, and TGFβ have in the regulation of FSH secretion is unknown.

**EVALUATION OF MALE GONADAL FUNCTION**

**CLINICAL EVALUATION**

**Clinical Presentation**

The clinical presentation of patients with deficient testosterone production or action depends on the age at onset of hypogonadism. Androgen deficiency during the second to third months of fetal development results in varying degrees of ambiguity of the genitalia and male pseudohermaphroditism. If the deficiency develops during the third trimester, defects in testicular descent leading to cryptorchidism as well as micropenis may occur. These topics are covered in Chapters 14 and 15.

Prepubertal androgen deficiency leads to poor secondary sexual development and eunuchoid skeletal proportions. The penis fails to enlarge, the testes remain small, and the scrotum does not develop the marked rugae characteristic of puberty. The voice remains high-pitched and the muscle mass does not develop fully, resulting in less than normal strength and endurance. The lack of appropriate stimulation of sexual hair growth results in sparse axillary and pubic hair (which receive some stimulation from adrenal androgens) and absent or very sparse facial, chest, upper abdominal, and back hair. Although the androgen-mediated pubertal growth spurt fails to take place, the epiphysial plates of the long bones continue to grow under the influence of insulin-like growth factor-I and other growth factors. Thus, the long bones of the upper and lower extremities grow out of proportion to the axial skeleton. Healthy white men have an average upper segment (crown to pubis) to lower segment (pubis to floor) ratio of greater than 1, whereas prepubertal hypogonadism results in a ratio of less than 1. Similarly, the ratio of total arm span to total height averages 0.96 in white men. Because of the relatively greater growth in the upper extremities, the arm span of eunuchoid individuals exceeds height by 5 cm or more.

If testosterone deficiency develops after puberty, the patient may complain of decreased libido, erectile dysfunction, and low energy. Patients with mild androgen deficiency or androgen deficiency of recent onset may not note a decrease in facial or body hair growth; it appears that although adult androgen levels must be achieved to stimulate male sexual hair growth, relatively low levels of androgens are required to maintain sexual hair growth. With long-standing hypogonadism, the growth of facial hair will diminish, and the frequency of shaving may also decrease (Figure 12–5). In addition, fine wrinkles may appear in the corners of the mouth and eyes and, together with the sparse beard growth, result in the classic hypogonadal facies.
CHAPTER 12  Testes 401

FIGURE 12-5  A. Hypogonadal habitus. Note absence of body and facial hair as well as feminine body distribution. B. Hypogonadal facies. Note absence of facial hair and fine wrinkles around the corners of the eyes and lips.

Genital Examination

Adequate assessment of the genitalia is essential in the evaluation of male hypogonadism. The examination should be performed in a warm room in order to relax the dartos muscle of the scrotum. The penis should be examined for the presence of hypospadias, epispadias, and chordee (abnormal angulation of the penis due to a fibrotic plaque), which may interfere with fertility. The fully stretched dorsal penile length should be measured in the flaccid state from the pubopeneal skin junction to the tip of the glans. The normal range in adults is 12 to 16 cm (10th and 90th percentiles, respectively).

Assessment of testicular volume is also vital to the evaluation of hypogonadism. Careful measurement of the longitudinal and transverse axes of the testes may be made and testicular volume \( V \) calculated from the formula for a prolate spheroid: \( V = 0.52 \times \text{length} \times \text{width}^2 \). The mean volume for an adult testis is 18.6 ± 4.8 mL. Alternatively, volume may be estimated with the Prader orchidometer, which consists of a series of plastic ellipsoids ranging in volume from 1 to 25 mL. Each testis is compared with the appropriate ellipsoid. Adults normally have volumes greater than 15 mL by this method.

Because about half of testicular volume is composed of seminiferous tubules, decrease in volume indicates lack of tubular development or regression of tubular size. The consistency of the testicle should be noted. Small, firm testes are characteristic of hyalinization or fibrosis, as may occur in Klinefelter syndrome. Small, rubbery testes are normally found in prepubertal males; in an adult, they are indicative of deficient gonadotropin stimulation. Testes of soft consistency are characteristically found in individuals with postpubertal testicular atrophy.

The epididymis and vas deferens should also be examined. One of the most important parts of the examination is evaluation for the presence of varicocele resulting from incompetence of the internal spermatic vein. As will be discussed later, this is an important and potentially correctable cause of male infertility. The patient should be examined in the upright position while performing the Valsalva maneuver. The examiner should carefully palpate the spermatic cords above the testes. A varicocele can be felt as an impulse along the posterior portion of the cord. About 85% of varicoceles are located on the left side, and 15% are bilateral.

LABORATORY TESTS OF TESTICULAR FUNCTION

Semen Analysis

With some exceptions, a normal semen analysis excludes gonadal dysfunction. However, a single abnormal semen analysis is not a sufficient basis for a diagnosis of disturbance of testicular function, because marked variations in several of the parameters may be seen in normal individuals: at least three semen samples should be
examined over a 2- to 3-month interval in order to evaluate this facet of male gonadal function. As noted earlier, approximately 3 months are required for completion of the spermatogenic cycle and movement of the mature spermatozoa through the ductal system. Therefore, when an abnormal semen sample is produced, one must question the patient about prior fever, trauma, drug exposure, and other factors that may temporarily damage spermatogenesis.

The semen should be collected by masturbation after 2 to 7 days of sexual abstinence and examined within 1 hour after collection. Normal semen has a volume of more than 2 to 4 mL, with $20 \times 10^6$ or more sperms per milliliter. Over half of the spermatozoa should exhibit progressive motility, and 30% or more should have normal morphology.

**Steroid Measurements**

Each of the gonadal steroids may be measured by specific assays. Although single determinations may distinguish between normal individuals and patients with severe hypogonadism, mild defects in androgen production may be missed. In normal individuals, there are frequent, rapid pulsatile changes in serum testosterone concentration as well as a slight early morning elevation. Therefore, at least three separate blood samples should be collected at 20- to 40-minute intervals during the morning for testosterone measurement. The testosterone may be measured in each of the serum samples, or equal aliquots of each of the three serum samples may be combined, mixed, and subjected to testosterone analysis. The latter procedure provides a savings in cost as well as a mean serum testosterone concentration that takes into account the pulsatile release of testosterone.

Androgen and estrogen immunoassays measure total serum steroid concentrations. This is the sum of the free, biologically active hormone and the protein-bound moiety. There is a great deal of variability with different testosterone immunoassays, especially in the lower ranges. The most reliable methods are specific immunoassays following extraction of serum or gas chromatography (GC)- or liquid chromatography (LC)-tandem mass spectrometry. Although in most circumstances it is not necessary to determine the actual quantity of free steroid hormones, in some situations alterations in the binding protein concentration may occur. Lowered concentrations of SHBG are seen in patients with hypothyroidism, obesity, and acromegaly. In these circumstances, the free testosterone concentration should be measured, because it may be normal when the total serum testosterone level is decreased. The normal male serum concentrations of gonadal steroids collected in the basal state are given in Table 12–2.

**Gonadotropin and Prolactin Measurements**

LH and, to a lesser extent, FSH are released in pulsatile fashion throughout the day. In addition, there is a diurnal variation with higher levels in the morning than in the evening. Therefore, as with testosterone, at least three blood samples should be obtained at 20- to 40-minute intervals during the morning. FSH and LH may be measured in each of the samples or in a single pooled specimen. Although many laboratories give a numerical value for the lower limits of normal for gonadotropins, some normal males have undetectable concentrations of FSH and LH by presently available immunoassay techniques. Furthermore, the concentrations of gonadotropins measured in one laboratory may not be directly comparable to those measured in another because of differences in the reference preparations used. The primary use of basal FSH and LH concentrations is to distinguish between hypergonadotropic hypogonadism, in which either or both of the gonadotropins are elevated, and hypogonadotropic hypogonadism, in which the gonadotropins are low or inappropriately normal in the presence of decreased androgen production.

Elevations of serum prolactin (PRL) inhibit the normal release of pituitary gonadotropins (shown by a reduced LH pulse frequency), probably through an effect on the hypothalamus. Thus, serum PRL measurements should be performed in any patient with hypogonadotropic hypogonadism. Serum PRL concentrations are generally stable throughout the day; therefore, measurement of this hormone in a single sample is usually sufficient. However, the patient should abstain from eating for 3 hours before the blood sample is obtained, because a protein meal may acutely stimulate the release of PRL from the pituitary. The normal ranges for serum PRL and gonadotropins are shown in Table 12–2.

**Chorionic Gonadotropin Stimulation Test**

Human chorionic gonadotropin (hCG) is a glycoprotein hormone with biologic actions similar to those of LH. Following an injection of chorionic gonadotropin, this hormone binds to the LH receptors on the Leydig cells and stimulates the synthesis and secretion of testicular steroids. Therefore, the Leydig cells may be directly assessed by the intramuscular injection of 4000 IU of chorionic gonadotropin daily for 4 days. A normal response is a doubling of the testosterone level following the last injection. Alternatively, a single intramuscular dose of chorionic gonadotropin (5000 IU/1.7 m² in adults or 100 IU/kg in children) may be given, with blood samples taken for testosterone measurements 72 and 96 hours later. Patients with primary gonadal disease have a diminished response following administration of chorionic gonadotropin, whereas patients with Leydig cell failure secondary to pituitary or hypothalamic disease have a qualitatively normal response.

Testicular Biopsy

Testicular biopsy in hypogonadal men is primarily indicated in patients with normal-sized testes and azoospermia in order to distinguish between spermatogenic failure and ductal obstruction. Although germinal aplasia, hypospadias, maturation arrest, and other abnormalities of spermatogenesis may be diagnosed by examination of testicular tissue in oligospermic males, knowledge of the type of defect does not alter therapy. Therefore, testicular biopsy is not usually indicated for evaluation of mild to moderate oligospermia. If a testicular biopsy is carried out, testicular sperm extraction for possible intracytoplasmic sperm injection (ICSI) into ova may be performed at the same time.

Evaluation for Male Hypogonadism

Figure 12-6 outlines an approach to the diagnosis of male gonadal disorders. Semen analysis and determination of the basal concentrations of testosterone, FSH, and LH allow the clinician to distinguish patients with primary gonadal failure who have poor semen characteristics, low or normal testosterone, and elevated FSH or LH from those with secondary gonadal failure and abnormal semen analysis, decreased testosterone, and low or inappropriately normal gonadotropins.

In patients with elevations of gonadotropins resulting from primary testicular disease, chromosomal analysis helps to differentiate between genetic abnormalities and acquired testicular defects. Because no therapy exists that restores spermatogenesis in an individual with severe testicular damage, androgen replacement is the treatment of choice. Patients with isolated seminiferous tubule failure may have normal or elevated FSH concentrations in association with normal LH and testosterone levels and usually severe oligospermia. Patients with azoospermia require evaluation for the possible presence of ductal obstruction, because this defect may be surgically correctable. Fructose is added to seminal plasma by the seminal vesicles, and an absence of fructose indicates that the seminal vesicles are absent or bilaterally obstructed. The combination of a poor semen analysis with low testosterone, FSH, and LH is indicative of a hypothalamic or pituitary defect. Such patients need further evaluation of anterior and posterior pituitary gland function with appropriate pituitary function tests, as well as neuroradiologic and neuro-ophthalmologic studies (Chapter 4).

PHARMACOLOGY OF DRUGS USED TO TREAT MALE GONADAL DISORDERS

ANDROGENS

A variety of drugs are available for the treatment of androgen deficiency. Preparations for sublingual or oral administration such as methyltestosterone, oxymetholone, and fluoxymesterone have the advantage of ease of administration but the disadvantage of erratic absorption, potential for cholestatic jaundice, and decreased effectiveness when compared to the intramuscular preparations. Testosterone propionate is a short-acting androgen. Its main use is in initiating therapy in older men, whose prostate glands may be exquisitely sensitive to testosterone. A dose of 50 mg two or three times per week is adequate. Obstructive symptoms due to benign prostatic hypertrophy following therapy with this androgen usually resolve rapidly because of its short duration of action.

Androgen deficiency may be treated with testosterone enanthate or cyclopentylpropionate (cyproterone) given intramuscularly. Unlike the oral androgen preparations, both of these agents are capable of completely virilizing the patients. Therapy may be initiated with 50 mg intramuscularly every 4 weeks and gradually increased to a maintenance dose of 75 to 100 mg every week or 150 to 200 mg every 2 weeks. Testosterone undecanoate, a long-acting form of testosterone given intramuscularly every 3 months, is available in many countries, but is not yet approved by the FDA for use in the United States. Testosterone pellets may be implanted subcutaneously for a longer duration of effect. However, this therapy has not enjoyed much popularity. Transdermal delivery via membranes impregnated with testosterone (Androderm) is another method of replacement therapy. The patches can be placed on the skin of the back, shoulder, or abdomen and provide normal androgen concentrations. A testosterone gel (AndroGel 1%; Testim 1%) that is applied daily to the abdomen, shoulders, or upper arms also results in physiologic concentrations of testosterone. A buccal preparation (Striant) applied twice daily under the upper lip also is available, but is not widely used due to gum irritation.

Androgens, both oral and intramuscular, have been used (illegally) by some athletes to increase muscle mass and strength. Although this may achieve the anticipated result in some individuals, adverse effects include oligospermia and testicular atrophy—in addition to some of the complications noted below.

Androgen therapy is currently contraindicated in patients with prostatic carcinoma. About 1% to 2% of patients receiving oral methyltestosterone or fluoxymesterone develop intrahepatic cholestatic jaundice that resolves when the drug is discontinued. Rarely, these methylated or halogenated androgens have been associated with benign and malignant hepatocellular tumors.

Androgen therapy also may cause premature fusion of the epiphyses in an adolescent, and this may result in some loss of potential height. Therefore, androgen therapy is usually withheld until a hypogonadal male reaches 13 years of age. Sodium and water retention may induce hypertension or congestive heart failure in susceptible individuals. Because androgens stimulate erythropoietin production, erythrocytosis may occur during therapy. This is not usually clinically significant. Inhibition of spermatogenesis is mediated through suppression of gonadotropins by the androgens. Gynecomastia may develop during initiation of androgen therapy but usually resolves with continued administration of the drug. Sleep apnea may be precipitated. Priapism, acne, and aggressive behavior are dose-related adverse effects and generally disappear after reduction of dosage. Androgens decrease the production of thyroxine-binding globulin and corticosteroid-binding globulin by the liver. Therefore, total serum thyroxine and cortisol concentrations may be decreased, although the free hormone concentrations remain normal. High-density lipoprotein concentrations may also be reduced with oral androgens.
Semen analysis; basal testosterone, FSH, and LH

- Oligo- or azoospermia, reduced testosterone, increased LH and FSH
  - Primary gonadal failure
    - Chromosomal analysis
      - Normal
      - XXY or variants
        - Androgen therapy

- Oligospermia, normal testosterone and LH, increased FSH
  - Seminiferous tubule failure
    - Infertility counseling; ART
      - Congenital absence of vas deferens and seminal vesicles
        - Normal spermatogenesis
          - Ductal obstruction
            - Surgery

    - Serum PRL, chorionic gonadotropin stimulation test; pituitary-hypothalamic evaluation
      - Hyperthyroidism
        - Antithyroid drugs, \(^{131}I\), or surgery
      - Hyperthyroidism
        - Partial androgen insensitivity

- Oligo- or azoospermia, increased testosterone and LH, normal FSH
  - TSH
    - Suppressed
    - Normal
      - Partial androgen insensitivity

**FIGURE 12-6** Scheme for evaluation of clinical hypogonadism (ART, assisted reproductive technologies such as in vitro fertilization and sperm injection into ova).
GONADOTROPINS

In patients with hypogonadism due to inadequate gonadotropin secretions, spermatogenesis and virilization may be induced by exogenous gonadotropin injections. Because the gonadotropins are proteins with short half-lives, they must be administered parenterally two or three times a week.

The expense and inconvenience of this type of therapy preclude its routine use for the treatment of androgen deficiency. The two major indications for exogenous gonadotropins are treatment of cryptorchidism (see later) and induction of spermatogenesis in hypogonadal males who wish to father children.

To induce spermatogenesis, 2000 IU of chorionic gonadotropin may be given intramuscularly three times a week for 9 to 12 months. In some individuals with partial gonadotropin deficiencies, this may induce adequate spermatogenesis. In patients with more severe deficiencies, menotropins, available in vials containing 75 IU each of FSH and LH, or highly purified urinary FSH (urofolitropin) or FSH produced by recombinant DNA technology (folitropin beta), each containing 75 IU of FSH, is added to chorionic gonadotropin therapy after 9 to 12 months and is administered in a dosage of one vial intramuscularly three times a week.

Adverse reactions with such therapy are minimal. Acne, gynecomastia, or prostatic enlargement may be noted as a result of excessive Leydig cell stimulation. Reduction of the chorionic gonadotropin dosage or a decrease in the frequency of chorionic gonadotropin injections generally results in resolution of the problem.

GONADOTROPIN-RELEASING HORMONE

GnRH (gonadorelin acetate), administered in pulses every 60 to 120 minutes by portable infusion pumps, effectively stimulates the endogenous release of LH and FSH in hypogonadotropic hypogonadal patients. This therapy does not currently appear to offer any major advantage over the use of exogenous gonadotropins for induction of spermatogenesis or the use of testosterone enanthate or cypionate for virilization, and is no longer available in the United States. A long-acting analog of GnRH, leuprolide acetate, is available for the treatment of advanced prostatic carcinoma. Daily subcutaneous administration of 1 mg or monthly intramuscular injections of 7.5 mg of a depot preparation—22.5 mg for 3 months or 30 mg for 4 months—results in desensitization of the pituitary GnRH receptors, which reduces LH and FSH levels and so ultimately testosterone concentrations. Similar results are produced with a subcutaneous injection of the depot form of the GnRH analog goserelin or monthly intramuscular injections of triptorelin. With these therapies, initial remission rates for prostatic carcinoma are similar to those found with orchietomy or treatment with diethylstilbestrol (about 70%).

A long-acting GnRH antagonist, abarelix, also is an effective means of inducing medical castration by reducing LH, FSH, and testosterone secretion. Although GnRH agonists may produce an initial rise in LH, FSH, and testosterone levels, no such rise is seen with GnRH antagonists, making them better agents to use in the presence of metastasis in sensitive areas such as the spinal cord.

Nafarelin acetate is a GnRH agonist that is administered intranasally for the treatment of endometriosis and central precocious puberty. Central precocious puberty also may be treated with leuprolide acetate and another analog, histrelin acetate. Long-acting GnRH agonists also are used to suppress endogenous gonadal steroid production as part of the endocrine treatment of transsexual persons. Long-acting GnRH agonists combined with testosterone have been studied as a possible male contraceptive, but they do not uniformly induce azoospermia.

CLINICAL MALE GONADAL DISORDERS

Hypogonadism may be subdivided into three general categories (Table 12–3). A thorough discussion of the hypothalamic-pituitary disorders that cause hypogonadism is presented in Chapters 4 and 15. The defects in androgen biosynthesis and androgen action are described in Chapter 14. The following section emphasizes the primary gonadal abnormalities.

KLINFELETER SYNDROME (XXY SEMINIFEROUS TUBULE DYSGENESIS)

Klinefelter syndrome is the most common genetic cause of male hypogonadism, occurring in one of 600 male births. An extra X chromosome is present in about 0.2% of male conceptions and

0.1% to 0.2% of live-born males. Sex chromosome surveys of mentally retarded males have revealed an extra X chromosome in 0.45% to 2.5% of such individuals. Patients with an XXY genotype have classic Klinefelter syndrome; those with an XXXY, XXXXY, or XYYY genotype or with XXY/chromosomal mosaicism are considered to have variant forms of the syndrome.

**Etiology and Pathophysiology**

The XXY genotype is usually due to meiotic nondisjunction during parental gametogenesis, which results in an egg with two X chromosomes or a sperm with an X and a Y chromosome. After fertilization, nondisjunction during mitotic division results in mosaicism.

At birth there are generally no physical stigmas of Klinefelter syndrome, and during childhood there are no specific signs or symptoms. The chromosomal defect is expressed chiefly during puberty. As the gonadotropins increase, the seminiferous tubules do not enlarge but rather undergo fibrosis and hyalinization, which results in small, firm testes. Obliteration of the seminiferous tubules results in azoospermia.

