Limited observations have found that deletions occurring closer to the centromere of the X chromosome manifest a more severe phenotype that includes disruption of pubertal development. In contrast, deletions that occur in the distal regions tend to present with early reproductive aging and infertility. An example of a distal mutation on the long arm of the X chromosome is that in the FMRI gene (fragile X gene). An association has been described between the FMRI permutation state and POF. The prevalence of FMRI gene permutations accounts for approximately 2% to 3% of patients who present with sporadic POF and may be as high as 15% in familial cases. This permutation is also associated with the occurrence of a late-onset neurological disorder in male carriers designated as fragile-X tremor ataxia syndrome (FXTAS). Although a number of genes on the X chromosome have demonstrated involvement in ovarian physiology, the majority of patients with POF have no identifiable mutations on the X chromosome.

![FIGURE 13–10 Candidate genes on the X chromosome for premature ovarian failure (POF). (Reproduced, with permission, from Davison RM, Davis CJ, Conway GS. The X chromosome and ovarian failure. Clin Endocrinol. 1999;51:673.)](image-url)
Autosomal recessive genes that have been shown to contribute to POF are very rare. FSH receptor mutations have been identified in humans with POF. These individuals present with a phenotype that ranges from absent secondary sexual development to normal development and early reproductive failure. The prevalence of FSH receptor mutations varies but is most common in the Finnish population (1% carriers). This mutation has not been observed in North America. An inactivated LH receptor has been identified in patients with normal puberty and amenorrhea but is quite rare. Mutations in genes involved in steroidogenesis have also been associated with POF. These enzymes include CYP17α and aromatase. Patients with CYP17α mutations may have a 46,XX or 46,XY karyotype. They have a similar phenotype except that those with 46,XY have absent Müllerian structures because AMH is produced from their testes. Individuals with aromatase deficiency present with sexual ambiguity and clitoromegaly. Several other autosomal mutations have been discovered that may have a role in ovarian physiology. However, at this time, most cases of POF with normal pubertal development have not been associated with any specific mutation (see Chapter 14).

B. Autoimmune origin of POF Autoimmune ovarian destruction is another potential cause of POF. This diagnosis is difficult to make unless it presents with one of the autoimmune polyglandular syndromes (see Chapter 2). The circumstantial evidence supporting the diagnosis is found in the high incidence of concomitant autoimmune disease—20% or more in patients with POF. The strongest association is with autoimmune thyroid disease. In addition, 10% to 20% of individuals with autoimmune adrenal disease experience POF. Conversely, 2% to 10% of patients with idiopathic POF develop adrenal insufficiency. Autoimmune-associated POF is often diagnosed based on the presence of another autoimmune disease or detection of autoantibodies. Thyroid antibodies are most frequently screened. However, these antibodies are present in 15% to 20% of reproductive-aged women. Others have suggested measuring ovarian-specific autoantibodies. There is, however, significant inconsistency in the testing methodology, and this is not recommended. Although the diagnosis is imprecise, all patients suspected of having POF should be screened regularly for thyroid dysfunction. In addition, these patients should be evaluated for the autoimmune polyglandular syndrome (APS) and particularly tested for adrenal insufficiency, especially if there is no identifiable cause of POF. Testing for Addison disease can be performed using provocative ACTH testing or alternatively adrenal antibodies to identify patients at risk. There are commercially available tests for both antidiuretic antibodies and antibodies to 21-hydroxylase. The sensitivity of these tests for the diagnosis of adrenal insufficiency is 100%, the specificity 98%, and the PPV is 67%. If a patient has either of these antibodies they have a 25% to 50% risk of developing adrenal insufficiency within 5 to 10 years.

C. Iatrogenic causes of POF Iatrogenic causes of POF include radiation therapy, chemotherapy, and ovarian insults resulting from torsion or surgery. The risk of POF following radiation and chemotherapy is proportionate to the patient’s age. If the radiation dose is higher than 800 Gy, all women experience ovarian failure. Displacing the ovaries out of the radiation field (ovarian transposition) has shown to be very effective at preserving ovarian function in patients receiving pelvic radiation. Therefore, patients wishing to preserve their fertility should be offered this procedure. Chemotherapy alone, particularly with alkylating agents, may induce temporary or permanent ovarian failure. Studies have shown that the likelihood of experiencing amenorrhea during treatment is 50% to 100%, and on average 40% of patients experience irreversible menopause. In general, younger individuals with chemotherapy-induced ovarian injury are more likely to recover. In women older than age 40, the chance of recovery is less 10%. Modifications of chemotherapy drugs, duration of treatment, and dosing are modifiers of permanent ovarian injury.

D. Resistant ovary syndrome A rare cause of hypergonadotropic amenorrhea associated with numerous unstimulated ovarian follicles is the resistant ovary syndrome. These patients classically have no history of ovulatory dysfunction and present with secondary sexual characteristics and symptoms suggestive of estrogen deficiency. This diagnosis was established in an era when ovarian biopsy was used to determine the cause of menstrual disturbances. However, the definition of resistant ovary syndrome is not universally accepted. In fact, in the original series, cases were included in which patients had demonstrated ovulatory function in the past but later developed a clinical picture suggestive of ovarian resistance. This pattern is more typical of ovarian aging and follicular depletion.

The cause is not known. Histologic features of ovarian biopsy demonstrate that there is no plasma cell or lymphocytic infiltration, indicating that it is not caused by autoimmune destruction. The presence of numerous follicles indicates that POF is not due to follicular depletion. Several studies have looked at gonadotropins, FSH receptors, and antibodies that serve as blockers to the gonadotropin receptors, and the literature to date is inconclusive about the cause.

Diagnosis can be established with certainty only with ovarian biopsy. However, current recommendations for management of amenorrhea do not include surgery to make a diagnosis. The diagnosis is, therefore, one of exclusion. In the absence of autoimmune disease and of any history of ovulation, karyotyping should be performed to exclude chromosomal abnormalities. In patients with normal karyotypes, the diagnosis of POF and resistant ovary syndrome is difficult to make without biopsy. Improvements in ultrasound technology may make it possible to differentiate these entities by the measurement of ovarian volumes and antral follicle counts.

E. Summary In more than half of patients with POF, no specific cause can be identified. The age defining POF is somewhat arbitrary. By definition, menopause is preceded by reproductive failure. It is thought that the time interval between menopause and the end of fertility may be approximately 10 years, and we know that approximately 10% of women reach menopause by
46 years of age and 1% by 40 years. Therefore, women who experience menopause at 45 years of age probably encounter a decline in reproductive potential or even reproductive failure at 35 years of age. This has obvious implications for women who are delaying childbearing. Several studies have described a significant association between the menopausal ages of mothers and daughters, twins, and sisters. A number of studies have identified new genes that are involved in ovarian physiology. It is hoped that these investigations will help in the treatment of subfertility and result in a reduction in infertility. At a minimum, they may allow better prospective individual prediction of reproductive risk.

Women diagnosed with POF that is not readily explained must have an evaluation that consists of a karyotype, testing for fragile-X (FMR) permutation, and evaluation for APS. If a patient has an FMR permutation, one should offer screening to her father. If there is no identifiable cause of POF, screening for adrenal insufficiency is obligatory. All patients with POF should be considered for combination HRT. The increased risks associated with breast cancer are likely no greater than the age-adjusted risk of women with intact ovaries. Patients with absent secondary sexual characteristics should initially be given estrogen-only therapy in low doses and titrated every 3 to 6 months (see Chapters 14 and 15 and see below for management of menopause).

### ANOVULATION

Chronic anovulation may be defined as repetitive ovulation failure, which differs from ovarian failure in that viable oocytes remain in the ovary. Anovulation is the most common cause of amenorrhea during the reproductive years. There are several causes; those associated with hypothalamic and pituitary disorders have previously been mentioned and will not be considered in this section. Other conditions that cause anovulation include the peripheral endocrinopathies. These disorders result in a hormonal imbalance—mainly elevated androgens or estrogens—and lead to inappropriate feedback mechanisms and ovulatory failure. The peripheral endocrine disorders will be discussed later in greater detail.

### Hyperandrogenism and Anovulation

#### A. Polycystic ovarian syndrome

Hyperandrogenic anovulation accounts for more than 30% of cases of amenorrhea and up to 75% of all cases of anovulation. Most often it is due to polycystic ovarian syndrome (PCOS). The reported prevalence of PCOS depends on the criteria used to define it. Although there is considerable controversy over the definition, most investigators, until recently, have focused on the 1990 National Institutes of Health-National Institute for Child and Human Development (NIH-NICHD) diagnostic criteria (Table 13–4). This definition puts forth ovarian hyperandrogenism and anovulation as the cardinal features of PCOS. The criteria include ovulatory dysfunction with evidence of hyperandrogenism, either clinically or by laboratory testing, in the absence of identifiable causes of hyperandrogenism. Using these criteria, the prevalence of unexplained hyperandrogenic chronic anovulation approximates 4% to 6%, and it is considered the most common endocrine disorder in women of reproductive age. However, in 2003 the diagnostic criteria were revised by the Rotterdam consensus conference (see Table 13–4). The Rotterdam criteria consider a broader spectrum of ovarian dysfunction than previous definitions. Some experts criticize the new definition, because it encompasses many more women, notably those with hyperandrogenism and ovulatory cycles, in addition to women with anovulation without androgen excess. This is contrast to the 1990 NIH-NICHD definition, which required both androgen excess and irregular cycles. Most recently, the Androgen Excess Society task force proposed the criteria should be defined by the presence of hyperandrogenism and ovarian dysfunction (see Table 13–4). This definition expands upon the 1990 NIH-NICHD criteria and requires that all patients with PCOS are hyperandrogenic at some level. Although the revised criteria can include women with ovulatory cycles, the remaining discussion on PCOS focuses on women who have anovulatory cycles.