In addition to dysgenesis of the seminiferous tubules, the Leydig cells are also abnormal. They are present in clumps and appear to be hyperplastic on initial examination of a testicular biopsy. However, the Leydig cell mass is not increased, and the apparent hyperplasia is actually due to the marked reduction in tubular volume. Despite the normal mass of tissue, the Leydig cells are functionally abnormal. The testosterone production rate is reduced, and there is a compensatory elevation in serum LH. Stimulation of the Leydig cells with exogenous chorionic gonadotropin results in a subnormal rise in testosterone. The clinical manifestations of androgen deficiency vary considerably from patient to patient and may be related to the degree of diminished testosterone production and alterations in the androgen receptor.

Exon 1 of the androgen receptor gene contains a polymorphism with a variable number of CAG repeats. As the number of repeats increases, there is a progressive decrease in androgen action and more phenotypic abnormalities. Thus, some individuals have virtually no secondary sexual developmental changes, whereas others are indistinguishable from healthy individuals.

The elevated LH concentrations also stimulate the Leydig cells to secrete increased quantities of estradiol and estradiol precursors. The relatively high estradiol: testosterone ratio is responsible for the variable degrees of feminization and gynecomastia seen in these patients. The elevated estradiol also stimulates the liver to produce SHBG. This may result in total serum testosterone concentrations that are within the low-normal range for adult males. However, the free testosterone level may be lower than normal.

The pathogenesis of the eunuchoid proportions, personality, and intellectual deficits and associated medical disorders is presently unclear.

**Testicular Pathology**

Most of the seminiferous tubules are fibrotic and hyalinized, although occasional Sertoli cells and spermatogonia may be present in some sections. Absence of elastic fibers in the tunica propria is indicative of the dysgenetic nature of the tubules. The Leydig cells are arranged in clumps and appear hyperplastic, although the total mass is normal.

**Clinical Features (Figure 12-7)**

A. Symptoms and signs  There are usually no symptoms before puberty other than poor school performance in some affected individuals. Puberty may be delayed but not usually by more than 1 to 2 years. During puberty, the penis and scrotum undergo varying degrees of development, with some individuals appearing normal. Most patients (80%) have diminished facial and torso hair growth. The major complaint is often persistent gynecomastia, which is clinically present in over half of patients. The testes are uniformly small (<2 cm in longest axis and <4 mL in volume) and firm as a result of fibrosis and hyalinization. Other complaints include infertility or insufficient libido and potency. The patient may have difficulty putting into words his embarrassment in situations where he must disrobe in the presence of other men, and the subnormal development of the external genitalia along with gynecomastia may lead to feelings of inadequacy that may be partly responsible for the maladjusted social behavior some patients exhibit. Bone mineral density may be dramatically reduced in patients with long-standing androgen deficiency.

Patients with Klinefelter syndrome have abnormal skeletal proportions that are not truly eunuchoid. Growth of the lower extremities is relatively greater than that of the trunk and upper extremities; therefore, pubis-to-floor height (which represents appendicular bone growth) is greater than crown-to-pubis height.
(which predominantly represents axial bone growth), and span is less than total height. Thus, the abnormal skeletal proportions are not the result of androgen deficiency per se (which results in span greater than height).

Intellectual impairment is noted in many patients with Klinefelter syndrome, but the true proportion of affected individuals with subnormal intelligence is not known. Deficits in language and higher intellectual functions, such as concept formation and problem solving, have been noted. Poor social skills also are common (see earlier). Patients generally show lack of ambition and difficulties in maintaining permanent employment.

Several clinical and genotypic variants of Klinefelter syndrome have been described. In addition to small testes with seminiferous tubular hyalinization, azoospermia, deficient secondary sexual development, and elevated gonadotropins, patients with three or more X chromosomes uniformly have severe mental retardation. The presence of more than one Y chromosome tends to be associated with aggressive antisocial behavior and macronodular acne. Skeletal deformities such as radioulnar synostosis, flexion deformities of the elbows, and clinodactyly are more commonly seen in Klinefelter variants. Patients with sex chromosome mosaicism (XX/XXY) may have only a few of the Klinefelter stigmas. These patients may have normal testicular size and may be fertile if their testes contain the XY genotype.

Medical disorders found to be associated with Klinefelter syndrome with more than chance frequency include chronic pulmonary disease (emphysema, chronic bronchitis), varicose veins, extragonadal germ cell tumors, cerebrovascular disease, glucose intolerance, primary hypothyroidism, and taurodontism—with early tooth decay. Some studies suggest that there is a 20-fold increased risk of breast cancer, while others do not.

B. Laboratory findings Serum testosterone is low or normal, and FSH and LH concentrations are elevated. Azoospermia is present. The buccal smear is chromatin-positive (20% of cells having a Barr body), and chromosomal analysis reveals a 47,XXY karyotype.

Differential Diagnosis
Klinefelter syndrome should be distinguished from other causes of hypogonadism. Small, firm testes should suggest Klinefelter syndrome. Hypothalamic-pituitary hypogonadism may be associated with small, rubbery testes if puberty has not occurred or atrophic testes if normal puberty has occurred. The consistency of the testes in Klinefelter syndrome is also different from that noted in acquired forms of adult seminiferous tubular damage. The elevated gonadotropins place the site of the lesion at the testicular level, and chromosomal analysis confirms the diagnosis. Chromosomal analysis is also required to differentiate classic Klinefelter syndrome from the variant forms.

Treatment
A. Medical treatment Androgen deficiency should be treated with testosterone replacement. Patients with personality defects should be virilized gradually to decrease the risk of aggressive behavior. Testosterone enanthate or cypionate, 100 mg intramuscularly, may be given every 2 to 4 weeks initially and increased to 200 mg every 2 weeks if well tolerated. Patients with low-normal androgen levels may not require androgen replacement therapy. For those desiring fertility, sperm may be extracted directly from the testes in about half of the patients and used for ICSI with a live birth rate of up to 20%.

B. Surgical treatment If gynecomastia presents a cosmetic problem, mastectomy may be performed.

Course and Prognosis
Patients generally feel better after androgen replacement therapy has begun. However, the personality defects do not improve, and these patients often require long-term psychiatric counseling. Life expectancy is not affected.

BILATERAL ANORCHIA (VANISHING TESTES SYNDROME)

Approximately 3% of phenotypic boys undergoing surgery to correct unilateral or bilateral cryptorchidism are found to have absence of one testis, and in about 1% of cryptorchid males both testes are absent. Thus, bilateral anorchia is found in approximately one out of every 20,000 males.

Etiology and Pathophysiology
Functional testicular tissue must be present during the first 14 to 16 weeks of embryonic development in order for Wolffian duct growth and Müllerian duct regression to occur and for the external genitalia to differentiate along male lines. Absence of testicular function before this time results in varying degrees of male pseudohermaphroditism with ambiguous genitalia. Prenatal testicular injury occurring after 16 weeks of gestation as a result of trauma, vascular insufficiency, infection, or other mechanisms may result in loss of testicular tissue in an otherwise normal phenotypic male; hence the term vanishing testes syndrome.

Testicular Pathology
In most instances, no recognizable testicular tissue has been identified despite extensive dissections. Wolffian duct structures are generally normal, and the vas deferens and testicular vessels may terminate blindly or in a mass of connective tissue in the inguinal canal or scrotum.

Clinical Features
A. Symptoms and signs At birth, patients appear to be normal phenotypic males with bilateral cryptorchidism. Growth and development are normal until secondary sexual development fails to occur at puberty. The penis remains small; pubic and
axillary hair does not fully develop despite the presence of adrenal androgens; and the scrotum remains empty. If the patient does not receive androgens, eunuchoid proportions develop. Gynecomastia does not occur.

An occasional patient undergoes partial spontaneous virilization at puberty. Although anatomicly no testicular tissue has been identified in such patients, catheterization studies have demonstrated higher testosterone concentrations in venous blood obtained from the spermatic veins than in the peripheral venous circulation. This suggests that functional Leydig cells are present in some patients, although they are not associated with testicular germinal epithelium or stroma.

B. Laboratory findings Serum testosterone concentrations are generally quite low, and both LH and FSH are markedly elevated. Serum testosterone concentrations do not rise following a chorionic gonadotropin stimulation test. Serum Müllerian duct inhibitory factor levels are low. Chromosomal analysis discloses a 46,XY karyotype.

C. Imaging studies Testicular artery arteriograms, spermatic venograms, and gadolinium-infusion magnetic resonance venography show vessels that taper and end in the inguinal canal or scrotum without an associated gonad.

D. Special examinations Thorough inguinal and abdominal laparoscopic examination or retroperitoneal examination at laparotomy may locate the testes. If testicular vessels and the vas deferens are identified and found to terminate blindly together, it may be assumed that the testis is absent.

Differential Diagnosis

Bilateral cryptorchidism must be differentiated from congenital bilateral anorchia. A normal serum testosterone concentration that rises following stimulation with chorionic gonadotropin is indicative of functional Leydig cells and probable bilateral cryptorchidism. Elevated serum LH and FSH and a low testosterone that fails to rise after administration of exogenous chorionic gonadotropin indicate bilateral absence of functional testicular tissue.

Treatment

Androgen replacement therapy is discussed in the section on pharmacology (see “Androgens,” earlier in the chapter).

Implantation of testicular prostheses for cosmetic purposes may be beneficial after the scrotum has enlarged in response to androgen therapy.

**LEYDIG CELL APLASIA**

Defective development of testicular Leydig cells is a rare cause of male pseudohermaphroditism with ambiguous genitalia.

**Etiology and Pathophysiology**

Testes are present in the inguinal canal and contain prepubertal-appearing tubules with Sertoli cells and spermatogonia without germinal cell maturation. The interstitial tissue has a loose myxoid appearance with an absence of Leydig cells. The syndrome is caused by inactivating mutations in the LH receptor that alters receptor signal transduction. The presence of a vas deferens and epididymis in these patients indicates that the local concentration of testosterone was high enough during embryogenesis to result in differentiation of the Wolffian duct structures. However, the ambiguity of the genitalia indicates that the androgen concentration in these patients was insufficient to bring about full virilization of the external genitalia. The absence of Müllerian duct structures is compatible with normal fetal secretion of Müllerian duct inhibitory factor from the Sertoli cells.

**Clinical Features**

A. Symptoms and signs These patients may present in infancy with variable degrees of genital ambiguity, including a bifid scrotum, clitoral phallus, urogenital sinus, and blind vaginal pouch. Alternatively, they may appear as normal phenotypic females and escape detection until adolescence, when they present with primary amenorrhea, with or without normal breast development. The gonads are generally located in the inguinal canal. Axillary and pubic hair, although present, may be sparse. Mild defects may result in Leydig cell hypoplasia, a disorder whose clinical manifestations include micropenis, hypospadias, and variable suppression of fertility.

B. Laboratory findings Serum gonadotropins are elevated, and testosterone levels are below normal limits for a male and within the low-normal range for females. There is no increase in testosterone following chorionic gonadotropin administration.

**Differential Diagnosis**

Leydig cell aplasia should be differentiated from the vanishing testes syndrome, testosterone biosynthetic defects, disorders of androgen action, and 5α-reductase deficiency. The differential diagnostic features of these disorders are discussed in Chapter 14.

**Treatment**

Patients with Leydig cell aplasia respond well to the exogenous administration of testosterone, and it would be anticipated that they would be fully virilized and even develop some degree of spermatogenesis with exogenous testosterone administration. However, because the few patients who have been reported have been discovered either late in childhood or as adolescents and have been raised as females, it would be inappropriate to attempt a gender reversal at such a late period. Removal of the cryptorchid testes and feminization with exogenous estrogens would appear to be the most prudent course of therapy.
CRYPTORCHIDISM

Cryptorchidism is unilateral or bilateral absence of the testes from the scrotum because of failure of normal testicular descent from the genital ridge through the external inguinal ring. Between 2% and 4% of full-term and 20% to 25% of premature male infants have cryptorchidism. In most cases of cryptorchidism noted at birth, spontaneous testicular descent occurs during the first year of life, reducing the incidence to 0.2% to 0.8% by 1 year of age. Approximately 0.75% of adult males are cryptorchid. Unilateral cryptorchidism is 5 to 10 times more common than bilateral cryptorchidism.

Almost 50% of cryptorchid testes are located at the external inguinal ring or in a high scrotal position; 19% lie within the inguinal canal between the internal and external inguinal rings (canalicular); 9% are intra-abdominal; and 23% are ectopic (ie, located away from the normal pathway of descent from the abdominal cavity to the scrotum). Most ectopic testes are found in a superficial inguinal pouch above the external inguinal ring.

Etiology and Pathophysiology

Testicular descent usually occurs between the 12th week of fetal development and birth. Both mechanical and hormonal factors appear to be important for this process. Cryptorchidism is common in patients with congenital defects in androgen synthesis or action and in patients with congenital gonadotropin deficiency, and experimental studies have demonstrated that DHT is required for normal testicular descent. These observations suggest that prenatal androgen deficiency may be of etiologic importance in the development of cryptorchidism. Environmental endocrine disruptors with estrogen or antiandrogen activity, such as phthalates or bisphenol A, have been proposed as a cause of the increased incidence of cryptorchidism seen in recent years.

It is not known whether pathologic changes in the testes are due to the effects of cryptorchidism or to intrinsic abnormalities in the gonad. Experimental studies in animals have shown that an increase in the temperature of the testes by 1.5°C to 2°C (34.7°F -35.6°F) (the temperature differential between the abdomen and scrotum) results in depression of spermatogenesis. Serial testicular biopsies in cryptorchid patients have demonstrated partial reversal of the histologic abnormalities following surgical correction, suggesting that the extra-scrotal environment is partly responsible for the observed pathologic abnormalities.

An intrinsic abnormality in the testes in patients with unilateral cryptorchidism is suggested by the observation that such patients are at increased risk for development of germ cell neoplasms in the scrotal testis. Similarly, the observation that adults with unilateral cryptorchidism surgically corrected before puberty had low sperm counts, high basal serum LH and FSH concentrations, and an exaggerated FSH response to GnRH suggests either that both testes are intrinsically abnormal or that the cryptorchid gonad somehow suppresses the function of the scrotal testis.

Pathology

Histologic studies on cryptorchid testes have demonstrated a decrease in the size of the seminiferous tubules and number of spermatogonia and an increase in peritubular tissue. The Leydig cells usually appear normal. It is unclear at what age these changes first appear. Abnormalities have been detected as early as 6 months. It is well established that the longer a testis remains cryptorchid, the more likely it is to show pathologic changes. More severe changes are generally found in intra-abdominal testes than in canalicular testes.

Clinical Features

A. Symptoms and signs There are usually no symptoms unless a complication such as testicular torsion, trauma, or malignant degeneration occurs. School-age children may have gender identity problems. Adults may complain of infertility, especially if they have a history of bilateral cryptorchidism.

Absence of one or both testes is the cardinal clinical finding. This may be associated with a small scrotum (bilateral cryptorchidism) or hemiscrotum (unilateral cryptorchidism). Signs of androgen deficiency are not present.

B. Laboratory findings Basal or stimulated serum FSH, LH, and testosterone concentrations are not helpful in evaluating prepubertal unilaterally cryptorchid males. However, serum FSH and LH concentrations and the testosterone response to exogenous chorionic gonadotropin are useful in differentiating cryptorchid patients from those with congenital anorchia. The latter have high basal gonadotropins, low serum testosterone, and absent or diminished testosterone rise following chorionic gonadotropin stimulation. Alternatively, measurement of the serum concentration of Müllerian duct inhibitory factor can be used; children with no testicular tissue have very low levels in comparison to those with bilateral cryptorchidism.

Postpubertal adults may have oligospermia, elevated basal serum FSH and LH concentrations, and an exaggerated FSH increase following GnRH stimulation. Such abnormalities are more prevalent in patients with a history of bilateral cryptorchidism than with unilateral cryptorchidism.

C. Imaging studies Gadolinium-infusion magnetic resonance venography is a sensitive method for localizing the nonpalpable cryptorchid testes. Intravenous urography discloses an associated abnormality of the upper urinary tract in 10% of cases—horseshoe kidney, renal hypoplasia, ureteral duplication, hydroureter, and hydronephrosis.

Differential Diagnosis

Retractile testis (pseudocryptorchidism) is due to a hyperactive cremasteric reflex, which draws the testicle into the inguinal canal. Cold temperature, fear, and genital manipulation commonly activate the reflex, which is most prominent between the ages of 5 and 6 years. The child should be examined with warm hands in a warm room. The testis can usually be milked into the scrotum
with gentle pressure over the lower abdomen in the direction of the inguinal canal.

Bilateral anorchia is associated with elevated gonadotropins, decreased testosterone, and an absent or subnormal response to stimulation with chorionic gonadotropin. The virilizing forms of congenital adrenal hyperplasia may result in prenatal fusion of the labial-scrotal folds and clitoral hypertrophy (Chapter 14). Severely affected females have the appearance of phenotypic males with bilateral cryptorchidism. Because of the potentially disastrous consequences (acute adrenal insufficiency) if this diagnosis is missed, a chromosomal analysis should be performed on bilaterally cryptorchid phenotypic male infants.

Complications and Sequelae

A. Hernia  Approximately 90% of cryptorchid males have associated ipsilateral inguinal hernia resulting from failure of the processus vaginalis to close. This is rarely symptomatic.

B. Torsion  Because of the abnormal connection between the cryptorchid testes and its supporting tissues, torsion may occur. This should be suspected in any patient with abdominal or pelvic pain and an ipsilateral empty scrotum.

C. Trauma  Testes that lie above the pubic tubercle are particularly susceptible to traumatic injury.

D. Neoplasms  A cryptorchid testis is four to six times more likely to undergo malignant degeneration than a normal testis. The incidence of such tumors is greater in patients with intraabdominal testes than in patients with canalicular testes. Seminomas are the neoplasms most commonly associated with maldescended testes. In addition, there is an increased risk for development of testicular intraepithelial neoplasia (carcinoma in situ). Orchiopexy before or during puberty decreases the risk of malignancy. Because of the increased risk of neoplasia, many urologists recommend orchiopexy for a unilaterally undescended testicle in a patient first seen after puberty. Patients who present with bilateral cryptorchidism after puberty should have bilateral orchiopexy and testicular biopsies to preserve testicular endocrine function and to make palpation for detection of neoplasia easier.

E. Infertility  Over 75% of untreated bilaterally cryptorchid males are infertile. About 30% to 50% of bilaterally cryptorchid patients who undergo prepubertal orchiopexy have been found to be fertile. About half of patients with untreated unilateral cryptorchidism are infertile, whereas infertility is found in less than one-fourth of such patients whose cryptorchidism is surgically repaired before puberty.

Prevention

Although cryptorchidism cannot be prevented, the complications can be avoided. It is clear that the adverse changes that take place in the testes are related in part to the location of the maldescended testis and the duration of the cryptorchidism. Most testes that are undescended at birth enter the scrotum during the first year of life. However, it is rare for a cryptorchid testis to descend spontaneously after the age of 6 months. Because adverse histologic changes have been noted around the age of 2 years, hormonal or surgical correction should be undertaken at or before that time, ideally between 6 and 12 months.

Treatment

A. Medical

1. Intramuscular chorionic gonadotropin therapy—Because growth of the vas deferens and testicular descent are at least partially dependent on androgens, stimulation of endogenous testosterone secretion by chorionic gonadotropin may correct the cryptorchidism. Cryptorchidism is corrected in less than 25% of patients treated with a course of chorionic gonadotropin, and recent studies suggest that patients with conditions that respond to hormonal therapy may actually have retractile testes rather than true cryptorchidism. Nevertheless, this therapy may be tried prior to orchiopexy, because it is innocuous and may avoid the need for surgery. For bilateral cryptorchidism, give a short course of chorionic gonadotropin consisting of 3300 U intramuscularly every other day over a 5-day period (three injections). For unilateral cryptorchidism, give 500 U intramuscularly three times a week for 6½ weeks (20 injections).

2. Intranasal GnRH therapy—GnRH given three times a day for 28 days by nasal spray has been shown to be as effective as chorionic gonadotropin injections in correcting cryptorchidism in some patients. This therapy is not approved for treatment of cryptorchidism in the United States.

B. Surgical treatment  Several procedures have been devised to place the maldescended testis into the scrotum (orchiopexy). The operation may be performed in one or two stages. Inguinal hernia should be repaired if present. As noted earlier, the surgery is best performed between 6 and 12 months of age.

NOONAN SYNDROME (MALE TURNER SYNDROME)

Phenotypic and genotypic males with many of the physical stigmas of classic Turner syndrome have been described under a variety of names, including Noonan syndrome and male Turner syndrome. It has an incidence of 1:1000 to 1:2500 live births and may occur sporadically or may be familial—inherited in an autosomal dominant fashion with variable penetrance. Approximately half of the patients have a gain-of-function mutation in the protein-tyrosine phosphatase, nonreceptor type II (PTPN11) gene on chromosome 12, which encodes for Src homology region two-domain phosphatase (SHP-2), a signaling protein that modulates cellular proliferation, differentiation, and migration. A number of pathologic features have been noted, including reduced seminiferous tubular size with or without sclerosis, diminished or absent germ cells, and Leydig cell hyperplasia.
Clinical Features

A. Symptoms and signs  The most common clinical features are short stature, webbed neck, hypertelorism, cubitus valgus, and bleeding diathesis. Congenital cardiac defects are variably observed in these patients. Congenital cardiac anomalies are common and involve primarily the right side of the heart—in contrast to patients with XO gonadal dysgenesis.

Cryptorchidism is frequently present. Although some affected individuals are fertile, with normal testes, most have small testes and mild to moderate hypogonadism.

B. Laboratory findings  Serum testosterone concentrations are usually low or low-normal, and serum gonadotropins are high. The karyotype is 46,XY.

Differential Diagnosis

The clinical features of Noonan syndrome are sufficiently distinct so that confusion with other causes of hypogonadism is usually not a problem. However, a rare individual with XY/XO mosaic may have similar somatic anomalies requiring chromosomal analysis for differentiation. Some of the phenotypic features are shared with the Costello and cardiofaciocutaneous syndromes.

Treatment

If the patient is hypogonadal, androgen replacement therapy is indicated.

MYOTONIC DYSTROPHY

Myotonic dystrophies types 1 (DM1) and 2 (DM2) are autosomal dominant disorders of muscle with multisystem clinical features including primary hypogonadism. The underlying lesion in DM1 is an expansion of the CTG repeat in the 3’ untranslated region of a gene that encodes a serine-threonine protein kinase located on chromosome 19. The cause of DM2 is expansion of a CCTG repeat in intron 1 of the zinc finger protein-9 gene on chromosome 3.

Testicular histology varies from moderate derangement of spermatogenesis with germinal cell arrest to regional hyalinization and fibrosis of the seminiferous tubules. The Leydig cells are usually preserved and may appear in clumps.

The testes are normal in affected prepubertal individuals, and puberty generally proceeds normally. Testosterone secretion is normal, and secondary sexual characteristics develop appropriately. After puberty, seminiferous tubular atrophy results in a decrease in testicular size and change of consistency from firm to soft or mushy. Infertility is a consequence of disrupted spermatogenesis. If testicular hyalinization and fibrosis are extensive, Leydig cell function may also be impaired.

Clinical Features

A. Symptoms and signs  The disease usually becomes apparent in adulthood. Progressive weakness and atrophy of the facial, neck, hand, and lower extremity muscles is commonly observed. Severe atrophy of the temporalis muscles, prolix due to weakness of the levator muscles of the eye with compensatory wrinkling of the forehead muscles, and frontal baldness comprise the myopathic facies characteristic of the disorder. Myotonia is present in several muscle groups and is characterized by inability to relax the muscle normally after a strong contraction.

Testicular atrophy is not noted until adulthood, and most patients develop and maintain normal facial and body hair growth and libido. Gynecomastia is usually not present.

Associated features include mental retardation (type 1 disease only), cataracts, diabetes mellitus, cardiac arrhythmias, and primary hypothyroidism.

B. Laboratory findings  Serum testosterone is normal to slightly decreased. FSH is uniformly elevated in patients with atrophic testes. LH is also frequently elevated, even in patients with normal serum testosterone levels. Leydig cell reserve is generally diminished, with subnormal increases in serum testosterone following stimulation with chorionic gonadotropin. An excessive rise in FSH and, to a lesser extent, LH is found following GnRH stimulation.

Treatment

There is no therapy that will prevent progressive muscular atrophy in this disorder. Testosterone replacement therapy is not indicated unless serum testosterone levels are subnormal.

ADULT SEMINIFEROUS TUBULE FAILURE

Adult seminiferous tubule failure encompasses a spectrum of pathologic alterations of the seminiferous tubules that results in hypospermatogenesis, germinal cell arrest, germinal cell aplasia, and tubular hyalinization. Almost half of infertile males exhibit some degree of isolated seminiferous tubule failure.

Etiology, Pathology, and Pathophysiology

Etiologic factors in seminiferous tubule failure include mumps or gonococcal orchitis, leprosy, cryptorchidism, irradiation, uremia, alcoholism, paraplegia, lead poisoning, and therapy with antineoplastic agents such as cyclophosphamide, chlorambucil, vincristine, methotrexate, and procarbazine. Vascular insufficiency resulting from spermatic artery damage during herniorrhaphy, testicular torsion, or sickle cell anemia may also selectively damage the tubules. Similar pathologic changes may be found in oligospermic patients with varicoceles. Deletions of portions of the Y chromosome may also present as adult seminiferous tubule failure. In many patients, no etiologic factors can be identified, and the condition is referred to as idiopathic.

The rapidly dividing germinal epithelium is more susceptible to injury than are the Sertoli or Leydig cells. Thus, pressure necrosis (eg, mumps or gonococcal orchitis), increased testicular temperature (eg, cryptorchidism and primary varicocele and
paraplegia), and the direct cytotoxic effects of irradiation, alcohol, lead, and chemotherapeutic agents primarily injure the germ cells. Although the Sertoli and Leydig cells appear to be morphologically normal, severe testicular injury may result in functional alterations in these cells.

Several different lesions may be found in testicular biopsy specimens. The pathologic process may involve the entire testes or may appear in patches. The least severe lesion is hypospermatogenesis, in which all stages of spermatogenesis are present but there is a decrease in the number of germinal epithelial cells. Some degree of peritubular fibrosis may be present. Cessation of development at the primary spermatocyte or spermatogonial stage of the spermatogenic cycle is classified as germinal cell arrest. More severely affected testes may demonstrate a complete absence of germ cells with morphologically normal Sertoli cells (Sertoli cell-only syndrome). The most severe lesion is fibrosis or hyalinization of the tubules. This latter pattern may be indistinguishable from that seen in Klinefelter syndrome.

Irrespective of the etiologic factors involved in damage to the germinal epithelium, the alterations in spermatogenesis result in oligospermia. If the damage is severe, as in the Sertoli cell—only syndrome or tubular hyalinization, azoospermia may be present. Because testicular volume consists chiefly of tubules, some degree of testicular atrophy is often present in these patients. Some patients have elevations in basal serum FSH concentrations and demonstrate a hyperresponsive FSH rise following GnRH, suggesting that the Sertoli cells are functionally abnormal despite their normal histologic appearance.

**Clinical Features**

**A. Symptoms and signs** Infertility is usually the only complaint. Mild to moderate testicular atrophy may be present. Careful examination should be made for the presence of varicocele by palpating the spermatic cord during Valsalva maneuver with the patient in the upright position. The patients are fully virilized, and gynecomastia is not present.

**B. Laboratory findings** Semen analysis shows oligospermia or azoospermia, and serum testosterone and LH concentrations are normal. Basal serum FSH levels may be normal or high, and an excessive FSH rise following GnRH may be present. Serum inhibin B levels generally are low, but they add little information beyond that of the serum FSH measurement.

**Differential Diagnosis**

Patients with hypothalamic or pituitary disorders may have oligospermia or azoospermia and testicular atrophy. The serum FSH and LH concentrations are often in the low-normal range, and the testosterone level is usually (not always) diminished. The presence of neurologic and ophthalmologic abnormalities, diabetes insipidus, anterior pituitary trophic hormone deficiencies, or an elevated serum PRL concentration distinguishes these patients from those with primary seminiferous tubule failure. Other causes of primary testicular failure are associated either with clinical signs and symptoms of androgen deficiency or with enough somatic abnormalities to allow differentiation from isolated seminiferous tubule failure.

**Prevention**

In many instances, damage to the seminiferous tubules cannot be prevented. Early correction of cryptorchidism, adequate shielding of the testes during diagnostic radiologic procedures or radiotherapy, and limitation of the total dose of chemotherapeutic agents may prevent or ameliorate the adverse effects.

**Treatment**

**A. Medical** Attempts to treat oligospermia and infertility medically have included low-dose testosterone, exogenous gonadotropins, thyroid hormone therapy, vitamins, bromocriptine, aromatase inhibitors, tamoxifen, and clomiphene citrate. None of these agents have been found to be uniformly beneficial, and several may actually lead to a decrease in the sperm count.

**B. Surgical** Some of the pathologic changes in the testes have been reversed by early orchiopexy in cryptorchid individuals. If a varicocele is found in an oligospermic, infertile male, it should be ligated.

**Course and Prognosis**

Patients who have received up to 300 cGy of testicular irradiation may show partial or full recovery of spermatogenesis months to years following exposure. The prognosis for recovery is better for individuals who receive the irradiation over a short interval than for those who are exposed over several weeks. Radiation therapy for prostate cancer may cause an acute reduction in spermatogenesis and testosterone followed in most patients by partial or full recovery.

Recovery of spermatogenesis may also occur months to years following administration of chemotherapeutic agents. The most important factor determining prognosis is the total dose of chemotherapy administered.

Improvement in the quality of the semen is found in 60% to 80% of patients following successful repair of varicocele. Restoration of fertility has been reported in about half of such patients. The prognosis for spontaneous improvement of idiopathic oligospermia due to infection or infarction is poor.

**ADULT LEYDIG CELL FAILURE (ANDROPAUSE)**

In contrast to the menopause in women, men do not experience an abrupt decline or cessation of gonadal function. However, a gradual diminution of testicular function does occur in many men as part of the aging process (see Chapter 23). It is not known how many men develop symptoms directly attributable to this phenomenon.
Etiology, Pathology, and Pathophysiology

After age 50, there is a gradual decrease in the total serum testosterone concentration, although the actual values remain within the normal range. The levels of free testosterone decrease to a greater extent because of an increase in SHBG. The testosterone production rate declines and Leydig cell responsiveness to hCG also decreases. A gradual compensatory increase in serum LH levels has also been noted. Aging also is associated with alterations in the hypothalamic-pituitary portion of the axis.

Histologic studies of the aging testes have shown patchy degenerative changes in the seminiferous tubules with a reduction in number and volume of Leydig cells. The pathologic changes are first noted in the regions most remote from the arterial blood supply. Thus, microvascular insufficiency may be the etiologic basis for the histologic tubular changes and the decrease in Leydig cell function noted with aging. In addition, virtually all of the conditions that cause adult seminiferous tubule failure may lead to Leydig cell dysfunction if testicular injury is severe enough.

Clinical Features

A. Symptoms and signs  A great many symptoms have been attributed to the male climacteric (andropause), including decreased libido and potency, emotional instability, fatigue, decreased strength, decreased concentrating ability, vasomotor instability (palpitations, hot flushes, diaphoresis), and a variety of diffuse aches and pains. There are usually no associated signs unless the testicular injury is severe. In such patients, a decrease in testicular volume and consistency may be present as well as gynecomastia.

B. Laboratory findings  Serum testosterone may be low or low-normal. Serum LH concentration is usually high-normal or slightly high, but a number of men have a normal LH and borderline low total and free testosterone. Oligospermia is usually present. Bone mineral density may be decreased.

C. Special examinations  Because many men with complaints compatible with Leydig cell failure have borderline low testosterone concentrations and LH concentrations within the normal adult range, a therapeutic testosterone/placebo trial may be attempted. The test is best performed double-blind over an 8-week period. During the first or last 4 weeks, the patient receives testosterone enanthate, 100 mg intramuscularly per week; during the other 4-week period, placebo injections are administered. The patient is interviewed by the physician 2 weeks after the last course of injections. After the interview, the code is broken; if the patient notes amelioration of symptoms during the period of androgen administration but not during the placebo period, the diagnosis or adult Leydig cell failure is substantiated. If the patient experiences no subjective improvement following testosterone, or if improvement is noted following both placebo and testosterone injections, Leydig cell failure is effectively ruled out.

Differential Diagnosis

Erectile dysfunction from vascular, neurologic, or psychologic causes must be distinguished from Leydig cell failure. A therapeutic trial of androgen therapy does not help erectile dysfunction that is not due to androgen deficiency.

Treatment

Androgen replacement therapy is the treatment of choice for both symptomatic and asymptomatic Leydig cell failure. This results in increases in lean body mass, bone mineral density, hemoglobin, libido, strength, and sense of well-being and decreases in total and high-density lipoprotein cholesterol and markers of bone resorption.

MALE INFERTILITY

About 15% of married couples are unable to produce offspring. Male factors are responsible in about 30% of cases, female factors in about 45%, and couple factors in 25%.

Etiology and Pathophysiology

In order for conception to occur, spermatogenesis must be normal, the sperm must complete its maturation during transport through patent ducts, adequate amounts of seminal plasma must be added to provide volume and nutritional elements, and the male must be able to deposit the semen near the female's cervix. Any defect in this pathway can result in infertility due to a male factor problem. The spermatozoa must also be able to penetrate the cervical mucus and reach the uterine tubes, where conception takes place. These latter events may fail to occur if there are female reproductive tract disorders or abnormalities of sperm motility or fertilizing capacity.

Table 12-4 lists the identified causes of male infertility. Disturbances in the function of the hypothalamus, pituitary, adrenals, or thyroid are found in approximately 4% of males evaluated for infertility. Sex chromosome abnormalities, cryptorchidism, adult seminiferous tubule failure, and other forms of primary testicular failure are found in 15% of infertile males. Congenital or acquired ductal problems are found in approximately 6% of such patients, and poor coital technique, sexual dysfunction, ejaculatory disturbances, and anatomic abnormalities such as hypospadias are causative factors in 4% to 5% of patients evaluated for infertility. Idiopathic infertility, in which no cause can be identified with certainty, accounts for approximately 35% of patients. Some of these patients may have mild forms of androgen receptor defects, microdeletions of the Y chromosome, or mutations in the cystic fibrosis gene. Autoimmune disturbances that lead to sperm agglutination and immobilization causes infertility in only a small fraction of patients. Varicoceles are found in 25% to 40% of patients classified as having idiopathic infertility, and experimental studies have shown an adverse effect of varicoceles on spermatogenesis. However, it is unclear why some individuals appear to be more susceptible to testicular problems from

varicoceles, as the presence of a varicocele is not uniformly associated with infertility and they are found in 8% to 20% of healthy males in the general population.

Clinical Features

A. Symptoms and signs The clinical features of the hypothalamic-pituitary, thyroid, adrenal, testicular, and sexual dysfunctional disorders have been discussed in preceding sections of this chapter. Examination for the presence of varicocele has also been described.

Patients with immotile cilia syndrome have associated mucociliary transport defects in the lower airways that result in chronic pulmonary obstructive disease. Some patients with this disorder also have Kartagener syndrome, with sinusitis, bronchiectasis, and situs inversus. Infections of the epididymis or vas deferens may be asymptomatic or associated with scrotal pain that may radiate to the flank, fever, epididymal swelling and tenderness, and urethral discharge. The presence of thickened, enlarged epididymis and vas is indicative of chronic epididymitis. Chronic prostatitis is usually asymptomatic, although a perineal aching sensation or low back pain may be described. A boggy or indurated prostate may be found on rectal palpation. A careful examination for the presence of penile anatomic abnormalities such as chordee, hypospadias, or epispadias should be made, because these defects may prevent the deposit of sperm in the vagina.

B. Laboratory findings A carefully collected and performed semen analysis is mandatory. A normal report indicates normal endocrine function and spermatogenesis and an intact transport system. Sperm function can be further evaluated through sperm penetration assays, the inducibility of the acrosome reaction, and motility evaluation on a postcoital test. Immunologic infertility can be examined with a mixed antiglobulin reaction test for anti-sperm antibodies.

If semen analysis shows abnormalities, at least two more specimens should be obtained at monthly intervals. Persistent oligospermia or azoospermia should be evaluated by studies outlined in Figure 12–6. Patients with severe oligospermia or azoospermia should undergo chromosome analysis and testing for Yq microdeletions. If congenital absence of the vas deferens is present, testing for cystic fibrosis transmembrane conductance regulator gene mutations should be performed.

The female partner should be thoroughly examined to verify patency of the uterus and uterine tubes, normal ovulation, and normal cervical mucus. This examination must be performed even in the presence of a male factor abnormality, because infertility is due to a combination of male and female factors in about 20% of cases.

C. Imaging studies In patients with azoospermia or severe oligospermia, transscrotal ultrasound allows an assessment of the seminal vesicles and ejaculatory ducts. Patency of the ducts can be examined with scrotal vasography or seminovesculography.

Treatment

A. Endocrine disorders Correction of hyperthyroidism, hypothyroidism, adrenal insufficiency, and congenital adrenal hyperplasia generally restores fertility. Patients with hypogonadotropic hypogonadism may have spermatogenesis initiated with gonadotropin therapy. Chorionic gonadotropin (2000 units intramuscularly three times per week) with urofollitropin or follitropin beta (75 units intramuscularly three times per week) added after 12 to 18 months if sperm cells do not appear in the ejaculate, restores spermatogenesis in most hypogonadotropic men. The sperm count following such therapy usually does not exceed 10 million/mL but may still allow impregnation. Patients with isolated deficiency of LH may respond to chorionic gonadotropin alone. There is no effective therapy for adult seminiferous tubule failure not associated with varicocele or cryptorchidism. However, if the oligospermia is mild (10-20 million/mL), cup insemination of the female partner with concentrates of semen may be tried. In vitro fertilization (IVF) and other assisted reproductive techniques, including direct injection of a spermatozoon into an egg (intracytoplasmic sperm injection; ICSI), are increasingly being utilized as a method for achieving pregnancy in couples in which the male is oligospermic.

B. Defects of spermatogenesis There is no treatment for immotile cilia syndrome or for chromosomal abnormalities associated with defective spermatogenesis. Drugs that interfere with spermatogenesis should be discontinued. These include the antimetabolites, phenytoin, marijuana, alcohol, monoamine oxidase inhibitors, sulfasalazine, and nitrofurantoin. Discontinuing use of these agents may be accompanied by restoration of normal sperm function.
production. In some patients with maturation arrest, severe hypospermatogenesis or incomplete Sertoli cell only, retrieval of sperm through testicular aspiration or testicular biopsy followed by IVF or ICSI have resulted in pregnancies.

C. Ductal obstruction  Localized obstruction of the vas deferens may be treated by vasovasostomy. Sperm are detected in the ejaculate of 60% to 80% of patients following this procedure. However, the subsequent fertility rate is only 40% to 50%; the presence of antisperm antibodies that agglutinate or immobilize sperms probably accounts for the high failure rate. Epididymovasostomy may be performed for epididymal obstruction. Sperm in the postoperative ejaculate have been found in approximately half of patients treated with this procedure, but subsequent fertility has been demonstrated in only 20% of cases.

D. Genital tract infections  Acute prostatitis may be treated with daily sitz baths, prostatic massage, and antibiotics. A combination of trimethoprim (400 mg) and sulfamethoxazole (2000 mg), twice a day for 10 days followed by the same dosage once a day for another 20 days, has been used with some success. Chronic prostatitis requires a longer period of treatment or a switch to a fluoroquinolone, such as ciprofloxacin 500 mg orally twice daily for 4 weeks. Acute epididymitis may respond to injections of local anesthetic into the spermatic cord just above the testicle. Appropriate antibiotic therapy should also be given. The prognosis for fertility following severe bilateral chronic epididymitis or extensive scarring from acute epididymitis is poor.

E. Varicocele  The presence of varicocele in an infertile male with oligospermia is considered an indication for surgical ligation of the incompetent spermatic veins or radiographic embolization of the veins. Improvement in the semen is noted in 60% to 80% of treated patients, and about half are subsequently fertile.

F. Retrograde ejaculation  Ejaculation of semen into the urinary bladder may occur following disruption of the internal bladder sphincter or with neuropathic disorders such as diabetic autonomic neuropathy. Normal ejaculation has been restored in a few patients with the latter problem following administration of phenylpropanolamine, 15 mg orally twice daily in timed-release capsules. Sperm can also be recovered from the bladder following masturbation for the purpose of direct insemination of the female partner.