Approximately 50% of women diagnosed with PCOS are obese, and most have polycystic ovaries present on sonography (see later). Underlying these features are numerous biochemical abnormalities that have been associated with this syndrome, including elevated circulating total testosterone, free testosterone, DHEAS, and insulin as well as decreased SHBG and an elevated LH-FSH ratio. However, these abnormalities are not present in all PCOS patients. In fact, 40% of women who present with only hirsutism have elevated total testosterone levels, and 30% to 70% have elevated DHEAS levels. Similarly, the evaluation of increased LH pulsatility, in association with low-normal FSH levels (LH-FSH ratio), is not a reliable diagnostic test. Although elevated LH-FSH ratios are common findings in thin women, in obese patients with PCOS, the ratio is within the normal range about half of the time. The short half-life of LH (~20 minutes) is likely another major contributor to the inaccuracy of LH testing. Hyperinsulinemia has recently been hypothesized to play a major role in the pathogenesis of PCOS (see later). The prevalence of insulin resistance may approximate 50% to 60%, compared with 10% to 25% observed in the general population. However, insulin resistance is difficult to measure in the clinical setting. Part of the

difficulty is that there is no universally agreed on definition of insulin resistance, and the laboratory tests are not standardized. Furthermore, baseline insulin levels vary depending on population and body weight. For example, up to 60% of ovulatory obese patients have demonstrated some form of insulin resistance. Nonetheless, there is good evidence that a subset of normal-weight women and obese women with PCOS have a greater degree of insulin resistance and compensatory hyperinsulinemia compared with weight-matched controls.

There is increasing evidence for a strong genetic component in the etiology of PCOS. Several candidate genes have been investigated, including genes involved in steroidogenesis and carbohydrate metabolism, but none has been conclusively linked with the disease. PCOS is heterogeneous clinically, raising the possibility of different genetic causes and a variable environmental contribution to the syndrome.

1. Diagnosis of PCOS—The diagnosis of PCOS is typically based on clinical features (irregular menstrual cycles, acne, hirsutism), although additional information may be obtained with biochemical testing and sonographic examination. Known causes of hyperandrogenism and anovulation should be excluded in all patients (ie, androgen-secreting tumors, thyroid and adrenal gland dysfunction, hyperprolactinemia).

In most situations, the manifestations of PCOS emerge in the peripubertal years, occasionally with premature pubarche, and likely irregular cycles that persist through much of reproductive life. The diagnosis may be challenging, however, because adolescent girls commonly display irregular cycles during the 5 years following menarche. Ultrasonography may help to solidify the diagnosis of PCOS in children given that the likelihood of restoration of normal ovarian morphology is small as long as irregular menses persist.

Polycystic ovaries tend to be enlarged and have been defined in multiple ways: (1) the presence of 10 or more follicles that are between 2 and 8 mm in diameter and arranged along the subcapsular edge of the ovary in a string of pearls fashion; and (2) 12 or more follicles 2 to 9 mm in either ovary and/or an ovarian volume of 10 cm³ or greater. The increased ovarian volume and displacement of follicles toward the periphery may be explained by the hyperplastic stroma. The stroma contains hilar cells and secondary interstitial cells (theca cells) that are capable of androgen synthesis.

Polycystic-appearing ovaries are very common in women with clinical features suggestive of hyperandrogenism, independent of menstrual disturbances. This finding suggests that ovarian hyperandrogenism can occur in ovulatory states and should be considered in the spectrum of PCOS, if polycystic ovaries are present. However, the finding of polycystic ovaries alone does not establish the diagnosis of PCOS. In fact, based on the Rotterdam definition, more than 30% of normal women have this ovarian morphologic feature. The prevalence is significantly impacted by age. Approximately 60% of women with regular cycles between the ages of 25 to 30 have morphologic characteristics consistent with polycystic ovaries compared to 7% of women between the ages of 41 to 45. Furthermore, the morphogenesis of polycystic ovaries is not unique to PCOS as it has been observed in other scenarios (ie, late-onset congenital adrenal hyperplasia, HIV, epilepsy).

2. Hyperandrogenism—The origin of sex steroids is from two sources: the gonads and the adrenal gland. The adrenal gland is responsible for most of the precursor hormones in the general circulation, which serve as reservoirs for the more potent androgens and estrogens. The ovary produces bioactive androgens and estrogens as well as precursor hormones. Figure 13-11 illustrates the relative contribution of each organ to the pool of circulating sex steroids. DHEAS is the most abundant steroid in the circulation, and serves as a precursor to the more potent androgens and estrogens. Over 98% of DHEAS is secreted from the adrenal gland. Approximately half of the circulating levels of androstenedione are equally derived from the adrenal gland and gonads and the remaining half from conversion of DHEAS (DHEA) in the periphery. DHEA also serves as a substrate for the ovary to produce bioactive sex steroids. It is evident that the majority of bioactive androgen is derived from precursor steroids that undergo peripheral conversion. It is suggested over 60% of the testosterone is derived from circulating androstenedione, and the remaining is by direct secretion. The contribution of testosterone from the ovary and the adrenal gland is not completely known. The fact that the various methods to obtain secretion rates are difficult and that assays used to measure testosterone can be unreliable with resultant variability contributes to the uncertain interpretation.

A common clinical sign of hyperandrogenism is hirsutism. Hirsutism affects approximately 5% to 15% of the population. The prevalence depends on the population and the method used to establish the diagnosis. The most common scoring method used to diagnose hirsutism is based on the Ferriman and Gallwey system. It is based on evaluating 9 to 11 body areas and assigning a score of 0 to 4 based on the density of hair. This method is primarily used for research purposes. Clinically, it is often diagnosed by history and the presence of excess hair growth in centrally located regions, not commonly found in women. For example, those areas most affected are the face (sideburns, mustache, and beard), chest, linea alba, or the inner aspect of the thighs. The characteristics and distribution of body hair may be influenced by ethnic or racial factors. Alternatively, hyperandrogenism may present as acne or alopecia.

The diagnostic evaluation of hirsutism should include a thorough history and physical examination (Figure 13–12). The etiology can be divided between nonandrogenic and androgenic causes. Organic causes of hyperandrogenism must be excluded. Nonandrogenic causes include chronic skin irritation, anabolic medications, and rarely acromegaly. The most common androgenic cause is PCOS which affects at least 70% of hirsute women. Less common is late-onset congenital adrenal hyperplasia, which affects approximately 5% of patients. PCOS is a diagnosis of exclusion—measurements of serum androgen levels should play only a limited role in the evaluation. Most patients who have hyperandrogenemia present with obvious clinical manifestations, and the presence of normal androgen levels in a patient with hirsutism or acne does not exclude the diagnosis of PCOS. However, there are subsets of amenorrheic patients (ie, Asians) who are hyperandrogenemic without clinical manifestations, most likely as a result of their relative insensitivity to circulating androgens. It is in these patients that assessing androgen levels may be of value in determining the cause of amenorrhea. More commonly, androgens such as DHEAS and testosterone are measured to exclude other causes of hyperandrogenic anovulation such as nonclassic adrenal hyperplasia and androgen-secreting tumors (see later).
Another cause of hirsutism, made only after excluding other diagnoses, is characterized by regular menstrual cycles, normal androgen levels, and the absence of polycystic-appearing ovaries; it is termed idiopathic hirsutism. This common disorder occurs more frequently in certain ethnic populations, particularly those of Mediterranean descent. It is thought that the etiology of hirsutism in these patients is related to higher 5α-reductase activity (increased sensitivity) within the pilosebaceous unit.

3. Mechanism of anovulation—The mechanism of anovulation in PCOS remains unclear. It is evident that the population of antral follicles is increased and that follicular development is arrested. It is also known that the development of preantral follicles is not primarily under hormonal control. Evidence supports the components of the intraovarian network as regulators of antral follicle development. It is known that many of the accumulated follicles in PCOS remain steroidogenically competent and are capable of producing estrogen and progesterone. In fact, it is interesting that women with PCOS produce both androgens and estrogen (estrone) in excess.

One of the most frequently described characteristics of PCOS is the functional derangement of LH secretion. Numerous studies have shown that frequency, amplitude, and mean levels of LH are increased. The aberration in LH secretion may be a result of heightened pituitary responsiveness and increased hypothalamic GnRH activity. Under normal conditions, follicles respond to LH after they reach approximately 10 mm in diameter. However, polycystic ovarian follicles acquire responsiveness to LH at a much smaller diameter, which may lead to inappropriate terminal differentiation of granulosa cells and result in disorganized follicular development. It has been suggested that the theca cells increase their expression of steroidogenic enzymes following stimulation by LH, whereas the granulosa display resistance to FSH (see later). The elevated LH levels and relative hyperinsulinemia that exist in some PCOS patients may synergistically potentiate disordered folliculogenesis. Although hyperandrogenism is part of the diagnostic criteria for PCOS, its direct impact on folliculogenesis is not clear. It is conceivable that androgens contribute to the effects of LH and insulin on follicular maturation. It is also possible that the excess estrogens may result in a negative-feedback loop to inhibit FSH release and prevent further follicular development.

Most experts are of the opinion that excess androgen production is a fundamental abnormality in women with PCOS. Androgens within the ovary are produced mainly by the thecal interstitial cells that surround the follicle and to a lesser extent by the secondary interstitial cells located in the stroma (see earlier). The CYP17α complex is thought to be the key enzyme in biosynthesis of ovarian androgens. Under normal conditions, a large proportion of the androgens produced by the theca cells diffuses into the granulosa cell layer of the follicle where they are rapidly converted to estrogen as shown in Figures 13-7 and 13-11 (two-cell theory). The intrinsic control of androgen production in the ovary is modulated by intraovarian factors and hormones (see section on ovarian steroidogenesis at the beginning of this chapter). It is the dysregulation of hormone production that is most likely responsible for PCOS.

Several studies have shown that women with PCOS have an exaggerated ovarian androgen response to various stimuli. To illustrate, hyperstimulation of 17-hydroxyprogesterone levels was noted when women diagnosed with PCOS were given a GnRH agonist or hCG, suggesting increased CYP17α activity. This study is supported by in vitro studies in which measurement of steroids in cultured human theca cells from polycystic ovaries revealed concentrations of androstenedione, 17α-hydroxyprogesterone, and progesterone that were respectively 20-fold, 10-fold, and 5-fold higher than levels in control cells. Additional studies have found increased expression of the genes encoding CYP17α hydroxylase, P450scc, the LH receptor, and StAR. These findings reflect a global enhancement of

FIGURE 13–12 An algorithm for women with hirsutism. All women should be screened for known causes of hyperandrogenism. Hyperandrogenism suggests either PCOS or late-onset congenital adrenal hyperplasia (CAH). If hirsutism is rapid in onset or rapidly progressive in nature or the patient is frankly virilized, an evaluation for an androgen-secreting tumor is required. Management of hirsutism in late-onset CAH or PCOS is similar. Late-onset CAH can present with regular cycles. Depending on the specific criteria (see Table 13–4), PCOS can present with regular cycles. Serum hormones are not required for the diagnosis of idiopathic hirsutism or PCOS.

Steroidogenesis. This situation is compounded by the hypertrophy of theca cells that is present in women with PCOS.

Several studies have evaluated intraovarian modulators as participants in the pathogenesis of PCOS (Figure 13–13). IGF-binding proteins (IGFBPs), especially IGFBP-2 and IGFBP-4, are found to be increased in the follicular fluid of polycystic ovaries. They may act locally to decrease free IGF-2 and, thus, decrease the effects of FSH on the oocyte and granulosa cells. Alternatively, the granulosa cells may down-regulate their insulin receptors as a result of hyperinsulinemia. This would deprive the granulosa cells of their co-gonadotropin, IGF-2, and account for the relative FSH insensitivity. Inhibin is also a likely candidate, because a large proportion of women with PCOS have relative FSH suppression (Figure 13–13). However, studies have not shown consistent results, suggesting that if inhibin is involved, the effect is minimal. Follistatin, the activin-binding protein, was in the past thought to play an important role in the development of PCOS. It was initially implicated because activin functions to inhibit androgen production and enhance FSH expression. However, current studies do not demonstrate a significant association between abnormalities in follistatin and PCOS.

The adrenal gland may be significantly involved in the pathogenesis of some cases of PCOS. The connection seems plausible because adrenal androgens can be converted to more potent androgens in the ovary. Furthermore, a significant portion of women with congenital adrenal hyperplasia have polycystic ovaries (see later). Several studies have shown that DHEAS is elevated in 25% to 60% of patients with PCOS. However, ACTH levels are normal in PCOS women. Interestingly, it has been reported that there is an increased response of androstenedione and 17α-hydroxyprogesterone to exogenous ACTH. These
4. Hyperinsulinemia and PCOS—A relationship between insulin and hyperandrogenism has been postulated based on several observations. This association may be demonstrated in the peripubertal years with premature pubarche, which is more commonly associated with insulin resistance than with congenital adrenal hyperplasia or androgen excess. Various case reports have shown that acanthosis nigricans—hyperpigmentation of skin in the intertriginous areas—is associated with severe insulin resistance. A number of these patients also presented with hyperandrogenism and anovulation. The relationship was substantiated when it was observed that the degree of hyperinsulinemia was correlated with the degree of hyperandrogenism. Further studies revealed that hyperinsulinemia is frequently identified in women with PCOS.

It has been shown that the cause of hyperinsulinemia is insulin resistance and that the defect lies in the postreceptor signaling pathway. The frequency and degree of hyperinsulinemia in women with PCOS is amplified in the presence of obesity. Although many women with PCOS exhibit insulin resistance, some do not. However, insulin resistance is also observed in some thin PCOS patients.

Insulin may cause hyperandrogenism in several different ways, although the exact mechanism has not been well defined. It has been suggested that insulin has a stimulatory effect on CYP17α. There is evidence from in vitro models that insulin may act directly on the ovary (see Figure 13-13). It has been shown that the ovary possesses insulin receptors and IGF receptors. In addition, several studies have reported that insulin stimulates ovarian estrogen, androgen, and progesterone secretion and that its effects are greatly enhanced by the addition of gonadotropins. Administration of an insulin-sensitizing agent (e.g., metformin or a thiazolidinedione) to obese women with PCOS leads to a substantial reduction in 17α-hydroxyprogesterone levels, reflecting decreased CYP17α activity. However, clinical studies, in which insulin infusions were administered to normal women, failed to demonstrate increased testosterone production, and there were no changes in androgen levels when normal women were given insulin-sensitizing agents. These observations suggest that insulin has more of a modifying rather than a predisposing effect on androgen production.

The relationship between insulin and adrenal androgen production is less clear. Some studies have shown that insulin increases secretion of 17α-hydroxyprogesterone and DHEAS in response to ACTH. Other studies have shown that DHEAS decreases after acute insulin infusions are administered to

**FIGURE 13-13** Regulation of sex steroid production in the theca and granulosa cells of the ovary. Several autocrine and paracrine factors such as insulin and insulin-like growth factors (IGFs) work synergistically with luteinizing hormone (LH) to stimulate androgen production through increased 17α-hydroxylase activity. (Redrawn with permission from Ehrmann DA, Barnes RB, Rosenfield RL. Polycystic ovary syndrome as a form of functional ovarian hyperandrogenism due to dysregulation of androgen secretion. *Endocr Rev.* 1995;16:322.)
normal men and women. Furthermore, when insulin-sensitizing agents were administered to women with PCOS, a decrease in DHEAS was observed. Although there is less evidence to support the association of insulin and adrenal androgen production, if there is an insulin effect, it is as a modulator of adrenal secretory activity.

Insulin may indirectly affect androgen levels. Several studies have reported that insulin directly inhibits SHBG production. There is an inverse correlation between insulin levels and SHBG, so that decreasing insulin levels would decrease the circulating bioavailable androgen level (via increases in SHBG). It has also been shown that insulin decreases IGFBP-1. This would increase free IGF-1, which could modulate ovarian androgen production in a fashion similar to insulin (see Figure 13–13). Although these indirect mechanisms may play a role, the literature suggests that insulin acts directly to augment androgen production (see Figure 13–13). However, it appears that a dysregulation in steroidogenesis must also exist in order for insulin to cause hyperandrogenism.

Increasing attention is being directed to the possibility that PCOS begins before adolescence. In fact, the initial insult may begin in utero, where there is ample exposure to androgens derived from the fetal adrenal gland and ovary. This hormonal environment may reprogram the ovary and alter steroidogenesis in a manner that predisposes to PCOS. The phenotypic expression of PCOS would then be determined by environmental factors such as diet and exercise.

The various biochemical abnormalities associated with PCOS have led to studies investigating metabolic sequelae of this syndrome. Long-term health problems such as the development of cardiovascular disease and diabetes have been linked to PCOS. In fact, several studies have suggested that the metabolic syndrome is significantly more prevalent in women with PCOS. However, studies looking at whether women with PCOS actually experience increased cardiovascular events are limited. Several observational studies have demonstrated that women with PCOS have alterations in their lipid profiles, including increased triglycerides and LDL and decreased high-density lipoprotein (HDL) compared with weight-matched controls. Furthermore, the degree of dyslipidemia has been correlated with the magnitude of insulin resistance. The fact that insulin resistance occurs with greater frequency in women with PCOS suggests that they are at higher risk for the development of diabetes mellitus. It is known that up to 30% to 40% of women with PCOS have impaired glucose tolerance, although it is most often seen in patients who are obese. Limited retrospective studies have suggested that women with PCOS have an increased frequency of developing type 2 diabetes. In summary, as demonstrated by surrogate markers, the available data show that these patients have increased risk factors for cardiovascular events and diabetes. Long-term prospective studies will be required to determine if these patients are actually at risk for increased mortality and morbidity.

The fact that hyperinsulinemia underlies many of the potential adverse sequelae raises a question about whether insulin resistance should be assessed in all patients diagnosed with PCOS. There are several methods of measuring insulin resistance (Table 13–5). However, the potential impact of hyperinsulinemia is unknown. Furthermore, there is no universal laboratory criterion or standardization for establishing the diagnosis of insulin resistance, which raises doubts about whether any potential adverse sequelae can be prevented if insulin resistance is identified. Further data are necessary, prior to widespread use of medications such as metformin or a thiazolidinedione to reduce insulin resistance in patients with PCOS to determine (1) if these patients are indeed at risk for cardiovascular events, (2) if hyperinsulinemia is an independent risk factor, and (3) whether long-term treatment with any insulin-sensitizing agent will decrease the potential sequelae.

5. Additional risks associated with PCOS—Another concern is that women who are anovulatory do not produce a significant amount of progesterone. This leads to a situation in which the uterine lining is stimulated by unopposed estrogens, which is a significant risk factor for development of endometrial cancer. In fact, an association has been found between endometrial cancer and PCOS. There is also evidence to suggest an association of PCOS with both breast cancer and ovarian cancer, but PCOS has not been conclusively shown to be an independent risk factor for either disease.

6. Management of PCOS—The management of PCOS should be dictated by the patients’ risk factors for cardiovascular disease, diabetes, malignant sequelae, and symptomatology (see also “Infertility”). All patients should have a lipid profile measured. In addition, oral glucose tolerance tests should be performed—at least in obese women. In patients who have a long history of irregular cycles (>1 year), an endometrial biopsy should be considered.

Cardiovascular risk factors, weight loss, and progression to diabetes can be improved with diet and exercise. In the subset of patients with glucose intolerance, administration of insulin-sensitizing agents should be considered. Metformin, a biguanide, is the most widely studied. Several studies have shown modest transitory weight loss, and possibly a decreased incidence of diabetes in patients with PCOS due to its use. Metformin is not effective for treatment of hyperandrogenic symptomatology. The use of metformin is not recommended unless there is evidence of metabolic derangements that are not fixed with diet and exercise alone.

Irregular bleeding can be improved by the administration of oral contraceptives which induce scheduled withdrawal bleeding. However, another benefit of oral contraceptives has been the significant reduction in endometrial cancer in the general population. It is rational to expect that a similar benefit would
Acne and hirsutism in women diagnosed with PCOS or of idiopathic origin can be treated with oral contraceptives. The mechanism is not completely known, but oral contraceptives decrease the amount of bioavailable androgens by increased SHBG production and by ovarian suppression. It has also been shown that progestins can inhibit 5α-reductase activity, which further decreases the production of dihydrotestosterone, the major androgen that stimulates hair growth. The maximal effect is evident after 6 months of treatment (the hair cycle length is estimated to be 4 months). If hirsutism is severe or if oral contraceptives alone are not effective, the addition of spironolactone may be beneficial. Spironolactone is an antimineralocorticoid agent that inhibits androgen biosynthesis in the adrenal gland and ovary, inhibits 5α-reductase, and is a competitive inhibitor of the androgen receptor. Side-effects are minimal and include diuresis in the first few days; dyspepsia; nausea; skin hypersensitivity; breast tenderness; and abnormal bleeding, which can be alleviated by increasing the dose to desired amount over 3 weeks. Spironolactone is used concomitantly with oral contraceptives. Because oral contraceptives and spironolactone act by different mechanisms, the combined effect is synergistic.