G. Antibodies to sperm or seminal plasma  Antibodies in the female genital tract that agglutinate or immobilize sperm may be difficult to treat. Older methods such as condom therapy or administration of glucocorticoids have not been uniformly successful. Currently, intrauterine insemination with washed spermatozoa, IVF, and gamete intrafallopian transfer are considered the most effective treatments.

H. Anatomic defects of the penis  Patients with hypospadias, epispadias, or severe chordee may collect semen by masturbation for use in insemination.

I. Poor coital technique  Couples should be counseled not to use vaginal lubricants or postcoital douches. In order to maximize the sperm count in cases of borderline oligospermia, intercourse should not be more frequent than every other day. Exposure of the cervix to the seminal plasma is increased by having the woman lie supine with her knees bent up for 20 minutes after intercourse.

Course and Prognosis
The prognosis for fertility depends on the underlying cause. It is good for patients with nontesticular endocrine abnormalities, varicoceles, retrograde ejaculation, and anatomic defects of the penis. If fertility cannot be restored, the couple should be counseled regarding intrauterine insemination with concentrated sperm, artificial insemination, IVF, ICSI, or adoption.

ERECTILE DYSFUNCTION
Erectile dysfunction is the inability to achieve or maintain an erection of sufficient duration and firmness to complete satisfactory sexual activity in more than 25% of attempts. It may occur with or without associated disturbances of libido or ejaculation. Approximately 5% of men have complete erectile dysfunction by age 40 and 15% by age 70. Some degree of erectile dysfunction is present in about 50% of men between ages 40 and 70.

Etiology and Pathophysiology
Penile erection occurs when blood flow to the penile erectile tissue (corpora cavernosa and spongiosum) increases as a result of dilation of the urethral artery, the artery of the bulb of the penis, the deep artery of the penis, and the dorsal artery of the penis following psychogenic or sensory stimuli transmitted to the limbic system and then to the thoracolumbar and sacral autonomic nervous system. The relaxation of the cavernosal arterial and cavernosal trabecular sinusoidal smooth muscle occurs following stimulation of the sacral parasympathetic (S2-4) nerves, which results in the release of acetylcholine, vasoactive intestinal peptide, and an endothelial cell-derived nitric oxide, which activates guanylyl cyclase. As the sinuosids become engorged, the subtunical venous plexus is compressed against the tunica albuginea, preventing egress of blood from the penis. Contraction of the bulbocavernosus muscle through stimulation of the somatic portion of the S2 to S4 pudendal nerves further increases the intracavernosal pressure. These processes result in the distention, engorgement, and rigidity of the penis that constitute erection.

Broadly speaking, erectile dysfunction may be divided into psychogenic and organic causes. Major epidemiologic factors that have been associated with erectile dysfunction include diabetes, hypertension, depression, smoking, aging, low high-density lipoprotein cholesterol, metabolic syndrome, cardiovascular disease, lower urinary tract symptoms of benign prostatic hyperplasia, and a low serum DHEA sulfate level. Table 12–5 lists various pathologic conditions and drugs that may be associated with erectile dysfunction.
Most organic causes of erectile dysfunction result from disturbances in the neurologic pathways essential for the initiation and maintenance of erection or in the blood supply to the penis. Many of the endocrine disorders, systemic illnesses, and drugs associated with erectile dysfunction affect libido, the autonomic pathways essential for erection, or the blood flow to the penis. Venous incompetence because of anatomic defects in the corpora cavernosa or subtunical venous plexus is being recognized with increasing frequency. Local urogenital disorders such as Peyronie disease (idiopathic fibrosis of the covering sheath of the corpus cavernosum) may mechanically interfere with erection. In some patients, the cause of erectile dysfunction is multifactorial. For example, some degree of erectile dysfunction is reported by over 50% of men with diabetes mellitus. The basis of the erectile dysfunction is usually autonomic neuropathy. However, vascular insufficiency, antihypertensive medication, uremia, and depression may also cause or contribute to the problem in diabetics.

**Clinical Features**

**A. Symptoms and signs**

Patients may complain of constant or episodic inability to initiate or maintain an erection, decreased penile turgidity, decreased libido, or a combination of these difficulties. The degree of erectile dysfunction can be assessed by questionnaires such as the International Index of Erectile Function or the Sexual Health Inventory for men. Besides the specific sexual dysfunction symptoms, symptoms and signs of a more pervasive emotional or psychiatric problem may be elicited. If an underlying neurologic, vascular, or systemic disorder is the cause of erectile dysfunction, additional symptoms and signs referable to the anatomic or metabolic disturbances may be present. A history of claudication of the buttocks or lower extremities should direct attention toward arterial insufficiency. Lower urinary tract disorders may be screened for through the use of the International Prostate Symptom Score questionnaire. A thorough history of medication, herb, illicit drug and alcohol use should be obtained.

The differentiation between psychogenic and organic erectile dysfunction can usually be made on the basis of the history. Even though the patient may be selectively unable to obtain or maintain a satisfactory erection to complete sexual intercourse, a history of repeated normal erections at other times is indicative of psychogenic erectile dysfunction. Thus, a history of erections that occur nocturnally, during masturbation, or during foreplay or with other sexual partners eliminates significant neurologic, vascular, or endocrine causes of erectile dysfunction. Patients with psychogenic erectile dysfunction often note a sudden onset of sexual dysfunction concurrently with a significant event in their lives such as loss of a friend or relative, an extramarital affair, or the loss of a job.

Patients with organic erectile dysfunction generally note a more gradual and global loss of potency. Initially, such individuals may be able to achieve erections with strong sexual stimuli, but ultimately they may be unable to achieve a fully turgid erection under any circumstances. In contrast to patients with psychogenic erectile dysfunction, patients with organic erectile dysfunction generally maintain a normal libido. However, patients with systemic illness may have a concurrent diminution of libido and
potency. Hypogonadism should be suspected in a patient who has never had an erection (primary erectile dysfunction).

During the physical examination, the patient's secondary sexual characteristics should be assessed and examination performed for gynecomastia, discordant or diminished femoral pulses, reduced testicular volume or consistency, penile plaques, and evidence of peripheral or autonomic neuropathy. The bulbocavernosal reflex tests the integrity of the S2 to S4 nerves. It is performed by inserting a finger into the patient's rectum while squeezing his glans penis. Contraction of the anal musculature represents a normal response.

B. Laboratory findings and special examinations

Serum testosterone measurements may uncover a mild and otherwise asymptomatic androgen deficiency. If the testosterone level is low, serum PRL should be measured because hyperprolactinemia—whether drug-induced or due to a pituitary or hypothalamic lesion—may inhibit androgen production. Diabetes mellitus is a relatively common cause of erectile dysfunction and erectile dysfunction may be the presenting symptom of diabetes; therefore, fasting and 2-hour postprandial blood glucose measurements should be ordered.

In a patient with a normal physical examination and screening blood tests, many clinicians elect to begin with a therapeutic trial of a type 5 phosphodiesterase (PDE5) inhibitor that potentiates the effects of nitric oxide by inhibiting the breakdown of cyclic guanosine monophosphate. The initial oral dose is usually 50 mg of sildenafil (Viagra), 10 mg of tadalafil (Cialis), or 10 mg vardenafl (Levitra). This should be tried only if the patient is not taking nitrates, has not had a myocardial infarction in the last 6 months, and does not have unstable angina, hypotension, severe congestive heart failure, or retinitis pigmentosa.

The integrity of the neurologic pathways and the ability of the blood vessels to deliver a sufficient amount of blood to the penis for erection to occur may be objectively examined by placement of a strain gauge behind the glans penis and at the base of the penis at the time the patient retires for sleep. The occurrence of nocturnal penile tumescence can thus be recorded. Healthy men and those with psychogenic erectile dysfunction have three to five erections a night associated with rapid eye movement sleep. Absence or reduced frequency of nocturnal tumescence indicates an organic lesion. Penile rigidity as well as tumescence can be evaluated with an ambulatory monitor called RigiScan. The vascular integrity of the penis may be examined by Doppler ultrasonography with spectral analysis following intracavernosal injection of a vasoactive drug. This method allows detection of venous leaks with a sensitivity of 55% to 100% and specificity of 69% to 88%. Arterial problems are also detected with a sensitivity of 82% to 100% and specificity of 64% to 96%. The choice of other laboratory tests such as cavernosometry, cavernosography, or arteriography depends on associated organic symptoms or signs.

Treatment

Discontinuation of an offending drug usually results in a return of potency. Similarly, effective therapy of an underlying systemic or endocrine disorder may cure the erectile dysfunction. For psychogenic erectile dysfunction, simple reassurance and explanation, formal psychotherapy, and various forms of behavioral therapy have a reported 40% to 70% success rate. Sildenafil, 25 to 100 mg taken orally about 1 hour before anticipated intercourse is approximately 70% to 80% effective in patients with a wide variety of causes of erectile dysfunction, including psychogenic ones. This agent is absolutely contraindicated in men receiving oral or transdermal nitrates for vascular disease. Side effects include headache (16%) and visual disturbances (3%). Other PDE5 inhibitors that are available include vardenafil (2.5-20 mg) and tadalafl (2.5-20 mg).

Vasoactive drugs including prostaglandin E1, papaverine hydrochloride, and phentolamine mesylate, either alone or in combination, may induce an erection following intracavernous injection. Of these, the only Food and Drug Administration-approved agent is prostaglandin E1 (alprostadil), which needs to be individualized within the dosage range of 2.5 to 60 μg per injection. In clinical studies, up to 90% of men with erectile dysfunction developed erections with intracavernosal injections. Side effects include penile pain (33% of patients), hematoma (3%), penile fibrosis (3%), and priapism (0.4%). Intraurethral insertion of a 1.4-mm pellet containing alprostadil leads to satisfactory erections in two-thirds of patients, with effects beginning within 10 minutes and lasting 30-60 minutes. The major side effects are penile pain (36%), urethral pain (13%), and dizziness (4%).

Devices have been developed that use suction to induce penile engorgement and constrictive bands to maintain the ensuing erection. Erections are achieved in 90% of patients with an approximately 70% couple satisfaction rate. Alternatively, a surgically implanted semirigid or inflatable penile prosthesis provides satisfactory results in 85% to 90% of cases, but the device must be replaced every 5 to 10 years.

Repair of venous leaks and microsurgical revascularization of arterial lesions have had variable success rates. Patients with permanent erectile dysfunction due to organic lesions that cannot be corrected should be counseled in noncoit al sensate focus techniques.

GYNECOMASTIA

Gynecomastia is common during the neonatal period and is present in about 70% of pubertal males (Chapter 15). Clinically apparent gynecomastia has been noted at autopsy in almost 1% of adult males, and 40% of autopsied males have histologic evidence of gynecomastia.

Etiology and Pathophysiology

The causes of gynecomastia are listed in Table 12-6. Several mechanisms have been proposed to account for this disorder. All involve a relative imbalance between estrogen and androgen concentrations or action at the mammary gland level. Decrease in free testosterone may be due to primary gonadal disease or an increase

in SHBG as is found in hyperthyroidism and some forms of liver disease (eg, alcoholic cirrhosis). Decreased androgen action in patients with the androgen insensitivity syndromes results in unopposed estrogen action on the breast glandular tissue. Acute or chronic excessive stimulation of the Leydig cells by pituitary gonadotropins alters the steroidogenic pathways and favors excessive estrogen and estrogen precursor secretion relative to testosterone production. This mechanism may be responsible for the gynecomastia found with hypergonadotrophic states such as Klinefelter syndrome and adult Leydig cell failure. The rise of gonadotropins during puberty may lead to an estrogen-androgen imbalance by similar mechanisms. Patients who are malnourished or have systemic illness may develop gynecomastia during refeeding or treatment of the underlying disorder. Malnourishment and chronic illness are accompanied by a reduction in gonadotropin secretion, and during recovery the gonadotropins rise and may stimulate excessive Leydig cell production of estrogens relative to testosterone.

Excessive stimulation of Leydig cells may also occur in patients with hCG-producing trophoblastic or nontrophoblastic tumors. In addition, some of these tumors are able to convert estrogen precursors into estradiol. Feminizing adrenocortical and Leydig cell neoplasms may directly secrete excessive quantities of estrogens. The mechanisms by which PRL-secreting pituitary tumors and hyperprolactinemia produce gynecomastia are unclear. Elevated serum PRL levels may lower testosterone production and diminish the peripheral actions of testosterone, which may result in an excessive estrogen effect on the breast that is not counteracted by androgens.

Drugs may reduce androgen production (eg, spironolactone, ketoconazole), peripherally antagonize androgen action (spironolactone, cimetidine), or interact with breast estrogen receptors (spironolactone and phytoestrogens in marijuana).

Finally, it has been proposed that patients with idiopathic and familial gynecomastia have breast glandular tissue that is inordinately sensitive to normal circulating levels of estrogen or excessively converts estrogen precursors to estrogens.

**Pathology**

Three histologic patterns of gynecomastia have been recognized. The florid pattern consists of an increase in the number of budding ducts, proliferation of the ductal epithelium, periductal edema, and a cellular fibroblastic stroma. The fibrous type has dilated ducts, minimal duct epithelial proliferation, no periductal edema, and a virtually acellular fibrous stroma. An intermediate pattern contains features of both types.

Although it has been proposed that different causes of gynecomastia are associated with either the florid or the fibrous pattern, it appears that the duration of gynecomastia is the most important factor in determining the pathologic picture. Approximately 75% of patients with gynecomastia of 4 months’ duration or less exhibit the florid pattern, whereas 90% of patients with gynecomastia lasting a year or more have the fibrous type. Between 4 months and 1 year, 60% of patients have the intermediate pattern.
Clinical Features

A. Symptoms and signs  The principal complaint is unilateral or bilateral concentric enlargement of breast glandular tissue. Nipple or breast pain is present in one-fourth of patients and objective tenderness in about 40%. A complaint of nipple discharge can be elicited in 4% of cases. Histologic examination has demonstrated that gynecomastia is almost always bilateral, although grossly it may be detected only on one side. The patient often complains of discomfort in one breast despite obvious bilateral gynecomastia. Breast or nipple discomfort generally lasts less than 1 year. Chronic gynecomastia is usually asymptomatic, with the major complaint being the cosmetic one. Symptoms and signs of underlying disorders may be present. Gynecomastia may be the earliest manifestation of an hCG-secreting testicular tumor; therefore, it is mandatory that careful examination of the testes be performed in any patient with gynecomastia. Enlargement, asymmetry, and induration of a testis may be noted in such patients.

B. Laboratory findings  Once pubertal and drug-induced gynecomastia have been excluded, a biochemical screen for liver and renal abnormalities should be performed. If those are normal and the gynecomastia is of recent onset, then serum hCG, LH, testosterone, and estradiol levels should be measured. The interpretation of the results is outlined in Figure 12–8. For chronic, asymptomatic gynecomastia detected on physical examination, measurement of a morning serum testosterone level is a reasonable screen for hypogonadism.

Differential Diagnosis

Gynecomastia should be differentiated from lipomas, neurofibromas, carcinoma of the breast, and obesity. Breast lipomas, neurofibromas, and carcinoma are usually unilateral, painless, and eccentric, whereas gynecomastia characteristically begins in the subareolar areas and enlarges concentrically. The differentiation between gynecomastia and enlarged breasts due to obesity may be difficult. The patient should be supine. Examination is performed by spreading the thumb and index fingers and gently palpating the breasts during slow apposition of the fingers toward the nipple. In this manner, a concentric ridge of tissue can be felt in patients with gynecomastia but not in obese patients without glandular tissue enlargement. The examination may be facilitated by applying soap and water to the breasts.

Complications and Sequelae

There are no complications other than possible psychologic damage from the cosmetic defect. With the possible exclusion of patients with Klinefelter syndrome, individuals with gynecomastia do not have an increased risk of development of breast carcinoma.

Treatment

A. Medical treatment  The underlying disease should be corrected if possible, and offending drugs should be discontinued. Antiestrogens or selective estrogen receptor modulators, such as tamoxifen or raloxifene, have been found useful in relieving pain and reversing gynecomastia in some patients. Whether these

![Diagram of diagnostic evaluation for endocrine causes of gynecomastia](image-url)
therapies will be useful in most patients with gynecomastia remains to be seen. Aromatase inhibitors have also been tried but are not as beneficial as tamoxifen. Tamoxifen is also useful in preventing development of gynecomastia in many patients who are starting therapy for prostate cancer with antiandrogens.

**B. Surgical treatment** Reduction mammoplasty should be considered for cosmetic reasons in any patient with long-standing gynecomastia that is in the fibrotic stage.

**C. Radiologic treatment** Patients with prostatic carcinoma may receive low-dose radiation therapy (900 cGy or less) to the breasts before initiation of antiandrogen monotherapy for prostate cancer. This may prevent or diminish the gynecomastia that usually results from such therapy, although tamoxifen is more effective. Radiotherapy should not be given to other patients with gynecomastia.

**Course and Prognosis**

Pubertal gynecomastia usually regresses spontaneously over 1 to 2 years. Patients who develop drug-induced gynecomastia generally have complete or near-complete regression of the breast changes if the drug is discontinued during the early florid stage. Once gynecomastia from any cause has reached the fibrotic stage, little or no spontaneous regression occurs, and medical therapy is ineffective.

### TESTICULAR TUMORS

Testicular neoplasms account for 1% to 2% of all male-specific malignant neoplasms and 4% to 10% of all genitourinary neoplasms. They are the most frequent type of cancer in men between 20 and 34 years of age. The incidence is 5.4 per 100,000 men in the United States and 4.6 to 7.3 per 100,000 men in Europe. The incidence is lower in nonwhite than in white populations. Ninety-five percent of testicular tumors are of germ cell origin; 5% are composed of stromal or Leydig cell neoplasms.

### Etiology and Pathophysiology

The cause of germ cell testicular tumors is not known. Predisposing factors include testicular maldescent and dysgenesis. About 4% to 12% of testicular tumors are found in association with cryptorchidism, and such a testicle has a 20- to 30-fold greater risk of developing a neoplasm than does a normally descended one. Almost 20% of testicular tumors associated with cryptorchidism arise in the contralateral scrotal testis, suggesting that testicular dysgenesis may be of etiologic importance in the development of germ cell neoplasms. Although trauma is frequently cited as an etiologic factor in testicular tumors, no causal relationship has been established. What is more likely is that testicular trauma serves to call the patient's attention to the presence of a testicular mass. Familial predisposition is found in 1% to 2% of patients. An increased incidence has been noted in patients with Down and Klinefelter syndromes and prenatal exposure to exogenous estrogens. Increased risk also has been associated with smoking and possibly HIV infection. Extra copies of a portion of chromosome 12 (isochromosome 12p) have been found in testicular germ cell tumors.

Bilateral gynecomastia is uncommon in patients who present with germ cell tumors. It is generally associated with production of hCG by the trophoblastic elements in the tumor. The hCG stimulates the Leydig cells to produce excessive estrogens relative to androgen production, resulting in estrogen-androgen imbalance and gynecomastia. In addition, the trophoblastic tissue in some of the germ cell tumors may convert estrogen precursors to estrogens, as can Leydig and Sertoli cell tumors.

### Pathology

**A. Germ cell tumors** Seminomas account for 33% to 50% of all germ cell tumors. They are composed of round cells with abundant cytoplasm, prominent nuclei, and large nucleoli. The cells are arranged in cords and nests and have a thin delicate network of stromal connective tissue. Embryonal cell neoplasms comprise 20% to 33% of germ cell tumors. These tumors have multiple histologic patterns composed of cuboidal pleomorphic cells. One distinct pattern of cellular arrangement is the endodermal sinus tumor (yolk sac tumor), the most frequent germ cell neoplasm found in infants. Immunohistochemical techniques have localized alpha-fetoprotein to the embryonal cells. About 10% of germ cell tumors are teratomas, which are composed of well-differentiated cells derived from all three germ layers. When one or more of the teratoid elements are malignant or are mixed with embryonal carcinoma cells, the term teratocarcinoma is applied. These tumors account for one-tenth to one-third of germ cell neoplasms. Choriocarcinoma is the rarest form of germ cell tumor (2%) and is composed of masses of large, polymorphic, multinucleated syncytiotrophoblastic cells. Although pure choriocarcinoma is rare, many testicular tumors contain an occasional trophoblastic giant cell. Immunohistochemical techniques have shown that these cells are the source of hCG in such tumors.

**B. Leydig and Sertoli cell tumors** Leydig cell (interstitial cell) tumors are rare. Most are benign and are composed of sheets of oval to polygonal cells arranged in lobules separated from one another by thin strands of connective tissue. Malignant Leydig cell tumor disseminates by both lymphatic and venous channels, with initial metastatic deposits being found in the regional lymph nodes, followed by metastases to liver, lung, and bone. Sertoli cell tumors also are rare, are generally benign, and are composed of large tubules, a thick basement membrane with enlarged cuboidal Sertoli cells. There may be extensive calcification within the tumors and the tumors may be multifocal and bilateral.

### Clinical Features

**A. Symptoms and signs**

1. **Germ cell tumors**—Testicular tumors usually present as painless enlargement of a testicle with an associated feeling of fullness or heaviness in the scrotum. Thus, about 80% of
patients note a testicular swelling or mass, whereas only 25% complain of testicular pain or tenderness. About 6% to 25% of patients give a history of testicular trauma that brought the testicular mass to their attention. Gynecomastia may be present initially in 2% to 4% of patients and develops subsequently in another 10%. About 5% to 10% of patients present with symptoms of distant metastatic disease, including backache, skeletal pains, gastrointestinal symptoms and abdominal pains, inguinal adenopathy, cough, hemoptysis, and neurological dysfunction.

A testicular mass or generalized enlargement of the testis is often present on examination. In 5% to 10% of patients, a coexisting hydrocele may be present. In the presence of metastatic disease, supraclavicular and retroperitoneal lymph node enlargement may be present.

2. Leydig and Sertoli cell tumors—In children, Leydig cell tumors of the testes may produce sexual precocity, with rapid skeletal growth and development of secondary sexual characteristics. Adults with such tumors usually present with a testicular mass and occasionally gynecomastia. Decreased libido may also be present in such patients. Sertoli cell tumors are associated with gynecomastia and feminization due to excessive aromatase activity. In addition, these tumors are associated with the autosomal dominant Peutz-Jeghers syndrome (gastrointestinal polyposis and oval, irregularly pigmented lip macules) and the Carney complex (cardiac myxomas, spotty cutaneous pigmentation, primary pigmented nodular adrenocortical disease with hypercortisolism).

B. Laboratory findings

1. Germ cell tumors—The tumor markers hCG, alpha-fetoprotein, and lactate dehydrogenase (LDH) should be measured in every male presenting with a testicular mass. hCG is found in the sera of 5% to 10% of males with seminoma, over half of patients with teratocarcinoma or embryonal cell carcinoma, and all patients with choriocarcinoma. hCG should be measured as the beta subunit or other hCG-specific immunoassay method. Elevated serum immunoreactive alpha-fetoprotein concentrations are found in almost 70% of patients with nonseminomatous forms of germ cell neoplasms. Both markers are elevated in over 50% of patients with nonseminomatous germ cell tumors, and at least one of the markers is elevated in 85% of such patients. These markers can also be used to monitor the results of therapy. LDH measurements have an independent prognostic significance and reflect tumor growth rate and cellular proliferation. It is increased in about 80% of patients with advanced seminomas and 60% of advanced nonseminomatous tumors. The results of the three marker measurements are included in the formal staging classification from the American Joint Committee on Cancer.

2. Leydig and Sertoli cell tumors—Serum DHEA sulfate, urinary 17-ketosteroid, and both urinary and serum estrogen levels may be increased, while serum testosterone concentrations tend to be low or within the normal adult range in patients with Leydig cell tumors. Individuals with Sertoli cell tumors have elevated estradiol levels.

C. Imaging studies Testicular ultrasonography may be required to visualize small tumors. Staging of testicular tumors requires chest and abdominal CT scans and other radiologic procedures depending on the type of tumor and the symptoms.

Differential Diagnosis

Testicular tumors are sometimes misdiagnosed as epididymitis or epididymo-orchitis. An inflammatory reaction of the epididymis often involves the vas deferens. Therefore, both the vas and the epididymis are thickened and tender on examination during the acute disease. Pyuria and fever also help to differentiate between epididymitis and testicular tumor. Because hydrocele may coexist with testicular tumor, the testes should be carefully examined following aspiration of the hydrocele.

Other conditions that can cause confusion with testicular tumors include inguinal hernia, hematocele, hematomy, torsion, spermatocele, varicocele, and (rarely) sarcoidosis, tuberculosis, and syphilitic gumma. Ultrasonic examination of the scrotum may help distinguish between testicular tumors and extratesticular disease such as acute or chronic epididymitis, spermatocele, or hydrocele.

Benign Leydig cell tumors of the testes must be differentiated from adrenal rest tumors in patients with congenital adrenal hyperplasia. Because the testes and the adrenals are derived from the same embryologic source, ectopic adrenal tissue may be found to migrate with the testes. This tissue can enlarge under the influence of ACTH in patients with congenital adrenal hyperplasia or Cushing disease. Adrenal rest tumors tend to be bilateral, whereas patients with Leydig cell tumors generally have unilateral disease. Both may be associated with elevated urine 17-ketosteroids and elevated serum DHEA sulfate concentrations. Elevated serum and urinary estrogen concentrations are found with both disorders. However, patients with congenital adrenal hyperplasia or Cushing disease have a decrease in 17-ketosteroids, DHEA sulfate, and estrogen concentrations, as well as a decrease in tumor size, following administration of dexamethasone, while those with Leydig cell tumors do not.

Treatment

A. Germ cell tumors Seminomas are quite radiosensitive, and disease localized to the testes is usually treated with radical inguinal orchietomy and 2000 to 4000 cGy of conventional radiotherapy delivered to the ipsilateral inguinal-iliac and bilateral para-aortic lymph nodes to the level of the diaphragm. For disease that has spread to the lymph nodes below the diaphragm, additional whole abdominal radiotherapy and prophylactic mediastinal and supraclavicular lymph node irradiation are usually given. Widely disseminated disease is generally treated with a combination of radiotherapy and chemotherapy, especially with bleomycin, etoposide, and cisplatin.

Nonseminomatous tumors are treated with orchietomy, retroperitoneal lymph node dissection, and, if necessary, radiotherapy or chemotherapy (or both). Although many chemotherapeutic agents have been used, combinations of etoposide, bleomycin, and cisplatin currently appear to produce the best overall results. Patients with nonseminomatous tumors treated by these means should be monitored with serial measurements of serum hCG and alpha-fetoprotein.

B. Leydig and Sertoli cell tumors Leydig and Sertoli cell tumors of the testes are treated by unilateral radical inguinal...
Orchiectomy. Objective remissions of malignant Leydig cell tumors have been noted following treatment with mitotane.

**Course and Prognosis**

**A. Germ cell tumors** In patients with seminoma confined to the testis, the 5-year survival rates after orchiectomy and radiotherapy are 98% to 100%. Disease in the lymph nodes below the diaphragm also has an excellent prognosis, with 5-year survival rates of 80% to 85%. Disease above the diaphragm and disseminated disease have overall 5-year survival rates of about 70%.

In patients with nonseminomatous germ cell tumors, aggressive surgery and combination chemotherapy have raised the 5-year survival rates from less than 20% to 60% to 90%.

**B. Leydig and Sertoli cell tumors** Removal of a benign Leydig or Sertoli cell tumor is accompanied by regression of iso- or heterosexual precocious puberty in children or feminization in adults. The prognosis for malignant Leydig cell tumor is poor, with most patients surviving less than 2 years from the time of diagnosis.

</table>
No gene has yet been identified that generates an ovary from an undifferentiated gonad. It is only in the absence of the sex-determining region of the Y gene (SRY) that the gonad develops into an ovary. (For more details, see the discussion of sexual differentiation in Chapter 14.) Primordial germ cells, which give rise to oocytes or spermatogonia, are first identifiable in the yolk sac endoderm (hindgut) at 3 to 4 weeks’ gestation. Once specified, they migrate and proliferate en route through the dorsal mesentery into the gonadal ridge, which is located lateral to the dorsal mesentery of the gut and medial to the mesonephros (Figure 13-1). Studies in mice have suggested that the process of proliferation and navigation to the gonad depends on several genes, including Steel (kit ligand and receptor), β₁ integrin, and many cytokines. Failure of primordial germ cells to develop or migrate into the gonadal ridge results in failure of ovarian development. In contrast, it is suggested that male gonadal development may continue to develop into functional testis despite the absence of germ cells.

The germ cells that reach the gonadal ridge (6 weeks’ gestation) continue to proliferate and are referred to as oogonia (premeiotic germ cells). At 10 to 12 weeks’ gestation, some oogonia leave the mitotic pool and begin meiosis, where they arrest in prophase 1 (dictyotene stage). These arrested germ cells are now called primary oocytes. By 16 weeks, primordial follicles are first identified, making a clear distinction for gonadal differentiation into an ovary. At approximately 20 weeks’ gestation, a peak of 6 to 7 million germ cells (two-thirds of them primary oocytes and one-third oogonia) are present in the ovaries. During the second half of gestation, the rate of mitosis rapidly decreases and the rate of oogonial and follicular atresia increases. Those oogonia that are not transformed into primary oocytes will undergo atresia before birth. This leads to a reduction in the number of germ cells, resulting in a total of 1 to 2 million germ cells at birth. No germ cell mitosis occurs after birth, whereas follicular atresia continues, with the result that the average girl entering puberty has only 300,000 to 400,000 germ cells.

The ovary is organized into an outer cortex and an inner medulla. The germ cells are located within the cortex. Along the outer surface of the cortex is the germinal epithelium. This cell layer is composed of cuboidal cells resting on a basement membrane and forms a continuous layer with the peritoneum. Even though it is called the germinal epithelium, there are no germ cells within this layer. During embryonic development, the epithelial cells proliferate and enter the underlying tissue of the ovary to form cortical cords. When the primordial germ cells arrive at the genital ridge, they are incorporated into these cortical cords. At the same time the germ cells migrate from the yolk sac, the stromal cells of the ovary (granulosa and interstitial cells) migrate from the mesonephric tubules into the gonad. Primordial follicles form within the cortical cords. They are composed of a primary oocyte and one layer of granulosa cells with its basement membrane. Oocytes not surrounded by granulosa cells are lost, probably by apoptosis. This finite follicle population represents the pool of germ cells that will ultimately be available to enter the follicular cycle.

During fetal development, the gonad is held in place by the suspensory ligament at the upper pole and the gubernaculum at the lower pole. The final location of the gonad is dependent on hormone production. In the presence of testosterone, the gubernaculum grows while the suspensory ligament regresses. As the gubernaculum continues to grow, the gonad (testis) descends into the scrotum. In contrast, when testosterone is absent, the suspensory ligament remains and the gubernaculum regresses. This process maintains the gonad (ovary) in the pelvis.

The remainder of the female internal reproductive organs are formed from the paramesonephric (Müllerian) ducts. In the absence of anti-Müllerian hormone (AMH), the paramesonephric system develops into the uterine (fallopian) tubes, uterus, cervix, and upper third of the vagina. Unlike Wolffian duct differentiation, the development of the female reproductive tract is not

**FIGURE 13-1** A. Schematic drawing of a 3-week-old embryo showing the primordial germ cells in the wall of the yolk sac, close to the attachment of the allantois. B. Drawing to show the migrational path of the primordial germ cells along the wall of the hindgut and the dorsal mesentery into the genital ridge. (Reproduced, with permission, from Langman J, Sadler TW. Langman’s Medical Embryology. 8th ed. Lippincott Williams & Wilkins; 2000.)
dependent on hormone production. (For more details, see "Human Sex Differentiation" in Chapter 14.) Briefly, the Müllerian buds are formed lateral to the Wolffian ducts and the gonadal ridge after 37 days' gestation (Figure 13-2). These buds elongate, extend caudally, and cross medially to the Wolffian ducts by 8 weeks' gestation. By 10 weeks, the adjacent paired Müllerian ducts meet in the midline as they join the Müllerian tubercle (urogenital sinus). Over the next couple of weeks, the Wolffian ducts degenerate, and the paired Müllerian ducts fuse and begin to canalize. The intervening septum resorbs between the 12th and 16th weeks of gestation, resulting in a single uterine cavity. The most cranial parts of the Müllerian ducts remain unfused and form the uterine tubes, which remain patent with the coelom (future peritoneal cavity). The caudal segments stimulate solid cords to extend from the Müllerian tubercle to the sinovaginal bulbs from the posterior aspect of the urogenital sinus. In turn, the sinovaginal bulbs extend cranially and fuse with the vaginal cords, forming the vaginal plate. The vagina is subsequently formed by vacuolization of the paramesonephric tissue and the lower portion by vacuolization of the sinovaginal bulbs. (Reproduced, with permission, from Langman J, Sadler TW. Langman's Medical Embryology. 8th ed. Lippincott Williams & Wilkins; 2000.)

The uterus is composed of endometrium (innermost lining), myometrium, and serosa. The adult uterus is a pear-shaped hollow organ. The cervical portion extends approximately 2 cm into the vagina, and the remaining corpus extends approximately 6 cm into the abdomen. The normal adult uterus weighs 40 to 80 g.

The uterus is located in the pelvis and rests on the pelvic floor. Seventy percent to 80% of the time, the uterine position is anteflexed (cervical-uterine corpus angle) and antverted (cervical-vaginal angle). Therefore, when a woman is standing, the corpus of the uterus is horizontal and resting on top of the bladder. The uterus has several paired ligaments that develop from thickenings of the peritoneum and serve to maintain this anatomic position. The cardinal ligament (Mackenrodt) is the main supporting ligament. It attaches to the lateral margins of the cervix at the upper vagina and extends to the lateral pelvic wall. The remaining ligaments—uterosacral, round, and broad—have a lesser role in supporting the uterus.

The uterine artery originates from the anterior division of the internal iliac artery (hypogastric), enters the cardinal ligament, and supplies the uterus. The uterine artery divides into a descending branch and an ascending branch known as the vaginal and arcuate arteries, respectively. The arcuate arteries anastomose with each other and form a vascular network around the uterus. The radial arteries branch off from the arcuate network and penetrate the uterus to supply the myometrium. Smaller basal branches and spiral arteries supply the endometrium.

The ovary is suspended in the pelvis and has three associated ligaments. The average adult ovary is 2.5 to 5 cm × 2.5 cm × 1 cm in size and weighs 3 to 8 g. The position of the ovary is variable, but in a nulliparous woman it is often located in a peritoneal depression on the pelvic sidewalls between the ureter and external iliac vein. The suspensory (infundibulopelvic) ligament attaches to the cranial pole of the ovary and extends to the pelvic brim. This ligament suspends the ovary in the pelvis and contains the ovarian vessels, lymphatics, and nerves. The utero-ovarian ligament attaches to the inferior pole of the ovary and extends to the uterus. The mesovarium connects the anterior portion of the ovary to the posterior leaf of the broad ligament. The blood supply of the ovary originates from the abdominal aorta, passes through the suspensory ligament, and enters the mesovarium to form an anastomotic network with branches from the uterine artery. The ovarian artery enters the ovarian hilum and branches into spiral arteries that enter the medulla and extend to the ovarian cortex. Other branches from the anastomotic network, located in the mesovarium, supply the uterine tubes.

OVARIAN STEROIDOGENESIS

The ovaries are not only the store for germ cells—they also produce and secrete hormones that are vital for reproduction and the development of secondary sexual characteristics. The next section will briefly discuss the biosynthesis of ovarian hormones.

In the ovary, the major source of hormone production is the maturing follicle. The components of the follicle are the theca cells, the granulosa cells, and the primary oocyte. The theca cells produce androgens, and the granulosa cells produce estrogens. The other stromal cells that contribute to androgen production can be divided into two populations of cells: the secondary interstitial cells (derived from theca) and the hilum cells. These cells are the major ones involved in ovarian hormone production during menopause (see below).

The ovarian hormones are derived from cholesterol. Steroidogenic cells acquire the cholesterol substrate from one of three sources. The most common source is plasma lipoprotein-carrying cholesterol, primarily in the form of low-density lipoprotein (LDL). Other minor sources include de novo synthesis from acetate and liberation from stored lipid droplets (cholesterol esters). Stimulation of ovarian cells by trophic hormones such as follicle-stimulating hormone (FSH) and luteinizing hormone (LH) facilitate uptake of cholesterol by increasing the number of LDL receptors on the cell surface. The LDL particle is subsequently internalized and degraded in the lysosome. The free cholesterol that is liberated from the lysosome is delivered to the mitochondria by an unknown mechanism, possibly via microfilaments and microtubules. The cholesterol is then translocated into the mitochondria by the steroidogenic acute regulatory protein (StAR). Thus, StAR is the rate-limiting step regulating substrate availability for steroidogenesis.

Although acute alterations in steroid production result from changes in delivery of cholesterol to the mitochondria, the long-term control of steroid synthesis results from regulation of gene expression. Most of the genes involved in steroidogenesis contain at least one steroidogenic factor-1 (SF-1) response element in the promoter region. These elements are critical for the regulation of steroidogenic genes as well as the development of adrenal gland, ovary, and testis. The importance of SF-1 for steroidogenesis is highlighted in knockout mice deficient in this transcription factor which lack adrenal glands and gonads. Although SF-1 is essential, the specific expression of each gene involves many other transcription factors that work independently or in concert with SF-1.

The rate-determining step that commits cholesterol to steroid synthesis is the cholesterol side chain cleavage enzyme reaction (P450scc) (Figure 13-3). This reaction converts cholesterol to pregnenolone, the precursor of steroid hormones, and takes place in the mitochondria. Pregnenolone is transported out of the mitochondrion, and the remaining steps in sex steroid production take place primarily within the smooth endoplasmic reticulum (SER).

Once pregnenolone is formed, the particular hormones that are synthesized are dependent on the endocrine organ and cell type. For example, the main sources of sex steroids in the female

![FIGURE 13-3 Pathways of steroid biosynthesis. The pathways for synthesis of progesterone and mineralocorticoids (aldosterone), glucocorticoids (cortisol), androgens (testosterone and dihydrotestosterone), and estrogens (estradiol) are arranged left to right. The enzymatic activities catalyzing each bioconversion are written in the boxes. For those activities mediated by specific cytochrome P450, the systematic name of the enzyme (CYP followed by a number) is listed in parentheses. CYPB2 and CYP17 have multiple activities. The planar structures of cholesterol, aldosterone, cortisol, dihydrotestosterone, and estradiol are placed near the corresponding labels. (Reproduced, with permission, from White PC, Speiser PW. Congenital adrenal hyperplasia due to 21-hydroxylase deficiency. Endocr Rev. 2000;21:245.)](image-url)
come from the adrenal gland, ovary, and the periphery. The specific type of hormone synthesized is dependent on the specific gene expression within each cell type.

In the adrenal gland, there are three zones: zona glomerulosa, zona fasciculata, and zona reticularis. The cells in the different zones start with the same hormone precursor but differ in their secretory products. The glomerulosa produces mainly aldosterone, whereas cortisol and androgen are produced by the zona fasciculata and zona reticularis, respectively. The major androgen produced by the adrenal gland is dehydroepiandrosterone sulfate (DHEAS). Differences in enzymatic activity among cells in the various zones are what regulate hormone production. The zona reticularis and zona fasciculata lack 11β-hydroxylase, which is necessary for aldosterone synthesis (see Figure 13–3; see Chapters 9 and 10). The zona glomerulosa lacks 17-hydroxylase and 17,20-lyase (CYP17), which are necessary for sex steroid synthesis.

Ovarian cells similarly secrete different hormones due to differential enzyme activity. The theca interstitial and secondary interstitial cells lack aromatase and hence are the androgen producers in the ovarian cortex. The granulosa cells, on the other hand, lack CYP17 and, therefore, secrete estrogens—mainly estradiol—from theca cell-derived androgens in the proliferative phase and progesterone in the luteal phase (see later).

Adipose and skin make significant contributions to plasma concentrations of some sex steroids. Adipose tissue is able to sequester most steroids due to their lipid solubility. Fat also expresses genes capable of sex steroid metabolism (ie, aromatase). Skin significantly contributes to the plasma concentration of testosterone by utilizing circulating DHEAS and androstenedione as precursors.