If oral contraceptives are not desired or have not improved the excess hair growth, there are several other methods that can be used in conjunction with oral contraceptives or administered alone. The only topical agent approved for hirsutism by the FDA is Vaniqa (Efformithine) cream, which is an inhibitor of L-ornithine decarboxylase. It has been shown to be effective for control of facial hair. Long-acting GnRH agonists and 5α-reductase inhibitors (finasteride) have been used for refractory cases with some success. Shaving, bleaching, chemical depilation, plucking, or waxing are temporary measures to control unwanted hair growth. However, several of these methods can cause skin irritation and result in progressive hair growth. Permanent techniques such as electrolysis or laser depilation have shown promising results.

### B. Congenital adrenal hyperplasia

Congenital adrenal hyperplasia is another disorder that may cause hyperandrogenism. It presents in a wide range of clinical forms, ranging from severe—which may be classified as classic, salt-wasting, or simple virilizing—to milder forms known as acquired, adult-onset, nonclassic, or late-onset congenital hyperplasia. The clinical manifestations reflect the severity of the enzymatic defect. Severe or classic forms are discussed in Chapter 14 and will not be considered here. This section will discuss the nonclassic forms, which affect 1% to 10% of the population, depending on the ethnicity of the patient. The clinical features are similar to those of patients diagnosed with PCOS and include menstrual irregularities, hyperandrogenism, and infertility, and up to 50% have polycystic ovaries.

The adrenal gland consists of a cortex and a medulla. The cortex is divided into three functional zones based on location and the principal hormone secreted (see Chapter 9). The zona glomerulosa is the outermost zone and lies adjacent to the adrenal capsule. It is primarily responsible for aldosterone production. The zona fasciculata lies immediately below the glomerulosa. It principally secretes glucocorticoids, although it is capable of producing androgens. The zona reticularis is located beneath the zona fasciculata and overlies the adrenal medulla. It is this zone that principally secretes androgens. Both the zona fasciculata and the zona reticularis are regulated by ACTH. It is the secretory activity of these two zones that results in nonclassic adrenal hyperplasia.

Congenital adrenal hyperplasia is an autosomal recessive disorder that is caused by mutations of genes involved with adrenal steroidogenesis. The mutations mostly occur in the 21-hydroxylase gene (P450c21B) and rarely in the 3β-hydroxysteroid dehydrogenase gene or 11β-hydroxylase genes (P450c11B and P450c11AS). In classic forms, the enzymatic defects are severe, affect both alleles, and result in cortisol deficiency diagnosed at birth. Owing to the cortisol deficiency, there is ACTH excess and hyperstimulation of the adrenal gland. The adrenal precursors produced proximal to the enzymatic defect accumulate and promote the synthesis of DHEA and androstenedione through the androgen synthetic pathway. These are converted in the periphery to more potent androgens, resulting in symptoms of hyperandrogenism. Approximately 50% of patients diagnosed with nonclassic congenital adrenal hyperplasia are compound heterozygotes with one of the mutant alleles coding for a severe defect. Typically, patients who are carriers have a normal phenotype. Therefore, most patients with nonclassic adrenal hyperplasia do not demonstrate deficient cortisol production or excess ACTH. It is suggested that most of the androgen excess in nonclassic adrenal hyperplasia arises as a consequence of subtle alterations in enzyme kinetics. Furthermore, some studies report a generalized adrenocortical hyperactivity rather than deficient enzyme activity.

The diagnosis can be established by measuring early morning basal 17-hydroxyprogesterone levels. Levels greater than 800 ng/dL (24.24 pmol/L) are diagnostic of 21-hydroxylase deficiency. However, the elevation in 17-hydroxyprogesterone is often not impressive and does not differ from that observed in PCOS. If the basal 17-hydroxyprogesterone levels are greater than 200 ng/dL (6.06 pmol/L) and less than 800 ng/dL (24.2 pmol/L), a provocative test with ACTH (250 μg intravenously) should be performed. If 17-hydroxyprogesterone levels are greater than 1000 ng/dL (30.30 pmol/L) 1 hour after administration of ACTH, the diagnosis of 21-hydroxylase deficiency can be made. Elimination of a false elevation in 17-hydroxyprogesterone due to ovulation must be excluded by simultaneous measurement of progesterone. A 17-hydroxyprogesterone screening level greater than 200 ng/dL has 100% sensitivity, but only 7% positive predictive value for the diagnosis of nonclassic adrenal hyperplasia. The other rare enzymatic defects that result in nonclassic adrenal hyperplasia can be assessed with measurements of steroid products proximal to the blockade following provocative testing.

Treatment of nonclassic adrenal hyperplasia is similar to that of PCOS, raising a question about whether an etiologic diagnosis is necessary. It is certainly an expense, leading to no change in management except with regard to infertility treatment and management of subsequent pregnancies (see later). Establishing a specific diagnosis may be advisable to facilitate genetic counseling in the woman with adrenal hyperplasia who intends future childbearing and to prepare for in utero treatment should an affected fetus be...
identified by amniocentesis. Although some experts suggest dexamethasone treatment for symptoms of hyperandrogenism, studies show inconsistent results, and there is concern about the consequent adrenal suppression.

C. Cushing syndrome Chronic glucocorticoid excess, whatever its cause, leads to the constellation of symptoms and physical features known as Cushing syndrome. The most common cause is iatrogenic as a result of glucocorticoid treatment. However, an ACTH-secreting microadenoma (Cushing disease) accounts for more than 70% of cases of endogenous hypercortisolism. Less common causes include primary adrenal disease (tumors or hyperplasia) and ectopic (not hypothalamic-pituitary) ACTH-producing or CRH-producing tumors. Patients with Cushing syndrome have a range of clinical manifestations that vary with age at onset and etiology. This section will discuss the adult clinical presentation briefly. For a more detailed discussion, see Chapter 9.

Cushing syndrome (noniatrogenic) is rare and occurs in approximately 2.6 patients per million individuals in the population. It is responsible for less than 1% of those individuals who present with hirsutism. Although Cushing syndrome is uncommon, it presents in a manner similar to PCOS and congenital adrenal hyperplasia and needs to be considered in the differential diagnosis of hyperandrogenism and anovulation. Patients with ACTH excess typically have additional clinical features suggestive of glucocorticoid or mineralocorticoid hypersecretion. The most common features include obesity with increased centripetal fat, moon facies, muscle weakness, and striae. Other manifestations may include diabetes, hypertension, and osteoporosis. Women with primary tumors tend to have a rapid onset of symptoms and often manifest with severe hyperandrogenism (frank virilization) that includes male pattern baldness, deepening voice, clitoromegaly, and feminization.

Hirsutism or acne is present in about 60% to 70% of women with Cushing syndrome. However, the exact mechanism of hyperandrogenic effects is not completely known. It is evident that excess ACTH causes hyperstimulation of the zona fasciculata and zona reticularis and results in hypersecretion of cortisol and androgens. It is also known that adrenal tumors may selectively overproduce androgens.

Menstrual irregularities occur in more than 80% of patients with Cushing syndrome. The exact cause of anovulation is unclear. It has already been observed that hyperandrogenemia may have a significant impact on ovulation. However, several studies have shown that glucocorticoids can also suppress the hypothalamic-pituitary axis. Thus, the elevated glucocorticoids may be an additional factor in the pathophysiology of anovulation associated with this syndrome (see Chapters 4 and 9 for the diagnosis and treatment of Cushing syndrome).

D. Androgen-secreting tumor If there is a rapid onset of androgenic symptoms, an androgen-secreting adrenal tumor should be suspected. Elevated testosterone (>200 ng/dL; 6.9 nmol/L) and DHEAS (>700 ng/mL; 19 µmol/L) levels should raise the suspicion of a tumor. However, more than 50% of adrenal androgen-secreting tumors have testosterone levels below 200 ng/dL (6.9 nmol/L). Furthermore, the majority of patients with high testosterone levels do not have tumors. Testosterone levels above 250 ng/dL are only 10% predictive for androgen-secreting tumor. Measurement of DHEAS levels in these patients yields similar inconsistencies. This suggests that laboratory tests have limited value in screening for androgen-secreting tumors, and a clinical history and physical examination are better predictors. The presence of systemic symptoms such as weight loss, anorexia, bloating, and back pain favor an androgen-secreting tumor. If suspicion is high, an abdominal computed tomography (CT) scan confirms the diagnosis. The treatment involves surgical resection, mitotane (adrenolytic), and steroid synthesis inhibitors.

Androgen-secreting tumors can also originate from the ovary. The incidence approximates 1:500 to 1:1000 hyperandrogenic patients. Testosterone levels >200 ng/dL (6.9 nmol/L) arouse suspicion, although in 20% of patients with ovarian androgen-producing tumors, testosterone levels are below this value. Again, the best screening procedures are the clinical history and physical examination. In the absence of Cushingoid features, adrenal and ovarian tumors present similarly. Ovarian tumors often have unilateral ovarian enlargement that can be palpated on pelvic examination. Ultrasonography often confirms the diagnosis. In selected cases, selective venous sampling may be performed if CT or sonography cannot identify the source of androgen production.

OBESITY

Obesity is the most prevalent chronic disease in the United States. Adverse health events are dramatically increased in obese subjects (see Chapter 20). These include cardiovascular disease, diabetes, joint disease, respiratory dysfunction, and colon, endometrial, and ovarian cancers. Obesity is often also associated with menstrual irregularities, and the relationship between the two is strengthened the earlier the onset of the obesity. Alterations in sex steroid metabolism are clearly evident in obese females, and the consequences are attenuated release of gonadotropins, which manifests as anovulation. Obese patients have increased production rates and MCRs of androgens; therefore, their serum levels of androgens are largely within the normal range. However, free testosterone levels tend to be in the high-normal range due to the decreased SHBG levels. A portion of androgen metabolism occurs in body fat. The excess adipose tissue aromatizes these androgens and increases the amount of circulating estrone causing a state of functional hyperestrogenism. In fact, studies have shown that the rate of peripheral conversion of androstenedione to estrone is correlated with body weight. Other studies have illustrated that the conversion of estrone to estradiol in adipose tissue is higher in visceral fat than subcutaneous fat. The increased visceral fat associated with obesity is also associated with hyperinsulinemia, which may have independent effects on ovarian function.