The major circulating androgens include DHEAS, androstenedione, and testosterone. During the reproductive years, the ovaries are directly responsible for one-third of the testosterone production. The remaining two-thirds come from the periphery (17β-hydroxysteroid dehydrogenase [HSD] types 3 and 5) and is derived from ovarian and adrenal gland precursors—notably androstenedione, which is produced in equal proportions by the adrenal gland and the ovary. The adrenal gland may directly secrete testosterones, but its major contribution is derived from its production of precursors. Therefore, the ovaries are responsible for nearly two-thirds of the circulating testosterone. This differs from males, in whom only 5% of the circulating testosterone is derived from peripheral conversion of androstenedione. It is also estimated that more than 60% of the most potent androgen, dihydrotestosterone (DHT) in women, is produced in the skin (5α-reductase type 1 and 2) and originates from androstenedione. DHEAS is the major androgen produced by the adrenal gland. The adrenal gland is responsible for more than 95% of the circulating DHEAS levels. Although it is the most abundant androgen circulating in the body, it contributes minimally to serum testosterone levels. The relative strengths of androgens are listed in Table 13–1.

The circulating estrogens include estrone, estrone sulfate, estradiol, and estriol (pregnancy). More than 95% of estradiol in the circulation is produced from the ovary. In contrast to estradiol, approximately one-half of the circulating estrone is secreted from the ovary, while the remaining is derived from peripheral conversion. The most significant precursor, androstenedione, is aromatized in the adipose tissue, hair follicles, and the liver to estrone. Estrone is also derived from estradiol through 17β-HSD type 2 activity or from estrone sulfate (steroid sulfatase). Almost all estriol is produced during pregnancy and is secreted from the placenta (see Chapter 16).

Ultimately, the serum concentration of sex steroids is dictated by the secretion rate (SR), production rate (PR), and metabolic clearance rate (MCR), as shown in Table 13–2. The SR of sex steroids from each organ determines the PR of the hormone. If the SR for a specific hormone in the ovary equals the PR, then there is no extraovarian formation. However, if there is extraovarian formation, then the PR exceeds the SR.

MCR is the volume of blood per unit of time cleared of the hormone. The metabolic clearance rate of sex steroids is inversely related to the affinity for sex hormone–binding globulin (SHBG) and/or albumin. Prior to excretion, steroids are conjugated to make them water soluble. The bulk of testosterone is bound to SHBG (~65%) and to a lesser extent albumin (~35%); only 1% (free hormone) is active and available for metabolism. The remaining androgens have negligible binding affinity for SHBG. Free testosterone may be converted to more potent androgens such as DHT or may be metabolized through androstenedione. Metabolites of androstenedione and DHT are conjugated with a sulfate or glucuronide and are excreted in the urine. The majority of estradiol is also bound, although it has less binding affinity than testosterone for SHBG (~38%) and more for albumin (~60%); approximately 2% is unbound. Estradiol may be directly conjugated (16α-hydroxylated or 2-hydroxylated) or is metabolized to estriol prior to conjugation. The remaining estrogens are weakly bound to proteins. Progesterone is metabolized into many intermediates prior to conjugation. Pregnane diol glucuronide is the major metabolite observed in the urine.

A variety of clinical conditions result from or cause deviations in normal secretion rates, leading to disturbances in the menstrual cycle. This chapter discusses the normal physiology and touches on several of these hormonal disturbances.

</table>

(GnRH), which stimulates the pituitary to release FSH and LH. These gonadotropins then trigger the ovary to release an oocyte that is capable of fertilization. Concurrently, the ovary secretes hormones, which act on the endometrial lining of the uterus to prepare for implantation. In addition, the ovarian hormones feed back to the hypothalamus and pituitary, regulating the secretion of gonadotropins during the phases of the menstrual cycle. This complex interaction will be discussed in greater detail below. The hormonal changes associated with menstruation are summarized in Figure 13–4.

The Hypothalamic-Pituitary Axis

GnRH is the central initiator of reproduction. GnRH is a 10 amino acid peptide with a short half-life of 2 to 4 minutes. It is processed in specialized secreting neurons that originate in the olfactory placode during development and migrate to the arcuate nucleus of the medial basal hypothalamus (MBH). These neurons project from the median eminence and secrete GnRH, with inherent rhythmic behavior (pulse generator), into the portal vessels to reach the gonadotropes within the anterior pituitary. GnRH binds to its receptor, a member of the G protein-coupled seven-transmembrane-spanning receptor superfamily. 1,4,5-inositol triphosphate and diacylglycerol act as second messengers for GnRH. The pulsatile frequency of GnRH secretion regulates gonadotropin synthesis and the secretion of pituitary gonadotropes (see Chapter 4).

During the late luteal-follicular phase, the slower pulsatile release of GnRH—every 90 to 120 minutes—favors FSH secretion. In response to FSH, the maturing follicle in the ovary secretes estradiol. This hormone is involved in a negative feedback loop that inhibits the release of FSH by indirectly decreasing the production of GnRH via gamma-aminobutyric acid neurons, in addition to possibly having a direct effect on the pituitary gland. Estradiol is also involved in a positive feedback loop that increases the frequency of GnRH pulses to every 60 minutes during the follicular phase and acts directly on the pituitary to stimulate LH secretion. LH stimulates the ovary to further increase estradiol production (see two-cell theory, later). There is no further change in GnRH pulsatility at this point in the cycle; however, estradiol and other regulatory factors (see later) increase pituitary sensitivity to GnRH. This increased sensitivity results in a rapid elevation of LH production—the LH surge—which stimulates ovulation. After ovulation, the ruptured follicle (corpus luteum) secretes progesterone. This hormone is involved in a negative-feedback loop, indirectly through increased endogenous opioid activity and possibly directly through a reduction in GnRH pulsatility to every 3 to 5 hours. This favors FSH synthesis during the luteal-follicular transition. As progesterone levels fall again, GnRH pulsatility increases, favoring FSH release.

Role of the Pituitary

Gonadotropes are located in the adenohypophysis and make up approximately 10% of the cells in the pituitary. These cells synthesize and secrete FSH and LH. These hormones, thyroid-stimulating hormone (TSH) and human chorionic gonadotropin (hCG), all belong to a family of glycoprotein hormones. Gonadotropins
are functional as heterodimers and are composed of an alpha and a beta subunit. The alpha subunit amino acid sequence is identical for all of the glycoprotein hormones while the beta subunits contain different amino acid sequence and confer unique specificity on the glycoproteins.

The synthesis of FSH and LH mostly occur in the same cell, yet their secretion patterns differ. The secretion of FSH is tightly linked to the expression of the FSH beta subunit. This suggests that there is minimal storage of FSH within the gonadotropes, and the majority of secretion follows more of a constitutive pathway. This is in contrast to LH secretion, in which it is first stored in organelles and then released with the appropriate trigger (regulated pathway). The different oligosaccharides on the beta subunits likely facilitate the intracellular sorting that results in different mechanisms of secretion.

The differential gene expression that leads to the production and release of gonadotropins by cells in the pituitary is influenced by GnRH and ovarian hormones through feedback loops. Slower GnRH pulse frequency enhances FSH beta subunit expression and increases LH amplitude. In turn, increased GnRH pulse frequency stimulates LH beta subunit expression while promoting FSH release. As a result, LH amplitude decreases while the mean concentration rises. Thus, ovarian steroid modification of hypothalamic GnRH pulsatility controls pituitary gonadotrophin production.

An intrapituitary network involves several factors that play a role in regulating gonadotropin synthesis and secretion. The gonadotropes produce and secrete peptides that are in the transforming growth factor (TGF) family. Activin is a local regulatory protein that is involved in control of gonadotrope function. Slow pulses of GnRH enhance activin synthesis, which subsequently enhances FSH transcription. Follistatin, another TGF-related protein that binds to activin, is stimulated by rapid pulses of GnRH. This decreases the bioavailability of activin and consequently reduces FSH synthesis. In addition to these local modifiers, ovarian transforming growth factors such as inhibin also modulate the expression of gonadotropins (see later).
Role of the Ovary

The ovary is intimately involved in regulating the menstrual cycle via steroid feedback to alter gonadotropin secretion. In addition, the ovary contains an intraovarian network involving factors that are synthesized locally and have a paracrine and autocrine role in the modulation of gonadotropin activity. The intraovarian regulators include the insulin-like growth factor (IGF) family, TGF superfamily, and epidermal growth factor (EGF) family. Furthermore, it is these factors that assist in the coordination of follicular development, steroidogenesis, and ovulation.

The menstrual cycle of the ovary includes a follicular phase and a luteal phase. The follicular phase is characterized by growth of the dominant follicle and ovulation. It typically lasts 10 to 14 days. It is, however, this phase that is variable in duration and most often accounts for the variability in menstrual cycle length in ovulatory women. The luteal phase starts after ovulation and is the period when the ovary secretes hormones that are essential to accommodate conceptus implantation. This phase is relatively constant and averages 14 days (range, 12-15 days) in duration. The next section will describe the two phases in some detail.

Primordial follicles are the fundamental reproductive units that comprise the pool of resting oocytes. Morphologically, they are composed of a primary oocyte that is surrounded by a single layer of squamous granulosa cells and a basement membrane. They have no blood supply. These primordial follicles develop between the sixth and ninth months of gestation and harbor the complete supply of ovarian follicles.

The initiation of follicular growth begins with the transition of the dormant primordial follicle into the growth phase. The exact mechanisms controlling the initial recruitment of the primordial follicle are under investigation. It is suggested that the resting follicular pool is probably under tonic inhibitory control. The initial recruitment process induces growth in some primordial follicles; other neighboring follicles remain quiescent for many months or years. It is thought that the recruitment of these follicles is a continuous process that begins once the germ pool is created and ends with follicular exhaustion. This complex process is gonadotropin independent. Several studies have suggested that an intraovarian signaling network, involving members of the TGF superfamily, is responsible for primordial follicle recruitment. It is also known that recruitment and growth of the follicle absolutely requires cell-to-cell contact with neighboring granulosa cells and the oocyte. These cells transfer various factors, nutrients, and waste to and from the oocyte through gap junctions derived from connexins.

One theory proposes that the oocyte actively influences its own fate by secreting various factors. These include two particular growth factors related to TGF-β, which are produced by the oocyte early in follicular development, growth differentiation factor (GDF)-9 and bone morphogenic protein (BMP)-15. Knockout mouse studies suggest that the oocyte induces granulosa cell proliferation through these growth factors, and the granulosa cell responds with factors (eg, follistatin, c-kit) to decrease the inhibitory influences (eg, activin A, Müllerian-inhibiting substance) and promote stimulators of oocyte growth (Figure 13–5).

**FIGURE 13-5** A theoretical model of follicular recruitment into the growth phase. Initiation of follicular growth may be regulated by many local inhibitory and stimulatory factors (ie, inhibin A, follistatin, kit ligand) and begins with transformation of the granulosa cells from squamous to cuboidal shape. Oocytes subsequently commence growth and regulate proliferation and differentiation of granulosa cells with members of the transforming growth factor β superfamily (ie, GDF-9, BMP15). Phase 1: transition of granulosa cells from flattened to cuboidal Phase 2: oocyte growth and proliferation and differentiation of granulosa cells. (Redrawn with permission of Braw-Tal R. The initiation of follicle growth: the oocyte of the somatic cells? Mol Cell Endocrinol. 2002;187:11.)
Several other local factors have been described to date, and many more will be identified in the future. The ongoing search for these growth factors and hormones will ultimately elucidate the physiology of primordial follicle recruitment. There is a finite number of germ cells, and each successive recruitment further depletes the germ pool. Any abnormality that alters the number of germ cells or accelerates recruitment could perhaps lead to early ovarian follicular depletion and, therefore, early reproductive failure (see section on infertility, later).

Primary follicle development is the first stage of follicular growth (Figure 13-6). Primary follicles differ from primordial follicles in several ways. The oocyte begins to grow. As growth progresses, the zona pellucida is formed. This is a thick layer of glycoprotein that is most likely synthesized by the oocyte. It completely surrounds the oocyte and forms a barrier between the oocyte and the granulosa cell layer. It serves a number of biologic functions that are critical for protection of the oocyte and conception. Finally, the granulosa cells undergo a morphologic change from squamous to cuboidal. This stage of development may last 150 days.

The progression to a secondary follicle includes attainment of maximal oocyte growth (120 µm in diameter), proliferation of granulosa cells, and acquisition of theca cells. The exact mechanism involved in acquiring theca cells is not completely understood, but they are thought to be derived from the surrounding ovarian mesenchyme (stromal fibroblasts) as the developing follicle migrates to the medulla. It is the development of this layer that gives rise to the theca interna and theca externa. With theca cell development, these follicles gain an independent blood supply, although the granulosa cell layer remains avascular. In addition, the granulosa cells in the secondary follicle develop FSH, estrogen, and androgen receptors. This phase of follicular development may take as long as 120 days, probably because of the long doubling time (>250 hours) of granulosa cells.

Further follicular development leads to the tertiary follicle or early antral phase. This phase is characterized by the formation of an antrum or cavity in the follicle. The antral fluid contains steroids, proteins, electrolytes, proteoglycans, and an ultrafiltrate that forms from diffusion through the basal lamina. Other changes in this phase include further theca cell differentiation. Subpopulations

---

**FIGURE 13-6** The chronology of folliculogenesis in the human ovary. Folliculogenesis is divided into two major periods, preantral (gonadotropin independent) and antral (FSH dependent). In the preantral period, a recruited primordial follicle develops into the primary/secondary (class 1) and early tertiary (class 2) stages, at which time cavity or antrum formation begins. The antral period includes the small graafian (0.9-5 mm, classes 4 and 5), medium graafian (6-10 mm, class 6), large graafian (10-15 mm, class 7), and preovulatory (16-20 mm, class 8) follicles. Time required for completion of preantral and antral periods is approximately 300 and 40 days, respectively. Number of granulosa cells (gc), follicle diameter (mm), and atresia (%) are indicated. (Reproduced, with permission, from Gougeon A. Regulation of ovarian follicular development in primates: facts and hypotheses. *Endocr Rev.* 1996;17:121.)
of thecal interstitial cells develop within the theca interna, acquire LH receptors, and are capable of steroidogenesis. The granulosa cells begin to differentiate into distinct cell layers. Starting from the basal lamina, the cells can be stratified into the membrana periantral, cumulus oophorus, and corona radiata layers. This developmental process is influenced by FSH and unidentified signals originating from the oocyte. It is suggested that oocyte-derived GDF-9, is an important factor in this process, where the relative concentration of GDF-9 dictates the specific subtype of granulosa cell. In addition, the granulosa cell—most likely in response to FSH—starts producing activin, a member of the TGF family. Activin is composed of two types of beta subunits, βA and βB, which are held together by disulfide bonds. It is the combination of these subunits that generates the various activins (activin A [βA,βA], AB [βA,βB], or BB [βB,βB]). It is unlikely that activin has an endocrine role, because serum activin levels do not change throughout the menstrual cycle and the activity of the aromatase enzyme. However, the pathway of estradiol biosynthesis is dictated by the type of 17β-HSD that is expressed. In humans, seven 17β-HSDs have been identified, each having different affinities for particular steroids. In the granulosa cell, it is type 1 17β-HSD that is expressed preferentially reducing estrone to yield estradiol. Type 3 17β-HSD preferentially reduces androstenedione to testosterone and is expressed in the Leydig cells and not in the ovary. However, type 5 17β-HSD is expressed in the theca cells and is likely the catalyst for the final step in testosterone synthesis from androstenedione in the ovary. In summary, the major pathway of estradiol biosynthesis within the granulosa cell entails androstenedione aromatization to estrone by aromatase, followed with a reduction to estradiol by type 1 17β-HSD.

The importance of estradiol on folliculogenesis with respect to its negative and positive feedback effects on gonadotropin secretion is well established. However, the role of estradiol in local ovocyte maturation and follicular growth remains controversial. There is evidence that estrogen is synergistic with FSH during the follicular phase by increasing FSH and LH receptors, stimulating proliferation of granulosa cells and gap junctions as well as aromatase activity. The aromatase knockout (ArKO) mouse suggests a local role for estrogen. The ArKO mouse initially has large antral follicles, but after the first year, there are no remaining antral follicles or secondary follicles and atresia is evident among the remaining primary follicles. However, the ArKO oocytes are capable of in vitro maturation and blastocyst formation. There is evidence that both estrogen receptors are expressed in the granulosa and theca cells. Studies with the estrogen receptor α knockout mice show these mice are infertile and lack graafian follicles. However, the estrogen receptor β knockouts are fertile but produce smaller litters. In humans, there are cases where follicular development has occurred in the absence of estradiol secretion. This was observed in a woman with CYP17a deficiency where promotion of follicular growth was noted with gonadotropins. Embryo development followed in vitro fertilization, but unfortunately no pregnancy resulted.

Intraovarian factors play a major modulatory role in both folliculogenesis and steroidogenesis. The oocyte-derived factor GDF-9 is expressed throughout folliculogenesis. It is thought not only to promote granulosa cell differentiation but also to have a stimulatory effect on theca cells and an inhibitory effect on luteal cell formation. The IGFs enhance the response to FSH. In vitro studies have shown that both IGF-1 and IGF-2 increase granulosa cell proliferation and estradiol secretion. However, it is suggested that IGF-2 rather than IGF-1 plays a dominant role in follicular maturation. This may be explained by the absence of IGF-1 expression in the granulosa cells of dominant follicles. Furthermore, women with Laron syndrome (IGF-1 deficiency) where promotion of follicular growth was noted with gonadotropins. Embryo development followed in vitro fertilization, but unfortunately no pregnancy resulted.
FIGURE 13-7 Two-cell hypothesis. A. The preovulatory follicle produces estradiol through a paracrine interaction between theca and granulosa cells. The theca cells provide the substrate, androstenedione, to the granulosa cell for estradiol production. The granulosa cells express the enzymes necessary for transformation of androstenedione to estradiol (P450 aromatase, 17β hydroxysteroid dehydrogenase-1). B. In the corpus luteum, granulosa-lutein cells gain vascularity, LH receptors, and the enzymes necessary for progesterone synthesis. The theca-lutein cells remain the source of androstenedione for estradiol production in granulosa-lutein cells. Gonadotropins, steroidogenic factor-1 (SF-1), and steroidogenic acute regulatory protein (StAR) play crucial roles in steroidogenesis with the ovary (ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; FSH, follicle-stimulating hormone receptor; LH, luteinizing hormone receptor; P450 arom, P450 aromatase; 17β- HSD-I, 17-β hydroxysteroid dehydrogenase-II). (Redrawn with permission from Larsen et al, eds. The physiology and pathology of the female reproductive axis. In: Williams Textbook of Endocrinology. Saunders; 2003; 604.)
and steroidogenesis is largely indirect; it suppresses pituitary FSH secretion. The serum concentrations of inhibin A and B are influenced by the menstrual rhythm. The circulating levels of inhibin A rise late in the follicular phase and remain elevated in the luteal phase whereas the concentration of inhibin B mirrors the menstrual pattern of serum FSH levels (see Figure 13–4). Although inhibin B expression is increased within the granulosa cell on stimulation with FSH, the follicular concentration of inhibin B does not change with follicular size. It has been suggested that the serum concentration of inhibin B reflects the volume of granulosa cells within the ovary, thereby serving as an indicator of the size of the growing cohort of follicles (ovarian reserve). Because inhibin B is the primary inhibitor of pituitary production of FSH in the follicular phase in the absence of estradiol, measuring baseline FSH circulating levels early in the follicular phase (cycle day 3) serves as indirect marker of ovarian reserve (see infertility).

The antral growth phase of follicular development is characterized by rapid follicle growth (1-2 mm/d) and is gonadotropin dependent. In response to FSH, the antral follicle rapidly grows to a diameter of 20 mm, primarily as a result of accumulation of antral fluid. The theca interna continues to differentiate into interstitial cells that produce increasing amounts of androstenedione for aromatization to estrone. The granulosa cell layers have continued to differentiate from each other. The membrana layer, through the action of FSH, acquires LH receptors. This differs from the cumulus layer, which lacks LH receptors. The final progression to a mature graafian follicle is a selection process that in most cases generates one dominant follicle destined for ovulation.

The selection process actually begins in the midluteal phase of the previous cycle. The rise in estrogen level that is generated by the preovulatory follicle augments FSH activity within the follicle while exerting negative feedback on the pituitary release of FSH. The decrease in pituitary release of FSH results in withdrawal of gonadotropin support from the smaller antral follicles, promoting their atresia. The dominant follicle continues to grow, despite decreasing levels of FSH, by accumulating a greater mass of granulosa cells with more FSH receptors. Increased vascularity of the theca cells allows preferential FSH delivery to the dominant follicle despite waning FSH levels. Increased estrogen levels in the follicle facilitate FSH induction of LH receptors on the granulosa cells, allowing the follicle to respond to the ovulatory surge of LH levels. Without estrogen, LH receptors do not develop on the granulosa cells.

The generation of the LH surge is absolutely required for ovulation and oocyte maturation. The amplified production of LH in the midcycle is due to an increase in pituitary sensitivity to GnRH. The sensitization is mediated by the positive feedback effect of the exponential rise in estrogen and possibly inhibin A. This surge results in the resumption of meiosis I in the oocyte with release of a polar body just prior to ovulation. Evidence suggests that the granulosa membrana cells secrete an oocyte maturation inhibitor (OMI), which interacts with the cumulus to block the progression of meiosis during most of folliculogenesis. It is theorized that OMI exerts its inhibitory influence by stimulating the cumulus to increase cAMP production, which diffuses into the oocyte and halts meiotic maturation. The LH surge overcomes the arrest of meiosis by inhibiting OMI secretion; thereby decreasing cAMP levels and increasing intracellular calcium, allowing the resumption of meiosis (Figure 13–8).

Just prior to the ovulation, progesterone production increases, and this may be responsible, at least in part, for the midcycle peak in FSH and the coordination of the LH surge. The FSH peak stimulates the production of an adequate number of LH receptors

![Regulation of oocyte maturation](image-url)
on the granulosa cells for luteinization. FSH, LH, and progesterone induce expression of proteolytic enzymes that degrade the collagen in the follicular wall, thereby making it prone to rupture. Prostaglandin (PG) production increases and may be responsible for contraction of smooth muscle cells in the ovary, aiding the extrusion of the oocyte.

The LH surge lasts approximately 48 to 50 hours. Thirty-six hours after onset of the LH surge, ovulation occurs. The feedback signal to terminate the LH surge is not known. Perhaps the rise in progesterone production results in a negative feedback loop and inhibits pituitary LH secretion by decreasing the pulsatility of GnRH. In addition, just prior to ovulation LH downregulates its own receptors, which decreases the activity of the functional hormonal unit. As a result, estradiol production decreases.

Following ovulation and in response to LH, the granulosa cells (membrana) and thecal interstitial cells that remain in the ovulated follicle differentiate into granulosa lutein and theca lutein cells, respectively, to form the corpus luteum. In addition, LH induces the granulosa lutein cells to produce vascular endothelial growth factor (VEGF), which plays an important role in developing the corpus luteum vascularization. This neovascularization penetrates the basement membrane and provides the granulosa lutein cells with LDL for progesterone biosynthesis. After ovulation, the luteal cells upregulate their LH receptors by an unknown mechanism. This is critical in that it allows basal levels of LH to maintain the corpus luteum. Rescue of the corpus luteum with hCG from the developing conceptus works through the LH receptor, which is vital for embryonic life.

Hormone production by the corpus luteum requires the cooperation of theca lutein and granulosa lutein cells, much like the preovulatory follicle (see Figure 13-7). In response to LH and hCG, the theca lutein cells increase the expression of all the enzymes responsible for androstenedione production (see earlier). Aromatase activity is increased in the granulosa lutein cells by LH to aromatize the androgens to estrogen. A notable difference in the granulosa lutein cells, as opposed to the preovulatory granulosa cells, is that LH also induces the expression of P450scc and 3β-HSD, which enables the cell to synthesize progesterone. The secretion of progesterone and estradiol is episodic and correlates with the LH pulses. FSH has minimal influence on progesterone production but continues to stimulate estrogen production during the luteal phase. The progesterone levels rise and reach a peak on approximately day 8 of the luteal phase. The luteal phase lasts approximately 14 days.

The corpus luteum starts to undergo luteolysis (programmed cell death) approximately 9 days after ovulation. The mechanism of luteal regression is not completely known. Once luteolysis begins, there is a rapid decline in progesterone levels. A number of studies suggest that estrogen has a role in luteolysis. It has been shown that direct injection of estrogen into the ovary containing a corpus luteum induces luteolysis and a fall in progesterone levels. Experimental data suggest that there is increased aromatase activity in the corpus luteum just prior to luteolysis. The rise in aromatase activity is secondary to gonadotropin (FSH and LH) stimulation, although later in the luteal phase, FSH probably plays a more important role. Consequently, estrogen production increases, and this decreases 3β-HSD activity. This may result in a decline in progesterone levels and lead to luteolysis. Furthermore, local modifiers such as oxytocin, which is secreted by luteal cells, have been shown to modulate progesterone synthesis. Other evidence supports the role of PGs in luteolysis. Experimental data suggest that PGF2α, which is secreted from the uterus or ovary during the luteal phase, stimulates the synthesis of cytokines such as tumor necrosis factor; this causes apoptosis and, therefore, may be linked to corpus luteum degeneration.

The process of luteolysis is known to involve proteolytic enzymes. Evidence suggests that matrix metalloproteinase (MMP) activity is increased during luteolysis. hCG is a known modulator of MMP activity. This may play an important role in early pregnancy, when hCG rescues the corpus luteum and prevents luteal regression. However, in the absence of pregnancy, the corpus luteum regresses, resulting in a decrease in progesterone, estradiol, and inhibit A levels. The decrease in these hormones allows for increased GnRH pulsatility and FSH secretion. The rise in FSH will rescue another cohort of follicles and initiate the next menstrual cycle.

**Role of the Uterus**

The sole function of the uterus is to accommodate and support a fetus. Furthermore, it is the endometrium, the lining of the uterine cavity, that differentiates during the menstrual cycle so that it can support and nourish the conceptus. Histologically, the endometrium is made up of an epithelium composed of glands and a stroma that contains stromal fibroblasts and extracellular matrix. The endometrium is divided into two layers based on morphology: the basalis layer and the functionalis layer. The basalis layer lies adjacent to the myometrium and contains glands and supporting vasculature. It provides the components necessary to develop the functionalis layer. The functionalis is the dynamic layer that is regenerated every cycle. More specifically, it is this layer that can accommodate implantation of the blastocyst.

During the menstrual cycle, the endometrium responds to hormones secreted from the ovaries. Somewhat like the other endocrine organs, it contains a network of local factors that modulate hormonal activity. The endometrial phases are coordinated with ovulatory phases. During the follicular phase, the endometrium goes through the proliferative phase. It begins with the onset of menses and ends at ovulation. During the luteal phase, the endometrium undergoes the secretory phase. It starts at ovulation and ends just before menses. If implantation does not occur, a degenerative phase follows the secretory phase within the endometrium. It is this phase that results in menstruation. The next section will discuss the phases of the endometrium in more detail.

During the follicular phase, the ovary secretes estrogen, which stimulates the glands in the basalis to initiate formation of the functionalis layer. Estrogen promotes growth by enhancing gene expression of cytokines and a variety of growth factors, including EGF, TGFα, and IGF. These factors provide a microenvironment within the endometrium to modulate the effects of hormones. At the beginning of the menstrual cycle, the endometrium is thin—usually less than 2 mm in total thickness. The endometrial glands
are straight and narrow and extend from the basalis toward the surface of the endometrial cavity. As the epithelium and the underlying stroma develop, they acquire estrogen and progesterone receptors. The spiral blood vessels from the basalis layer extend through the stroma to maintain blood supply to the epithelium. Ultimately, the lining (functionalis) surrounds the entire uterine cavity and achieves a thickness of 3 to 5 mm in height (total thickness 6 to 10 mm). This phase is known as the proliferative phase.

After ovulation, the ovary secretes progesterone, which inhibits further endometrial proliferation. This mechanism may be mediated by antagonizing estrogen effects. Progesterone down-regulates estrogen receptors in the epithelium and mediates estradiol metabolism within the endometrium by stimulating 17β-HSD activity and converting estradiol into the weaker estrogen, estrone. During the luteal phase, the glandular epithelium accumulates glycogen and begins to secrete glycopeptides and proteins—along with a transudate from plasma—into the endometrial cavity. It is this fluid that provides nourishment to the free-floating blastocyst. Progesterone also stimulates differentiation of the endometrium and causes characteristic histologic changes. The glands become progressively more tortuous, and the spiral vessels coil and acquire a corkscrew appearance. The underlying stroma becomes very edematous as a result of increased capillary permeability, and the cells begin to appear large and polyhedral, with each cell developing an independent basement membrane. This process is termed predecidualization. These cells are very active and respond to hormonal signals. They produce PGs along with other factors that play an important role in menstruation, implantation, and pregnancy. This phase is known as the secretory phase.

If there is no implantation of an embryo, the endometrium enters the degenerative phase. Estrogen and progesterone withdrawal promotes prostaglandin production—PGF2α and PGE2. These PGs stimulate progressive vasoconstriction and relaxation of the spiral vessels. These vasomotor reactions lead to endometrial ischemia and reperfusion injury. Eventually, there is hemorrhage within the endometrium with subsequent hematoma formation. The progesterone withdrawal triggers MMP activity, which facilitates degradation of the extracellular matrix. As ischemia and degradation progress, the functionalis becomes necrotic and sloughs away as menstruum consisting of endometrial tissue and blood. The amount of blood lost in normal menses ranges from 25 mL to 60 mL. Although PGF2α is a potent stimulus for myometrial contractility and limits postpartum bleeding, it has minimal impact on cessation of menstrual bleeding. The major mechanisms responsible for limiting blood loss involve the formation of thrombin-platelet plugs and estrogen-induced healing of the basalis layer by reepithelialization of the endometrium, which begins in the early follicular phase of the next menstrual cycle.

If conception takes place, implantation can occur in the endometrium during the midsecretory (midluteal) phase, at which time it is of sufficient thickness and full of sustenance. The syncytiotrophoblast subsequently secretes hCG, which rescues the corpus luteum and maintains progesterone secretion, essential for complete endometrial decidual development.

In summary, the ovary has two phases during the menstrual cycle: the follicular phase and the luteal phase. The endometrium has three phases and is synchronized by the ovary. The complex feedback loops between the ovary and the hypothalamic-pituitary axis regulate the menstrual cycle. During the follicular phase, the ovary secretes estradiol, which stimulates the endometrium to undergo the proliferative phase. After ovulation (luteal phase), the ovary secretes estrogen and progesterone, which maintains the endometrial lining and promotes the secretory phase. In a non-pregnant cycle, luteolysis occurs, resulting in cessation of hormone production. This hormone withdrawal results in the degenerative phase and the onset of menses.

### MENSTRUAL DISTURBANCES

#### AMENORRHEA

The mean age of menarche is 12.8 years. Normally, this event marks the completion of puberty. The onset of regular cyclicity in the menstrual cycle is determined by the duration of the maturation process of the HPO axis, which is quite variable. As a result, anovulation can occur in 50% to 80% of girls 2 years after menarche, and in more than 20% of girls, it can persist until 5 years after menarche. This period of time can be frustrating for many girls and their parents. The evaluation should include a clinical examination and reassurance. If positive findings are noted, limited, pertinent diagnostic tests (see later) are indicated.

Amenorrhea can be defined as either the absence of menarche by age 16 or no menses for more than three cycles in an individual who has previously had cyclic menses. The definition, although arbitrary, nonetheless gives a general guideline to the clinician for further evaluation. Although amenorrhea does not cause harm, in the absence of pregnancy, it may be a sign of genetic, endocrine, and/or anatomic abnormalities. If the outflow tract is intact, amenorrhea is most likely the result of disruption in the HPO axis. These aberrations can affect any level of control in the menstrual cycle and, thus, result in menstrual abnormalities.

Amenorrhea was formerly classified as primary or secondary depending on whether the individual had experienced menses in the past. This classification may lead to misdiagnosis of the cause of amenorrhea. Although primary amenorrhea is more often associated with genetic and anatomic abnormalities, each individual should be assessed by means of the history and clinical findings, including the presence or absence of secondary sexual characteristics (Table 13–3). The causes of amenorrhea are grouped according to the level of involvement in the regulatory systems that govern normal menstrual activity (ie, hypothalamic, pituitary, ovarian, and uterine). An algorithm for the workup of amenorrhea or oligomenorrhea in the presence of secondary sexual characteristics is illustrated in Figure 13–9.

HYPOTHALAMIC AMENORRHEA

Isolated GnRH Deficiency

The hypothalamus is the source of GnRH, which directs the synthesis and secretion of pituitary gonadotropins. Dysfunction at this level leads to hypogonadotropic hypogonadism or eugonadotropic hypogonadism. Disorders of GnRH production can result in a wide range of clinical manifestations. The individual's appearance is dependent on the age at onset and the degree of dysfunction.

Isolated GnRH deficiency results in hypogonadotropic hypogonadism. Female patients present with amenorrhea, and females and males present with absent or incomplete pubertal development secondary to absent or diminished sex steroids (estradiol in females, testosterone in males). They have normal stature with a eunuchoidal body habitus. Because the adrenal glands are unaffected by the absence of GnRH, body hair distribution is not affected.

A. Genetic origin Several genetic lesions associated with GnRH deficiency have been described. The best characterized form of GnRH deficiency is Kallmann syndrome, which involves the Kal-1 gene as well as a number of other genes. The Kal-1 gene normally codes for anosmin, an adhesion molecule that appears to be involved in the migration of GnRH and olfactory neurons from the olfactory placode to the hypothalamus. The Kal-1 gene is located on the short arm of the X chromosome. Most cases of Kallmann syndrome are sporadic, although the disorder has also been observed to have a familial pattern, and most often it is transmitted by X-linked recessive inheritance. Autosomal recessive and dominant patterns have been reported but are much less common. When mutations exist in the Kal-1 gene, there may be associated defects, including anosmia and, less frequently, midline facial defects, renal anomalies, and neurologic deficiency. The disorder affects both sexes, but because of the X-linked inheritance pattern it is more common in boys. Unlike males, the specific genetic mutations in the Kal-1 gene in females with hypogonadotropic hypogonadism have not been identified, suggesting there
are other genetic mutations that cause this disorder. Recently, it was determined that heterozygous mutations in fibroblast growth factor receptor 1 (FGFR1) gene, known as the Kal-2, were identified in cases of Kallmann syndrome. FGFR1 and Kal-1 are coexpressed at the same sites during development and are thought to have a functional interaction. Mutations in the Kiss-1 derived peptide receptor, GPR54, have also been identified in these patients. Several mechanisms of how GPR54 may regulate gonadotropin production via GnRH function or production have been proposed. Several studies have shown that females with presumed Kallmann syndrome demonstrate variable responses to exogenous GnRH administration, which suggests a GnRH receptor defect. In fact, mutations in the GnRH receptor have been identified in both sexes and are inherited in an autosomal recessive fashion.

Management of hypogonadotropic hypogonadism involves scheduled hormone replacement therapy (HRT) to stimulate the development of secondary sexual characteristics and increase bone mineral density. If pregnancy is desired, treatment involves the administration of pulsatile GnRH or gonadotropin treatment.

B. Endocrine causes

1. Functional hypothalamic amenorrhea—Functional hypothalamic amenorrhea is one of the most common types of amenorrhea and accounts for 15% to 35% of cases. It is an endocrine disorder, although the exact mechanism has not been definitively determined. It is characterized by a reduced GnRH drive (decrease in pulse frequency and amplitude), leading to low or low-normal serum levels of FSH and LH and...
resulting in anovulation. The ratio of serum FSH to LH in these patients is often equivalent to that of a prepubertal female with a relative FSH dominance.

The adipocyte hormone, leptin, has been implicated in the development of this disorder. Leptin is an important nutritional satiety factor, but it is also necessary for maturation of the reproductive system. The potential link to the reproductive system is thought to be through leptin receptors, which have been identified in the hypothalamus and gonadotropes. This is supported by the observation that leptin can stimulate GnRH pulsatility and gonadotropin secretion. Several studies suggest that women with functional hypothalamic amenorrhea have lower serum leptin levels in comparison with eumenorrheic controls. This relative deficiency may lead to dysfunctional release of GnRH and subsequent development of functional hypothalamic amenorrhea.

Abnormal, and often subtle, activation of the hypothalamic-pituitary-adrenal axis is associated with functional hypothalamic amenorrhea. The inciting event may be excessive production of corticotropin-releasing hormone (CRH), which has been shown to decrease the pulse frequency of GnRH and increase cortisol levels in vivo. In contrast, another study suggests that although acute elevations of CRH can suppress GnRH release, this suppression cannot be maintained with CRH alone. The cause of functional hypothalamic amenorrhea often remains unclear, but the associated hypercortisolism suggests that it is preceded by psychologic stress, strenuous exercise, or poor nutrition. There is support for the concept that these factors may act synergistically to further suppress GnRH drive. In fact, patients with functional hypothalamic amenorrhea resulting from psychologic stress are usually high achievers who have dysfunctional coping mechanisms when dealing with daily stress. The severity of hypothalamic suppression is reflected by the clinical manifestations. The significant interpatient variability in the degree of psychologic or metabolic stress required to induce a menstrual disturbance explains the heterogeneity of clinical presentations, ranging from luteal phase defects to anovulation with erratic bleeding to amenorrhea.

Functional hypothalamic amenorrhea is reversible. Interestingly, the factors that have predicted the rate of recovery are body mass index and basal cortisol levels. When patients recover, ovulation is preceded by return of cortisol levels to baseline. Some experts have shown that cognitive behavioral therapy, teaching the patient how to cope with stress—and nutritional consultation—reverse this condition. Complete reversal may be less likely if the functional insult occurs during the period of peripubertal maturation of the HPO axis.

The diagnosis of functional hypothalamic amenorrhea can be made if the FSH-LH ratio is greater than 1 in the presence of hypoestrogenemia. However, a minor disturbance of hypothalamic dysfunction may present with normal laboratory findings, a clinical history that coincides with stress, and a negative evaluation for other causes of anovulation. Interestingly, most of these patients, despite hypoestrogenism, do not have symptoms. The estrogen status should still be evaluated given the strong correlation between hypoestrogenemia and the development of osteoporosis. Estrogen status can be determined by means of the progesterone withdrawal test or by measurement of serum estradiol (<50 pg/mL). If there is no withdrawal or the estradiol is less than 50 pg/mL, HRT with combination contraceptive hormones (or traditional HRT) should be instituted. If withdrawal bleeding occurs, any cyclic progestin-containing therapy is adequate to combat unopposed estrogen and the development of endometrial hyperplasia.

2. Amenorrhea in the female athlete—Hypothalamic dysfunction has been observed in female athletes. Competitors in events such as gymnastics, ballet, marathon running, and diving can show menstrual irregularities ranging from luteal phase defects to amenorrhea. The female athletic triad as defined by the American College of Sports Medicine is characterized by disordered eating, amenorrhea, and osteoporosis. The associated nutritional deficiencies can lead to impaired growth and delayed sexual maturation. The neuroendocrine abnormalities are similar to those of women with functional hypothalamic amenorrhea.

These patients have very low body fat, often below the tenth percentile. There is evidence that a negative correlation between body fat and menstrual irregularities exists. In addition, there appears to be a critical body fat level that must be present in order to have a functioning reproductive system. Several studies have shown that these amenorrheic athletes have significantly lower serum leptin levels, which further supports leptin's role as a mediator between nutritional status and the reproductive system. The strenuous exercise these athletes engage in amplifies the effects of the associated nutritional deficiency. This synergism causes severe suppression of GnRH, leading to the low estradiol levels.

Amenorrhea alone is not harmful. However, low serum estradiol over a period of time may lead to osteoporosis and delayed puberty. An analysis of estrogen status may be obtained with measurement of serum estradiol levels or with the progesterone withdrawal test (see earlier). If estrogen is low, bone mineral density (BMD) should be assessed by dual-energy x-ray absorptiometry (DXA) scan. All patients diagnosed with female athletic triad need combination contraceptive therapy or HRT.

3. Amenorrhea associated with eating disorders—Anorexia nervosa is a disorder characterized by relentless dieting in pursuit of a thin body habitus. Approximately 95% of cases occur in females, and the onset is chiefly in adolescence. The clinical features include extreme weight loss leading to a body weight less than 85% of normal for age and height, a distorted body image, and intense fear of gaining weight. These patients usually have a preoccupation with food and are hyperactive, with an obsessive-compulsive personality. The associated symptoms include hyperthermia, mild bradycardia, dry skin, constipation, and symptoms of hypogonadism. Furthermore, as part of the diagnostic criteria, they must experience at least 3 months of no menses.