Management of Obesity

The management of obesity includes diet and exercise (see Chapter 20). In patients who have irregular uterine bleeding, an
Adrenal insufficiency is also seen following treatment of Cushing disease and with a variety of hypothalamic-pituitary lesions that result in hypopituitarism. These patients more commonly present with symptoms suggestive of acute adrenal insufficiency. The clinical features include abdominal pain, hypotension, fever, severe volume depletion, and possibly profound shock.

Menstrual disturbances are a frequent presentation in patients with adrenal insufficiency. Autoimmune adrenal insufficiency is often accompanied by gonadal failure. In the two forms of APS, POF develops in APS-1 in 50% of patients and in APS-2 in 10% of patients. It has been shown that antibodies—particularly to CYP17α and P450scc—are associated with POF. Other causes of adrenal failure are associated with menstrual disorders more than 25% of the time. The cause of anovulation is not known with certainty, but chronic illness itself is probably responsible.

Diagnosis and treatment are discussed in Chapter 9. The screening process includes blood chemistries and basal cortisol levels. The diagnosis is confirmed with provocative tests using exogenous ACTH.

B. Thyroid disorders The prevalence of overt thyroid dysfunction is 1% to 2% in women of reproductive age. Thyroid disorders can develop secondary to an insult in the hypothalamus, pituitary, or thyroid, the latter being most common. In order to understand the pathophysiology of these disorders, it is important to be familiar with the normal physiologic regulation (see Chapter 7). This section will briefly review the common causes of hyperthyroidism and hypothyroidism, their manifestations after the onset of puberty, and their impact on reproductive function.

1. Hyperthyroidism—Hyperthyroidism is the clinical syndrome associated with excessive thyroid hormone activity. The clinical presentation of hyperthyroidism (thyrotoxicosis) depends on the age at onset and the degree of thyrotoxicosis. The clinical manifestations can involve most organ systems, and the presentation ranges from asymptomatic to thyroid storm. Typical features include nervousness, malaise, palpitations, heat intolerance, weight loss, and inability to concentrate. Additional features may involve the eyes and include lid lag, proptosis, and ophthalmoplegia. The reproductive abnormalities include menstrual abnormalities, infertility, and spontaneous abortions.

The most common cause of hyperthyroidism is an autoimmune process that affects thyroid hormone production (Graves disease). Antibodies bind to the TSH receptor and stimulate the thyroid gland to secrete increased amounts of thyroid hormone. Less common causes include subacute thyroiditis, toxic multinodular goiter, and struma ovarii.

Excess thyroid hormone has an impact on sex steroids. Thyroid hormones stimulate hepatic production of SHBG. As a result, total serum estradiol, estrone, testosterone, and dihydrotestosterone are increased, yet free levels of these hormones remain within the normal range. The metabolic clearance pathways appear to be altered, which can be explained in part by the increased binding. The conversion rates of androstenedione to estrogen and testosterone are increased. The significance of the alterations in metabolism has not been determined.
Menstrual irregularities frequently occur in hyperthyroid states. The exact mechanism is unclear. Altered levels of TRH and TSH do not appear to have a significant impact on the HPO axis. The LH surge may be impaired, although studies have shown that hyperthyroid patients have normal FSH and LH responses to exogenous GnRH. It is possible that the weight loss and psychologic disturbances associated with this disease may contribute to the menstrual abnormalities. It is interesting to note that endometrial biopsies of many amenorrheic patients with hyperthyroidism have demonstrated a secretory endometrium, indicating that many of these women remain ovulatory. Menstrual abnormalities return to normal with treatment.

2. Hypothyroidism—A more common disorder than hyperthyroidism in women of reproductive age, hypothyroidism results from inadequate thyroid hormone production. Manifestations can involve almost any organ system, and the presentation can range from asymptomatic to myxedema coma. Common symptoms include lethargy, memory defects, cold intolerance, dry skin, hair loss or occasionally excess hair growth, deepening of the voice, nausea, and constipation. Physical findings include somnolence, bradycardia; mild hypertension; dry skin; periorbital puffiness; nonpitting edema of the hands, face, and ankles; and decreased tendon reflexes. Reproductive abnormalities include menstrual disorders, infertility, and spontaneous abortions.

The most common cause is autoimmune destruction of the thyroid (Hashimoto thyroiditis). It is mediated by humoral and cell-mediated processes. The antibodies are directed toward thyroglobulin (anti-Tg) and thyroid peroxidase (anti-TPO antibody). Histologic specimens show lymphocytic infiltration. Other causes include ablative therapy of the thyroid gland (postsurgery or radioactive iodine), end-stage Graves disease, and transient thyroiditis (viral, drug-induced, or postpartum).

Inadequate thyroid hormone levels influence the metabolism of sex steroids. The production of SHBG is decreased. As a result, serum estradiol and testosterone concentrations are decreased, but free hormone levels remain within the normal range. However, the metabolism of these steroids is altered and differs from that found in individuals with hyperthyroidism.

The mechanism underlying menstrual abnormalities in hypothyroidism is incompletely understood. Because primary hypothyroidism is associated with elevated serum PRL in up to one-third of patients, it is plausible that hyperprolactinemia is a contributing factor (see Chapter 4). However, menstrual abnormalities are also observed in the absence of elevated PRL. Alterations in FSH and LH levels have been investigated, and studies have shown inconclusive results, although several studies suggest that the midcycle surge is absent. Menstrual function returns to normal with thyroid hormone replacement.

Thyroid dysfunction often presents with nonspecific symptoms, which delays the diagnosis. If only menstrual abnormalities are present, it is prudent to screen for thyroid abnormalities. Most cases are detected by TSH assays. Confirmation is obtained with a repeat TSH level and serum thyroid hormone levels.

OUTFLOW TRACT DISORDERS

The true prevalence of Mullerian tract abnormalities is not known. It is reported in as many as 45% of women. The reproductive consequences depend on the type of abnormality identified. A septate uterus is the most common defect described. These patients often present with infertility or obstetric complications. Other abnormalities include unicornous, bicornous, and didelphic uteri. These abnormalities present most commonly with reproductive or obstetric complications. Mullerian agenesis, androgen insensitivity syndrome, and congenital outflow obstruction defects are abnormalities that present with primary amenorrhea with no history of menses. In the following section these two abnormalities are discussed in greater detail.

A. Mullerian agenesis Mullerian agenesis (Mayer-Rokitansky-Küster-Hauser syndrome) is the second most common cause of primary amenorrhea. It is a congenital condition that occurs in one in 5000 female births. These individuals have normal ovarian development, normal endocrine function, and normal female sexual development. The physical findings are a shortened or absent vagina in addition to absence of the uterus, although small masses resembling a rudimentary uterus may be noted (see the section “Embryology and Anatomy” at the beginning of this chapter). About one-third of patients have renal abnormalities, and several have had bone abnormalities and eighth nerve deafness. These individuals have a 46,XX karyotype.

The exact cause has not been identified. It is known that regression of Mullerian structures in males is controlled by AMH, which is secreted by the Sertoli cells of the testis. One hypothesis assigns the underlying defect to an activating mutation of either the AMH gene or its receptor. The genes for both AMH and AMH receptor have been investigated, but no mutations have yet been identified in patients with this syndrome.

B. Androgen insensitivity syndrome Androgen insensitivity syndrome (AIS) presents in somewhat the same way as Mullerian agenesis. The presentation differs in that individuals with complete AIS have minimal sexual hair. These patients have a male karyotype with a mutation of the androgen receptor on the X chromosome. They have normal testicular development and endocrine function. However, because the internal and external male sexual structures need testosterone for development, they are absent. This results in a female phenotype. Because the testis still secretes AMH, Mullerian regression does occur. Secondary sexual characteristics (female) develop as a result of peripheral conversion of testosterone to estradiol, effectively resulting in unopposed estrogen stimulation.

The diagnosis of either disorder is entertained when pelvic examination reveals a short or absent vagina and no uterus on rectal examination. Confirmation of absent uterus can be obtained with ultrasound, MRI, or laparoscopy. These two disorders can usually be differentiated based on physical examination; patients with AIS have no pubic hair. However, the differential diagnosis becomes more difficult when patients have incomplete AIS. A testosterone level and karyotype can easily differentiate the two syndromes. This disorder is further discussed in Chapter 14.

C. Congenital outflow obstruction Transvaginal septum and imperforate hymen are typical obstructive abnormalities.
These patients usually present with cyclic lower abdominal pain and amenorrhea. The physical findings are a shortened or absent vagina. However, this syndrome differs from Mullerian agenesis in that the pelvic organs are present. Behind either defect is old blood that has not escaped with menses. The differential diagnosis is sometimes difficult, although bulging of the introitus suggests imperforate hymen, because the defect is thinner than a transvaginal septum.

The embryologic formations of the transvaginal septum and imperforate hymen are similar but not identical. Transvaginal septum is due to failure of complete canalization of the vaginal plate (see the section “Embryology and Anatomy” at the beginning of this chapter). The septum can vary in thickness and can be located at any level in the vagina. The hymen represents the junction of the sinovaginal bulbs and urogenital sinus. Typically, the hymen is perforated during fetal development. The hymen is thin and is always at the junction of the vestibule and vagina. It is important to distinguish these defects because the surgical correction procedures are different and require different levels of expertise.

D. Asherman syndrome

Intrauterine adhesions or synechiae (Asherman syndrome) are an acquired condition that may obliterate the endometrial cavity. These patients usually present with a range of menstrual disturbances, infertility, and recurrent spontaneous abortions. The most frequent symptom is amenorrhea.

Intrauterine adhesions result from damage to the endometrial basal layer. A common antecedent factor is a surgical procedure within the uterine cavity, and most often it is endometrial curettage that occurs shortly after pregnancy. The concurrent presence of infection or heavy bleeding increases the risk. Endometrial tuberculosis and septic abortion are rare causes.

The diagnosis is entertained after demonstrating no withdrawal bleeding after administration of estrogen and progesterone. Confirmation is made with a hysterosalpingogram, saline sonogram, or hysteroscopy. Treatment involves lysis of adhesions and hormonal therapy.

**MENOPAUSE**

The ovary is unique in that the age at which it ceases to function in women appears to have remained constant despite the increase in longevity experienced by women over the last century. Because the loss of ovarian function has a profound impact on the hormonal milieu in women and the subsequent risk of the development of disease resulting from the loss of estrogen production, improving our understanding of reproductive aging is critical for optimal female health.

Human follicles begin development in the fourth gestational month. Approximately 1000 to 2000 germ cells migrate to the gonadal ridge and multiply, reaching a total of 6 to 7 million around the fifth month of intrauterine life. At this point, multiplication stops and follicle loss begins, declining to approximately 1 million by birth. In the human male, the germ cells become quiescent and maintain their stem cell identity. In contrast, in the human female, between weeks 12 and 18, the germ cells enter meiosis and differentiate. Thus, in the female, all germ stem cells have differentiated prior to birth. In the adult woman, the germ cells may remain quiescent, may be recruited for further development and ovulation, or may be destroyed by apoptosis. Over time, the population of oocytes is depleted (without regeneration) through recruitment and apoptosis until less than a thousand oocytes remain and menopause ensues. Approximately 90% of women experience menopause at a mean age of 51.2 years (range, 46-55). The remainder experiences menopause prior to age 46 (often termed early menopause), with 1% of women experiencing menopause before age 40 years (POF, as discussed above).

Understanding ovarian aging has been difficult. The variability in definitions has made comparisons from study to study difficult. The participants in the Stages of Reproductive Aging Workshop (STRAW) developed criteria for staging female reproductive aging. They utilized menstrual cyclicity and early follicular FSH levels as the primary determinants for this staging system. Five stages precede the final menstrual period and two stages follow it. Stages -5 to -3 include the reproductive interval; stages -2 to -1 are termed the menopausal transition; and stages +1 and +2 are the postmenopause (Figure 13–14). The menopausal transition begins with increased variability in menstrual cyclicity (>7 days) in women with elevated FSH levels. This stage ends with the final menstrual period, which cannot be recognized until after 12 months of amenorrhea. Early postmenopause is defined as the first 5 years following the final menstrual period. Late postmenopause is variable in length, beginning 5 years after the final menstrual period and continuing until death.

This system is said to include endocrinologic aspects of ovarian aging, but it still depends largely on menstrual cyclicity as a key indicator of ovarian age. The system includes measurement of FSH; however, by the time FSH is elevated, even in the face of cyclic menstrual cycles, oocyte depletion has already proceeded to such an extent that fertility (as a marker of reproductive aging) is significantly diminished. Evidence suggests that genetic and environmental factors influence both age at menopause and the decline in fertility, although the specific nature of these relationships is poorly characterized. Premature menopause can be due to failure to attain adequate follicle numbers in utero or to accelerated depletion thereafter. Potentially, either of these causes could be affected by genetic and environmental factors. The timing of menopause has a consistent impact on overall health with respect to osteoporosis, cardiovascular disease, and cancer risk. Over the next decade, it is estimated that more than 40 million women in the United States will enter menopause.

**OOCYTE DEPLETION**

As discussed earlier, the leading theory regarding the onset of menopause relates to a critical threshold in oocyte number. The theory that menopause is primarily triggered by ovarian aging is supported by the coincident occurrence of follicular depletion, elevation of gonadotropins, and menstrual irregularity with ultimate cessation.

In 1992 Faddy and colleagues developed a mathematical model to predict the rate of follicular decline. They utilized data from
multiple sources to construct a model that ultimately showed a biexponential decline with an acceleration in oocyte loss beginning in the late thirties. More recently, Hansen et al. utilized newer technology and a single population of specimens. They fit the data to multiple models and found that a pattern of gradually increasing atresia fits the decline in nongrowing follicles (Figure 13-15). This same model most closely follows the decline in the antral follicles—small (2-10 mm) growing follicles seen on ultrasound—seen across the reproductive-age span (Figure 13-16). As noted earlier, the loss of follicles (oocytes) is a constant process beginning in utero and continuing throughout reproductive life, even during pregnancy and in the absence of ovulation, until approximately 1000 follicles/oocytes remain and menopause ensues.

**ENDOCRINE SYSTEM CHANGES WITH AGING**

The entire endocrine system changes with advancing age. The somatotropic axis begins to decline in the fourth decade, prior to the decline in ovarian function. This decline is accelerated in the face of ovarian failure and may act to accelerate the decline in

ovarian function. However, pituitary concentrations of GH as well as ACTH and TSH remain constant into the ninth decade. While the thyroid gland undergoes progressive fibrosis with age and concentrations of T₃ decline by 25% to 40%, elderly patients still remain euthyroid. Beta cell function also undergoes degeneration with aging such that by age 65 years, 50% of subjects have abnormal glucose tolerance tests. Frank diabetes is less frequent, however, occurring in approximately 7% of the population. The female reproductive system, on the other hand, undergoes complete failure at a relatively early age.

Secretion of reproductive hormones during the menopausal transition (MT) was previously thought to decline progressively in a linear fashion, but hormone levels have since been shown to fluctuate widely. Studies in large cohorts of women have demonstrated that circulating FSH concentrations rise progressively during the MT. The initial monotropic rise in FSH is attributed to a decrease in ovarian inhibin secretion rather than to a decrease in estradiol production.

Inhibin and activin are proteins produced by the granulosa cells and have been shown to play major roles during the MT. Inhibin consists of a covalently bound dimer with an α subunit and one of two different β subunits, designated as β₁ and β₂; the resulting heterodimers are known as inhibin A and inhibin B. Inhibin A is secreted by the corpus luteum and inhibin B by antral and dominant follicles. Consequently, inhibin A levels increase during the luteal phase, and inhibin B concentrations rise during the follicular phase. Both inhibins inhibit pituitary FSH secretion. Activins are a related class of proteins that stimulate pituitary FSH release. The activin molecule is a homodimer composed of two covalently linked inhibin β subunits, designated as activin A (βₐβₐ) and activin B (βₐβ₆).

AMH is also secreted by the granulosa cells of secondary and preantral follicles. Circulating concentrations remain relatively stable across the menstrual cycle and correlate with the number of early antral follicles. Levels of AMH decrease markedly and progressively across the MT to a time point approximately 5 years prior to the final period when levels are below the limit of detection.

During the late reproductive stage (stage -3), follicular phase inhibin B levels decrease as FSH concentrations rise. As the MT progresses, luteal phase inhibin A levels also decline. Activin A concentrations also are elevated in perimenopausal women. Whereas activins clearly play a local role in regulating pituitary FSH secretion, their ability to act as endocrine factors to influence the production of FSH has not been established. Thus, a decrease in secretion of inhibin A and inhibin B, and a corresponding increase in activin production may favor increased FSH secretion in the absence of any decrease (and perhaps an increase) in estradiol production.

**Estrogens/Progesterone**

The main circulating estrogen during the premenopausal years is 17β-estradiol. Levels of this hormone are controlled by the developing follicle and resultant corpus luteum. The fact that oophorectomy reduces peripheral estradiol levels from 120 to 18 pg/mL confirms that over 85% of circulating estradiol is derived from the ovary. In perimenopausal women, estradiol production fluctuates with FSH levels and can reach higher concentrations than those observed in young women under age 35. Estradiol levels generally do not decrease significantly until late in the MT. Estradiol levels may be quite variable, with chaotic patterns and occasionally very high or very low levels. This dramatic variability may lead to an increase in symptomatology during the perimenopausal years (stages -2 to -1). As peripheral gonadotropins rise, LH pulsatile patterns become abnormal. There is an increase in pulse frequency, with a decrease in GnRH inhibition by opioids. Despite continuing regular cyclic menstruation, progesterone levels during the early MT are lower than in women of mid-reproductive-age and vary inversely with body mass index. Women in the late MT exhibit impaired folliculogenesis and an increasing incidence of anovulation, compared to mid-reproductive-aged women. Essentially all estradiol in postmenopausal women is derived from peripheral conversion from estrone.

The predominant estrogen in the postmenopausal woman is estrone, with a biologic potency approximately one-third that of estradiol. The circulating levels of estrone (and estrone sulfate) in older women are approximately one-third to one-half of the concentration observed in women of reproductive age (Table 13–6). This is due to estrone production, resulting largely from peripheral aromatization of androstenedione (see earlier). This aromatase activity increases with aging by two- to fourfold and is further amplified by the increased adiposity that typically accompanies the aging process (see earlier). Estrone and estradiol production rates during the postmenopausal years are 40 and 6 μg/d, respectively. This compares with 80 to 500 μg/d for estradiol during the reproductive years.

**Androgens**

In contrast to estrogens, circulating androgens (DHEAS, androstenedione, and testosterone) decrease less dramatically after physiologic menopause. DHEAS undergoes a linear reduction with aging in both men and women (~2% per year starting at age 30), but there is no specific decline associated with menopause. Changes in DHEAS levels have been associated with alterations in body composition with aging. Androstenedione production

similarly decreases with aging, but the circulating levels are affected less because ovarian secretion is maintained, albeit at a reduced rate (see Table 13-6). Testosterone levels do not vary appreciably during the MT. Testosterone levels decrease after menopause. Historically it was believed the postmenopausal ovary produced a larger percentage of testosterone (50%) than did the premenopausal ovary. However, the literature is conflicting on the origin of androgens in postmenopausal women. The conventional view was that the adrenals, ovaries, and periphery all contributed to circulating androgen levels in postmenopausal women. Contemporary data suggest that androgen production after menopause is largely derived from adrenal precursors. This is supported by studies that have shown that postmenopausal women receiving dexamethasone suppression, who have women. Contemporary data suggest that androgen production after menopause is largely derived from adrenal precursors. This is supported by studies that have shown that postmenopausal women receiving dexamethasone suppression, or who have endogenous adrenal insufficiency, have undetectable levels of circulating androgens. Investigators have also demonstrated that the postmenopausal ovary has no appreciable enzymatic activities capable of generating sex steroids. The fact that women of reproductive age who undergo a bilateral oophorectomy have less testosterone and androstenedione than menopausal women with intact ovaries challenges this concept. However, the conflict may be explained by the hypothesis that the postmenopausal ovary produces androgens for a limited time.

Hypothalamic/Pituitary

Significant additional information regarding the hormonal changes during the menopausal transition is being developed in the multiethnic, community-based, longitudinal study of perimenopausal women at seven sites throughout the United States, The Study of Women’s Health Across the Nation (SWAN). While most attention has been devoted to the role of the ovarian and oocyte decline in the onset of menopause, new evidence suggests potential alterations in the hypothalamic-pituitary feedback system. In evaluating the ability of estradiol to stimulate an effective LH surge, data from SWAN suggest the MT is characterized by three distinct hormonal patterns: (1) estrogen rise with rise in LH but anovulation; (2) estrogen rise without a concomitant rise in LH; or (3) failure of rise in either estradiol or FSH. Additionally, there may be ethnic differences in the sensitivity of the pituitary to negative feedback.