The dysfunction in the neuroendocrine system is similar to but often more severe than that described in association with functional hypothalamic amenorrhea. The severe reduction in GnRH pulsatility leads to suppression of FSH and LH secretion, possibly to undetectable levels, and results in anovulation and low serum estradiol levels. Given the severe psychologic and metabolic stress experienced by these individuals, the hypothalamic-pituitary-adrenal axis is activated. The circadian rhythm of adrenal secretion is maintained, but both cortisol production and plasma cortisol levels are persistently elevated secondary to increased pituitary secretion of adrenocorticotropic hormone (ACTH). Serum leptin levels in these individuals are significantly lower than normal healthy controls and correlate with percentage of body fat and body weight. A rise in
leptin levels in response to dietary treatment is associated with a subsequent rise in gonadotropin levels. This further suggests leptin’s role as a potential link between energy stores and the reproductive system.

The self-induced starvation state associated with anorexia nervosa leads to additional endocrine abnormalities not observed in other causes of hypothalamic amenorrhea. For instance, thyroid hormone metabolism is altered. TSH and T₄ levels are in the low-normal range, but T₃ levels are usually below normal. This is attributable to decreased peripheral conversion of T₄ to T₃ and increased conversion of T₄ to the metabolically inactive thyroid hormone, reverse T₃—a change that often resembles other states of starvation. This may be a protective mechanism in that the relative hypothyroid state attempts to reduce basal metabolic function in response to a highly catabolic state.

**Bulimia** occurs in about half of patients with anorexia and is defined as binge eating followed by self-induced purging. Not all bulimics have low body weight—in fact, normal-weight bulimic individuals are much more common. These patients also have a variety of neuroendocrine aberrations—often to a lesser degree than those with anorexia—which also lead to menstrual disturbances. Leptin levels are lower than in matched controls but not as low as in individuals with anorexia nervosa. They also have neurotransmitter abnormalities—notably low serotonin levels—which might help explain the often coexisting psychologic difficulties.

Anorexia nervosa is a life-threatening illness with a significant mortality rate due to its metabolic consequences. Anorexic patients should be considered for inpatient therapy and management with a multidisciplinary approach that includes nutritional counseling and psychotherapy. Force-feeding may be necessary in some patients. If weight gain cannot be achieved with oral intake, meals may need to be supplemented by enteral or parenteral feeding. Because anorexia nervosa is a hypoestrogenic state and there is a high potential for the development of osteoporosis, all patients should receive hormone therapy either in the form of HRT or combination contraceptive pills. Leptin levels are lower than in matched controls but not as low as in individuals with anorexia nervosa. They also have neurotransmitter abnormalities— notably low serotonin levels—which might help explain the often coexisting psychologic difficulties.

In summary, the hypothalamic amenorrhea endocrine syndromes are probably a continuum of disordered eating and nutritional deficiencies resulting in increasingly severe abnormalities in the reproductive system. Furthermore, the age at onset affects the potential complications of these disorders. If low estradiol levels are present before age 20, bone mineralization may be profoundly affected, because this period is critical for building peak bone mass. In addition, if these conditions occur prior to puberty, it may result in stunted growth and delayed development of secondary sexual characteristics.

**C. Anatomic causes** Numerous anatomic abnormalities within the central nervous system can result in menstrual disturbances. These include developmental defects, brain tumors, and infiltrative disorders. The most common anatomic lesion associated with delayed puberty and amenorrhea is a craniopharyngioma. It is derived from Rathke pouch and extends into the hypothalamus, pituitary, and third ventricle. The symptoms include headaches, visual loss, and hypoestrogenism.

Infiltrative disorders that involve the hypothalamus are uncommon but can result from systemic diseases, including sarcoidosis, histiocytosis, hemochromatosis, and lymphoma. These diseases do not initially present with amenorrhea. However, in the presence of these diseases, the hypothalamus may be affected, so they should be part of the differential diagnosis of amenorrhea.

**PITUITARY AMENORRHEA**

There are a few genetic mutations affecting the pituitary that cause amenorrhea. Rare autosomal recessive mutations may cause deficiencies in FSH, LH, TSH, prolactin (PRL), and growth hormone (GH). The clinical manifestations may include delayed puberty, a hypoestrogenic state, and infertility.

**A. Genetic causes** A deficiency in FSH and LH may be a result of GnRH receptor gene mutations. Such mutations are primarily compound heterozygous mutations that affect GnRH receptor–dependent signal transduction. The phenotype of these individuals is similar to that of those with isolated GnRH deficiency. In fact, some investigators speculate that these receptor mutations may be the cause of isolated GnRH deficiency in women, given that no mutations have yet been identified in the ligand or Kal-1 gene. The estimated prevalence of GnRH receptor mutations in women with hypothalamic amenorrhea is 2%. In a family with other affected females, the prevalence is 7%.

Other rare genetic defects have been associated with amenorrhea in women. Mutations in the FSHβ gene have been reported. These have an autosomal recessive pattern of inheritance and lead to low serum FSH and estradiol levels and high plasma LH levels. The clinical features include minimal development of secondary sexual characteristics and amenorrhea with no history of menses. Combined hormone deficiencies have also been described. Mutations in Prop-1, a pituitary transcription factor for Pit-1, lead to deficiencies in gonadotropins, TSH, PRL, and GH. These patients present with stunted growth, hypothyroidism, and delayed puberty in addition to amenorrhea.

**B. Endocrine causes** Hyperprolactinemia is one of the most common causes of amenorrhea, accounting for 15% to 30% of cases. In the absence of pregnancy or postpartum lactation, persistently elevated PRL is almost always associated with a hypothalamic-pituitary disorder. Normal PRL secretion is regulated by several stimulatory and inhibitory factors (see Chapter 4). PRL secretion is primarily under tonic inhibition by dopamine, so that any interference with dopamine synthesis or transport from the hypothalamus may result in elevated PRL levels. In addition to menstrual disturbances, individuals with hyperprolactinemia may present with galactorrhea. In fact, hyperprolactinemia is a common cause of galactorrhea, and up to 80% of patients with
amenorrhea and galactorrhea have elevated PRL levels. Other associated symptoms include headaches, visual field defects, infertility, and osteopenia.

The mechanism whereby hyperprolactinemia causes amenorrhea is not completely known. Studies have shown that PRL can affect the reproductive system in several ways. PRL receptors have been identified on GnRH neurons and may directly suppress GnRH secretion. Others have postulated that elevated PRL levels inhibit GnRH pulsatility indirectly by increasing other neuro-modulators such as endogenous opioids. There is also evidence that GnRH receptors on the pituitary may be downregulated in the presence of hyperprolactinemia. Furthermore, PRL may affect the ovaries by altering ovarian progesterone secretion and estrogen synthesis. The best data now available suggest that hyperprolactinemia causes amenorrhea primarily by suppression of GnRH secretion.

Approximately half of patients with elevated PRL levels have radiologic evidence of a pituitary tumor. The most common type is a PRL-secreting tumor (prolactinoma), accounting for 40% to 50% of pituitary tumors. Prolactinomas are composed mainly of lactotrophs, and they secrete PRL. Occasionally these tumors secrete both GH and PRL.

The diagnosis of a pituitary adenoma is usually made by examination of the pituitary with magnetic resonance imaging (MRI). These tumors are categorized into two groups based on their dimensions—microadenomas are those less than 10 mm in diameter and macroadenomas are larger than 10 mm. These tumors are usually located in the lateral wings of the anterior pituitary. Microadenomas are typically wholly contained within the confines of the pituitary gland. Very rarely, a microadenoma infiltrates the surrounding tissue, including the dura, cavernous sinus, or adjacent skull base. A macroadenoma may expand farther and grow out of the sella to impinge on surrounding structures, such as the optic chiasm or may extend into the sphenoid sinus. As a result, macroadenomas are more frequently associated with severe headaches, visual field defects, and ophthalmoplegia. The incidence of a microadenoma progressing to a macroadenoma is relatively low, only 3% to 7%. During pregnancy the risk of a microprolactinoma enlarging is also low, but in the presence of a macroadenoma, the chance of tumor growth is up to 25%.

Some investigators have found a correlation between pituitary adenoma size and serum PRL levels. If the serum PRL is less than 100 ng/mL, a microprolactinoma is more likely, whereas if it is greater than 100 ng/mL, a macroadenoma is often present. Although this correlation has been reported, the evidence supporting it is not strong. In fact, low PRL levels may also be associated with nonfunctioning macroadenomas. This is thought to reflect impingement of the adenoma on the pituitary stalk leading to reduced dopamine secretion and loss of the tonic suppression of prolactin secretion. These nonfunctioning tumors may synthesize glycoproteins such as FSH, LH, or their free alpha subunits. Rarely, functioning tumors may arise from other pituitary cells, resulting in excessive hormone secretion. If a macroadenoma is present, measurement of IGF-1, alpha subunit, TSH, and 24-hour urinary cortisol will begin to exclude other functioning adenomas.

Other tumors of nonpituitary origin may also result in delayed puberty and amenorrhea. The most common of these is a craniopharyngioma. Although craniopharyngiomas are commonly located in the suprasellar region, they can also involve the sella. These tumors have not been shown to produce hormones, but because they may compress the infundibulum, they can interfere with the tonic inhibition of PRL secretion and result in mildly elevated PRL levels.

Hyperprolactinemia in a patient with amenorrhea is defined as a PRL level greater than 20 ng/mL, although the limit of normal may vary between laboratories. Normal PRL release follows a sleep-circadian rhythm, but PRL may also be secreted in response to stress, physical exercise, breast stimulation, or a meal. Therefore, PRL should be measured in the midmorning hours and in the fasting state. Other causes of mildly elevated PRL include medications such as oral contraceptives, neuroleptics, tricyclic antidepressants, metoclopramide, methyldopa, and verapamil. Hyperprolactinemia has also been observed in several chronic diseases, including cirrhosis and renal disease. Furthermore, inflammatory diseases such as sarcoidosis and histiocytosis can infiltrate the hypothalamus or pituitary and result in hyperprolactinemia. Elevated PRL levels may be a physiologic response. During pregnancy, PRL levels may be two to four times baseline. With postpartum breast-feeding, the PRL level should be below 100 ng/mL after 7 days and below 50 ng/mL after 3 months. If a woman is not breast-feeding, PRL levels should return to baseline by 7 days postpartum.

Persistently elevated PRL levels may also be present in primary hypothyroidism. Approximately 40% of patients with primary hypothyroidism present with a minimal increase in prolactin (25-30 ng/mL), and 10% present with even higher serum levels. Individuals with primary hypothyroidism have an increase in thyrotropin-releasing hormone (TRH) from the hypothalamus, which stimulates TSH and PRL release and leads to hyperprolactinemia. Patients with long-standing primary hypothyroidism may eventually manifest profound pituitary enlargement due to hypertrophy of thyrotrophs. This mass effect with elevated PRL levels mimics a prolactinoma. Therefore, all patients with hyperprolactinemia should have their thyroid function investigated to exclude hypothyroidism as the cause.

Prolactinomas are the most common cause of persistent hyperprolactinemia. All patients with elevated PRL levels should have the test repeated for verification. In addition to blood tests, a careful clinical and pharmacologic history and physical examination should be performed to exclude other causes of hyperprolactinemia. If elevated PRL levels persist or if any measurement is found to be above 100 ng/mL, MRI of the hypothalamic-pituitary region should be performed. If a microadenoma is observed, the diagnosis of microprolactinoma can be made. If a macroadenoma is observed, other pituitary hormones should be measured to exclude other functioning adenomas or hypopituitarism. All patients diagnosed with macroadenoma should have a visual field examination.
The treatment of choice for prolactinoma is dopamine agonist therapy. These drugs (bromocriptine, cabergoline, pergolide, quinagolide) are very effective at lowering PRL levels, resolving symptoms, and causing tumor shrinkage. Treatment results in a rapid reduction in PRL levels in 60% to 100% of cases. Following reduction of PRL levels, 60% to 100% of women resume ovulatory menses within 6 weeks, and galactorrhea disappears within 1 to 3 months after starting treatment. Reduction in tumor size is usually evident after 2 to 3 months of drug therapy, but it may occur within days after initiation of treatment. The extrasellar portion of the tumor appears to be particularly sensitive to drug therapy, which explains the improvement in symptoms such as visual impairment or ophthalmoplegia with drug therapy. In patients diagnosed with a microadenoma that is manifested only as a menstrual disturbance, observation should only be considered if the patient does not desire conception. These individuals should be offered oral contraceptives to control the bleeding pattern and to protect bone from estrogen deficiency. However, the long-term sequelae of persistently elevated PRL levels are unknown. If dopamine agonist treatment is initiated for a microadenoma, therapy may be continued long term. If the tumor responds, the dose may be tapered and stopped after menopause. Many individuals with a macroadenoma take dopamine agonist therapy indefinitely. All patients diagnosed with a prolactinoma should have follow-up imaging, determination of serum PRL levels, and visual field examinations. Alternatively, patients with a micro- or macroprolactinoma may be offered discontinuation of therapy. Dopamine agonist therapy may be tapered and ultimately discontinued if follow-up PRL levels are normal, and follow-up MRI scans show no evidence of tumor (or tumor reduction of at least 50%, with the tumor at a distance of more than 5 mm from the optic chiasm and no evidence for tumor invasion of adjacent structures), and if follow-up after withdrawal is assured.

An alternative to medical management of pituitary tumors is transsphenoidal surgery, after which resolution of symptoms may be immediate. However, the success and recurrence rates vary and are dependent on the size of the tumor and the depth of invasion. The larger and more invasive the tumor is, the less chance there is for complete resection and the greater the chance of recurrence. In general, the success rate of surgery for a microadenoma in some centers may be 70% or higher; surgical cure rates for macroadenomas are generally less than 40%. Overall, the recurrence rate following surgery is approximately 50%. Surgery is a good alternative for resistant tumors or for patients intolerant of medical treatment. Because non-PRL-secreting pituitary tumors often do not respond well to medical therapy, operation is the treatment of choice for these tumors as well. The risks of surgery include infection, diabetes insipidus, and panhypopituitarism. Complete pituitary testing should be performed prior to surgery.

Women with hyperprolactinemia who desire to conceive should be administered dopamine agonist therapy. Elevated PRL levels can lead to anovulation and hormonal disturbances that can result in difficulty in achieving pregnancy. Once pregnant, patients with microadenomas may have their medication discontinued. If a macroadenoma is present, thought should be given to continuing dopamine agonist therapy throughout pregnancy. Women with prolactinomas may breast-feed since there is no evidence that it stimulates tumor growth. If breast-feeding, dopamine agonist therapy should be discontinued since these agents will interfere with lactation.

C. Anatomic causes

1. Pituitary destruction—Amenorrhea may be the result of not only pituitary neoplasms but also pituitary destruction. Infiltrative disorders that involve the hypothalamus can affect the pituitary. Other disorders that cause pituitary insufficiency may be situational. A rare autoimmune disease, lymphocytic hypophysitis, can cause pituitary destruction during the puerperium and ultimately results in panhypopituitarism. Pituitary necrosis may also occur secondary to a hypotensive event. Typically, 80% to 90% of the pituitary must be damaged before pituitary failure ensues, and the robust blood supply to the pituitary makes this an uncommon event. If pituitary ischemia and necrosis are related to postpartum hemorrhage, it is known as Sheehan syndrome; otherwise, it is called Simmond disease. Because this type of injury typically affects the entire pituitary, most often more than one or all the pituitary hormones may be deficient. Observation has suggested that hormone loss follows a pattern, starting with the gonadotropins, followed by GH and PRL; however, this is highly variable.

OVARIAN AMENORRHEA

The physiologic period in a woman's life when there is permanent cessation of menstruation and regression of ovarian function is known as menopause (see later). The cause of ovarian failure is thought to be depletion of ovarian follicles. The median age at menopause is 51.1 years. Premature menopause is defined as ovarian failure prior to age 40, which is reported to occur in 1% of the population. The etiology of premature ovarian failure (POF) may have a genetic basis. Several mutations that affect gonadal function have been identified and include defects in hormone receptors and steroid synthesis. Other potential causes include autoimmune ovarian destruction, iatrogenic ovarian injury, and idiopathic ovarian failure. The most severe form of POF presents with absent secondary sexual characteristics and is most often due to gonadal agenesis or dysgenesis (see Chapter 14). Less severe forms may result only in diminished reproductive capacity.

The other ovarian cause of amenorrhea is repetitive ovulation failure or anovulation. Other than menopause, it is the most common cause of amenorrhea. Chronic anovulation may be secondary to disorders of the hypothalamic-pituitary axis and has been previously discussed. Anovulation may also be due to systemic disorders. The causes of ovarian failure and anovulation due to peripheral disorders will be discussed later.

Ovarian failure is diagnosed based on the clinical picture of amenorrhea and the demonstration of elevated FSH (>40 IU/L). This may occur at any time from embryonic development onward. If it occurs prior to age 40, it is called POF. The presence or absence of secondary sexual characteristics defines whether ovarian activity was present in the past. The most common cause of hypergonadotropic amenorrhea, in the absence of secondary sexual characteristics, is abnormal gonadal development, which occurs in
more than half of these individuals. When the gonad fails to develop, this is known as gonadal agenesis. The karyotype of these individuals is 46,XX, and the cause of failure is usually unknown. If streak gonads are present, this indicates at least partial gonadal development and is called gonadal dysgenesis. The karyotype of these individuals may be normal, but it is more likely that there are alterations in sex chromosomes (see Chapter 14).

**Premature Ovarian Failure**

**A. Genetic origin of POF** Two intact X chromosomes are necessary for the maintenance of oocytes during embryogenesis, and the loss of or any alteration in the sex chromosome leads to accelerated follicular loss. This implies that two intact alleles are required for the normal function of some genes on the X chromosome. Turner syndrome is a classic example of complete absence of one X chromosome. It manifests as short stature, sexual infantilism, amenorrhea, and ovarian dysgenesis. This is a well-recognized condition that occurs in 1:2000 to 1:5000 females at birth. Turner syndrome is associated with a number of other phenotypic abnormalities, including a webbed neck, broad chest, low hairline, and cardiovascular and renal defects. It is interesting that fewer than half of patients with Turner syndrome have a single cell line with the karyotype 45,X. The majority of patients actually present with a mosaic karyotype such as 45,X/46,XX. These patients have varying degrees of the Turner syndrome phenotype and may display some secondary sexual development or may have a history of menstrual function. Some pregnancies have been reported.

The term mixed gonadal dysgenesis is used to describe chromosomal aneuploidies with a Y-chromosome component. The most common type is a mosaic pattern that has been associated with Turner syndrome (45,X/46,XY). These patients may have some functional testicular tissue and present with varying degrees of genital ambiguity. If enough testicular tissue is present to produce AMH, these patients may also present with abnormalities of the internal genitalia. Individuals who have both ovarian tissue and testicular tissue along with Wolffian and Müllerian structures internally are termed true hermaphrodites. Interestingly, most true hermaphrodites have 46,XX karyotypes (see Chapter 14) but others may have a 46,XY or 46,XX/46,XY chimeraism.

Patients with gonadal dysgenesis may be phenotypically normal, and the abnormality may be manifest only as delayed pubertal development and amenorrhea. They probably have normal Müllerian structures and streak gonads. These individuals can display an array of karyotypes, including 46,XY (Swyer syndrome). Patients with a male karyotype but a female phenotype presumably underwent testicular failure prior to internal or external genitalia differentiation. If a dysgenetic gonad contains a Y chromosome or a fragment of the Y chromosome, there is a 10% to 30% risk for future gonadal malignancy, and the risk is higher if a mutation in the SRY gene is present. These tumors may be hormonally active. The onset of spontaneous pubertal development in girls with mixed gonadal dysgenesis may be a clinical marker of tumor development. Gonadal extirpation is extirpation at the time of diagnosis.

POF is defined as ovarian failure before age 40 but after puberty. Because complete absence of an X chromosome results in a dysgenetic gonad, candidate genes for POF are probably those that escape X inactivation. In mammals, X inactivation occurs in all cells in order to provide dosage compensation for X-linked genes between males and females (Lyon hypothesis). Further observation has illustrated that terminal deletions in Xp and Xq present with varying degrees of early reproductive failure. Most of the genes involved in folliculogenesis appear to be located on the long arm of the X chromosome. Several regions on the X chromosome, including POF 1 and POF 2, have been evaluated with knockout models in animals and have shown varying effects on ovarian development (Figure 13–10).