**MENOPAUSAL CONSEQUENCES**

Given the endocrinologic changes associated with aging, many symptoms appearing in the aging female may be due to estrogen deficiency or diminished androgen or GH secretion. Disorders that are definitely due to estrogen deprivation include vasomotor symptoms and urogenital atrophy. Osteoporosis is also thought to be due largely to estrogen deficiency, and it may be exacerbated by the relative decline in GH levels. The same may be said for the hormone-related increase in the prevalence of atherosclerotic cardiovascular disease and psychosocial symptoms, including insomnia, fatigue, short-term memory changes, and possibly depression. Both DHEAS and GH may impact these phenomena as well. Most women who are symptomatic during the MT present with frequent or excessive bleeding or with hot flashes and other symptoms of estrogen deficiency. Other common symptoms during the MT include decreased libido, forgetfulness, vaginal dryness, and urinary incontinence.

Mood disorders also are increased during the MT. Community-based surveys have shown that perimenopausal women report significantly more psychological distress and have an increased risk for significant depression, compared with premenopausal or postmenopausal women. In an 8-year longitudinal study of perimenopausal women having no prior history of depression, a depressive disorder was more likely to be diagnosed during the MT than in the premenopausal years (OR, 2.5; 95% CI, 1.25-5.02, p = 0.01).

**Vasomotor Symptoms**

Vasomotor symptoms (hot flushes) are experienced with greatest frequency during stages −1 and +1, with about 75% to 85% of women complaining of this symptom. Although 80% of US women have symptoms lasting for at least 1 year, only 25% of women are still symptomatic at 5 years after the final menstrual period. Studies of hot flushes with external monitoring of skin temperature and resistance have shown a frequency of approximately 54 ± 10 minutes. In sleep studies, hot flush frequency has been shown to interrupt rapid eye movement sleep and may contribute to some of the psychosocial complaints. Hot flushes are temporarily correlated with pulses of LH, but exogenous LH does not induce a flush, suggesting that there is some central mediator leading to both the flush and the elevation in LH.

Sleep disturbances, most likely the result of vasomotor activity, also are very common during the MT. In longitudinal studies of perimenopausal women, the prevalence of sleep disturbances has ranged from 32% to 40% in the early MT and from 38% to 46% in the late MT.

Vasomotor symptoms during the MT can be treated with hormone therapy (HT) using estrogen or progestin alone or in combination, neuroactive agents, or other nonhormonal alternatives. Estrogen therapy provides the best treatment for severe vasomotor symptoms, reducing their frequency and severity in 80% to 85% of women over 12 weeks compared with 30% of women receiving placebo. Hormone therapy also may help in the management of depression associated with the MT. In a randomized, placebo-controlled, 12-week trial involving perimenopausal women ages 40 to 55, symptoms of depression were improved in 68% of women receiving unopposed estrogen treatment (0.1 mg transdermal estradiol patch), compared with 20% of those receiving placebo (p = 0.001).

Other drugs have been tried in women for whom estrogen is contraindicated, although none have the efficacy associated with ERT. These alternatives include transdermal clonidine, ergot alkaloids, and, more recently, selective serotonin reuptake inhibitors and gabapentin. High-dose progestins may also produce some relief.

**Genital Atrophy**

The vagina, vulva, urethra, and bladder trigone not only share embryonic proximity but all contain estrogen receptors. Atrophy
Cigarette smoking, caffeine usage, and alcohol consumption also increase the risk of osteoporosis. It is estimated that 15% of patients die within a year after a hip fracture, and the sites include the vertebrae and the long bones of the arms and legs. Coexisting disease also influences the development of osteoporosis. Based on studies, 2% per year compared with 3.9% per year following oophorectomy (see Chapter 8).

Secondary osteoporosis is caused by a specific disease (such as hyperparathyroidism) or medication usage (such as glucocorticoids) (see later), and local therapy by means of creams or vaginal rings may be advisable to limit systemic absorption. It should be noted, however, that vaginal absorption of steroids is quite efficient once estrogenization and revascularization have occurred. If the goal is to limit systemic absorption, slow-release rings may be superior to estrogen creams.

Vaginal estrogen frequently improves symptoms of urinary frequency, dysuria, urgency, and postvoid dribbling. Its direct effect to improve stress incontinence is less clear.

Osteoporosis

Osteoporosis is a condition in which bone loss is sufficient to allow fracture with minimal trauma. Major risk factors for the development of osteoporosis are the peak bone density attained in the late teens and early twenties (stress ing the importance of bone building in the young) and the rate of loss (accelerated with estrogen deficiency). Primary or senile osteoporosis usually affects women between the ages of 55 and 70 years. The most common sites include the vertebrae and the long bones of the arms and legs. Secondary osteoporosis is caused by a specific disease (such as hyperparathyroidism) or medication usage (such as glucocorticoids) (see later). Menopausal bone loss begins before the final menstrual period during stage -1. Postmenopausal osteoporosis causes over 1.3 million fractures annually in the United States. Most of the more than 250,000 hip fractures are due to primary osteoporosis, and—given that 15% of patients die within a year after a hip fracture and 75% of patients lose their independence—the social costs, not to mention the financial costs, are great.

Bone loss following natural menopause is approximately 1% to 2% per year compared with 3.9% per year following oophorectomy. A woman's genetic background, lifestyle, dietary habits, and coexisting disease also influence the development of osteoporosis. Cigarette smoking, caffeine usage, and alcohol consumption also negatively affect bone loss, whereas weight-bearing activity appears to have a positive influence. See Chapter 8 for a detailed discussion of bone and mineral metabolism and osteoporosis.

A. Osteoporosis treatment

1. Estrogen therapy—Estrogen therapy acts via the inhibition of bone resorption. Both BMD and fracture rate are improved with estrogen therapy. However, with cessation of estrogen therapy, there is a rapid and progressive loss of bone mineral content. By 4 years after therapy, bone density is no different from that of patients who were never treated with estrogen. Estrogen is approved for prevention of osteoporosis, and there is also some support for its usage as a treatment modality in established disease. Dosages of 0.625 mg of conjugated estrogens orally daily—and, more recently, as low as 0.3 mg—have been shown to slow bone loss and provide adequate protection against the development of osteoporosis. Higher dosages may be required to treat existing disease.

2. Alternative therapies for osteoporosis

a. Calcitonin—Calcitonin is a hormone normally secreted by the thyroid gland. Calcitonin (salmon) is available as a nasal spray specifically developed to decrease local side effects caused by subcutaneous injection. Although few studies have been performed and no data are available regarding reduction in hip fracture, it does seem to be especially beneficial for women with a recent and still painful vertebral fracture. Intranasal calcitonin has also been shown to improve spinal bone density and decrease the vertebral fracture rate in established osteoporosis. The increase in bone density appears to peak in as little as 12 to 18 months. The waning effects of calcitonin therapy over time may be due to downregulation of calcitonin receptors on osteoclasts and/or the development of neutralizing antibodies.

b. Bisphosphonates—These compounds are analogs of pyrophosphates and have a high affinity for hydroxyapatite in bone matrix. The basic structure of bisphosphonates allows a large number of manipulations of the basic molecule, producing different types of bisphosphonates that vary considerably in their potency on bone. In order of increasing potency are pamidronate, alendronate, risedronate, ibandronate, and zoledronic acid.

Alendronate has been evaluated extensively in patients with osteoporosis. Alendronate has been shown to inhibit markers of bone remodeling and increase BMD at the lumbar spine, hip, and total body and reduces fracture risk. Alendronate is taken orally; the recommended doses are 70 mg once weekly or 10 mg daily; alendronate must be taken according to a strict dosing schedule (in the morning on an empty stomach, with the patient required to remain upright for 30 minutes thereafter). The medication has very poor bioavailability (approximately 1%), and for that reason these instructions must be meticulously obeyed. Alendronate also has a propensity for causing irritation of the esophagus and stomach, especially in women with preexisting esophageal reflux, gastric or duodenal disease. Risedronate is similarly effective in the dosage of 35 mg weekly or 5 mg once daily, and the same dosing regimen is recommended. Ibandronate has the easiest schedule for administration 150 mg once monthly.

Increases in bone density with alendronate, risedronate, and ibandronate are greater than what is seen with calcitonin and similar to what is seen with HRT. The escape phenomenon seen with calcitonin is not seen with these oral bisphosphonates.

The final issue concerning long-term administration of bisphosphonates relates to their long half-lives in bone and their incorporation into the bone matrix. Although short-term fracture data appear favorable, the long-term effects of these agents on fracture incidence have never been assessed.

c. SERMs—Raloxifene is the first selective estrogen receptor modulator (SERM) approved for prevention and treatment of osteoporosis and for the prevention of breast cancer. SERMS act selectively as estrogen receptor agonists in some tissues (bone and heart) and antagonists in others (breast and uterus and possibly brain). Data with raloxifene show...
preservation of BMD, albeit less well than that seen with alendronate, risedronate, ibandronate, or HRT, and spinal fracture data support a protective effect.

It is believed that the differential effects of estrogens and antiestrogens are related to the transcriptional activation of specific estrogen response elements. Two different domains of the estrogen receptor (AF-1 and AF-2) are responsible for this transcriptional activation. Estrogens and antiestrogens appear to act via different domains, leading to their differential effects. Both act to maintain bone density—at least partially—via regulation of the gene for TGF-β.

d. Calcium and vitamin D—These are critical adjuvants for any type of antiresorptive therapy. Decreased ability to absorb calcium among older women is due in part to impaired vitamin D activation and effect. Older women may have limited exposure to sunlight, and their dietary vitamin D intake may be lower than that of younger women.

Daily intakes of 1000 to 1500 mg of calcium and 800 to 1200 IU of vitamin D are probably sufficient to reduce the risk of fragility fractures by 10% or more.

e. Anabolic therapy—The first anabolic therapy for the treatment of severe osteoporosis parathyroid hormone (1-34) or teriparatide has been approved for clinical use. Details about its efficacy and use in advanced postmenopausal osteoporosis are described in Chapter 8.

Atherosclerotic Cardiovascular Disease

Cardiovascular disease is the number one cause of mortality in both men and women in Western societies. This is largely attributed to age and lifestyle. Lifestyle modifications are known to decrease the incidence of atherosclerotic cardiovascular disease. For women, cardiovascular disease is largely a disease of the postmenopause. Women now spend more than a third of their lives in the postmenopausal years, and preventive measures are thus of paramount importance. Although a large body of observational evidence supported a protective effect of ERT on cardiovascular disease, observational data are limited by the confounding variables of patient self-selection. Animal and in vitro studies, as well as assessment of surrogate markers in women, have shown a positive effect of ERT and HRT against cardiovascular disease development. However, several large randomized, controlled studies have failed to support a protective role for HRT in preventing cardiovascular events.

One of the first such trials was the Heart and Estrogen-Progestin Replacement Study (HERS), a secondary prevention trial that evaluated the use of daily HRT (0.625 mg conjugated estrogens plus 2.5 mg medroxyprogesterone acetate [MPA]) in 2763 postmenopausal women with a mean age of 66.7 years and preexisting vascular disease. The study failed to demonstrate any overall difference in vascular events. This occurred despite improvements in lipid parameters in those patients receiving HRT. The Estrogen Replacement and Atherosclerosis (ERA) Trial compared 3.2 years of treatment with estrogen, combined estrogen and progestin, and placebo in postmenopausal women aged 42 to 80 years. It also failed to demonstrate a significant difference in the rate of progression of coronary atherosclerosis between the three groups. The importance of this study was the inclusion of an estrogen-only arm.

The Women's Health Initiative (WHI) was the first large randomized study to look at primary prevention of cardiovascular disease. This study compared (1) the combination of conjugated equine estrogen (CEE) and MPA with placebo and (2) CEE to placebo. It was designed to assess the overall risks and benefits of HRT in a prospective randomized fashion.

The WHI demonstrated that there was an unacceptable risk profile for the combination HRT arm of the trial. There was an increase in the incidence in breast cancer (an increase of 8 cases per 10,000 women) with no cardiovascular protection (and potentially increased cardiovascular risk). There was, in fact, an increase in venous thromboembolism, strokes, and coronary heart disease. The risk of stroke and thromboembolism continued for the 5 years of study, whereas most of the coronary heart disease was limited to the first year of treatment. There were, however, documented decreases in the risk of fracture and colon cancer.

In the CEE-only arm, there was an increased risk of stroke and a decreased risk in hip fractures compared to placebo. This study showed that the use of ERT had no protective effect on coronary heart disease. Interestingly, there appeared to be a trend toward a reduction in breast cancer (0.77, CI 0.59-1.01) with use of ERT. More recent studies and reevaluation of large datasets have suggested that combined estrogen/progestin has a more profound increased risk on breast cancer, than estrogen alone or cyclic progestins, consistent with increase in mitogenic activity of the breast during the normal luteal phase when progesterone levels are high.

Treatment—Summary

As noted earlier, long-term use of HT in older menopausal women has been associated with increased risks for venous thromboembolism, coronary events, stroke, and breast cancer. Although short-term treatment of symptomatic women during the MT likely poses significantly fewer risks, HT generally should be used in the lowest effective dose and for the shortest time required. Data suggest the use of HT does not increase the risk of breast cancer, on a yearly basis, more than would continuing spontaneous cycles for any given age. This suggests treatment of symptomatic women in their forties may not increase breast cancer risk over normal cycling. Low-dose estrogen regimens (conjugated equine estrogens, 0.3 mg daily, or its equivalent) can achieve as much as a 75% reduction in vasomotor symptoms over 12 weeks, approaching the efficacy of standard-dose HT regimens, and may be associated with fewer risks and side-effects. The decision to use HT should be made only after first carefully reviewing its risks and benefits for the individual.

The relative safety of HT during the MT has not been thoroughly investigated. The results of one observational study have suggested that women who start HT near menopause had a decreased risk of coronary heart disease when taking estrogen alone (relative risk [RR] = 0.66; 95% CI, 0.54-0.80) or in combination with progestin (RR = 0.72; 95% CI, 0.56-0.92). A secondary analysis conducted by the investigators involved in the WHI revealed that risk for coronary heart disease was not significantly increased in women under age 60 years of age or within 10 years of menopause. Further studies to evaluate the
Concerns about the risks of HT have increased interest in non-hormonal alternatives for the treatment of symptoms in the MT. In some women, vasomotor symptoms during the MT can be reduced by wearing layered clothing, avoiding caffeine and alcohol, and by keeping the ambient temperature a few degrees cooler. Herbal treatments such as black cohosh (Remifemin Menopause; Enzymatic Therapy, Green Bay, WI) have been shown to have marginal or no benefit in placebo controlled trials. Neuroactive agents, including selective serotonin reuptake inhibitors (SSRIs), serotonin-norepinephrine reuptake inhibitors (SNRIs), alpha adrenergic agents, and others all have some efficacy in the treatment of vasomotor symptoms (Table 13-7). Both SSRIs and SNRIs may be effective because norepinephrine and serotonin appear to be involved in the hypothalamic regulation of temperature homeostasis and to play a role in the development of hot flashes. Randomized placebo-controlled trials have shown that SSRIs (citalopram, sertraline, paroxetine) and SNRIs (venlafaxine) can help to reduce the severity and frequency of hot flushes. Clonidine (an alpha adrenergic agonist) and gabapentin also have some efficacy. Gabapentin is the only agent compared head-to-head with estrogen suggesting equivalent efficacy when used in high doses.

The WHI study did not address the effect of hormone treatment on hot flushes and vaginal atrophy. Clearly, there are alternatives for the treatment of osteoporosis and cardiovascular disease that are superior if prevention of both conditions is the sole reason for HRT. Every woman should discuss with her caregiver the optimal management for her as an individual. This should take into account medical and family history as well as symptomatology. It can be uniformly recommended, however, that menopausal women maintain appropriate nutrition, weight reduction, and exercise along with moderation in alcohol and caffeine intake and cessation of smoking.

### INFERTILITY

Infertility is defined as the inability of a couple to conceive after 1 year of frequent unprotected intercourse without contraception. This definition is based on observational data showing that approximately 85% of couples achieve pregnancy after 1 year of unprotected coitus. Using this definition, approximately 15% of reproductive-age couples experience infertility. However, the diagnosis of infertility does not mean that they cannot conceive—a more precise diagnosis term would be subfertility, or a diminished capacity to conceive. The actual probability of the fertility potential of a population may be better assessed with variables that can quantify a monthly cycle rate. The concepts that have been used for quantitative analysis are fecundability and fecundity. Fecundability is defined as the probability of achieving a pregnancy within one menstrual cycle, and in normal couples the chance of conception after 1 month is approximately 25%. Fecundity is a related concept that is defined as the ability to achieve a live birth within one menstrual cycle.

In the United States, demands for infertility treatment have dramatically increased. The 1995 National Survey of Family Growth reported that 9.3 million women received infertility treatment in their lifetime compared with 6.8 million in 1988. This rise in treatment is due not only to increased public awareness—it also reflects the significant demographic, societal, and economic changes in our society. These include the aging of the baby boom generation, which has increased the size of the reproductive-age population. Perhaps more important is the increased use of contraception and postponement of childbearing until the last two decades of a woman’s reproductive life. Approximately 20% of women in the United States now have their first child after 35 years of age.

Age alone has a significant impact on fertility and affects a woman many years before the onset of menopause. One factor is the age-dependent loss of ovarian follicles (see later). A 38-year-old woman has 25% of the fecundability of a woman under 30 years of age. Another age-related subfertility factor is that the spontaneous abortion rate increases with advancing age. The overall incidence of clinical abortion increases from 10% in women under age 30 to more than 40% in women over 40. The increased pregnancy loss can be largely attributed to abnormalities in the aging oocyte; older follicles have an increased rate of meiotic dysfunction, resulting in higher rates of chromosomal abnormalities.

The main causes of female subfertility can be classified in the following way: (1) ovulatory defects, (2) pelvic disorders, and (3) male factors. These factors account for 80% to 85% of couples diagnosed with infertility. They are not mutually exclusive—about 15% of couples have more than one cause of subfertility. In approximately 20% of couples, the cause remains unknown and is classified as unexplained infertility. This section will briefly discuss the causes of subfertility and review the diagnosis and management.

### DIAGNOSIS OF INFERTILITY

#### Ovulatory Defects

Ovulatory disorders are responsible for 25% of cases of infertility. Ovulatory status can be obtained from the history. If a woman experiences cyclic, predictable menses at monthly intervals, ovulation can be predicted 98% of the time. This is not an invariable rule, however, and irregular menstrual cycles are not a sure sign of anovulation.
The only way to confirm ovulation is by achieving pregnancy. However, a variety of methods can indicate that ovulation has occurred. For example, a thermal shift occurs around the time of ovulation. Prior to ovulation, morning basal body temperature (BBT) is below 98°F (36.7°C), and after ovulation the temperature increases at least 0.4°F (0.2°C) for at least 1 to 3 days. This rise in temperature reflects the progesterone that is secreted from the corpus luteum, which consequently raises the hypothalamic set point for BBT. The temperature rise occurs approximately 2 days after ovulation because of the time and dose required for the progesterone effect at the hypothalamus. BBT can therefore not be utilized to prospectively predict ovulation. Measurements of midluteal serum progesterone concentration can also be performed to document the occurrence of ovulation. If this level is greater than 3 µg/L (9.5 nmol/L), it is a strong indication that ovulation has occurred. An endometrial biopsy can confirm ovulation. It is performed during the luteal phase and gives a qualitative assessment of ovulation, because the duration of progesterone exposure produces predictable endometrial histology. Lastly, a sonographic examination documenting a decrease in follicle size—or disappearance altogether of the previously developed follicle—is suggestive of ovulation. All of these methods indicate that ovulation has occurred.

There are only a few ways to predict that ovulation is going to occur. The most common way is to detect the LH surge. Ovulation typically occurs 34 to 36 hours after the onset of the LH surge.

Although ovulation may occur, some women may have a luteal-phase defect. This is characterized by an inadequate quantity or duration of progesterone secretion by the corpus luteum. There is a distinct window of time for implantation. The theory is that the progesterone deficiency desynchronizes ovulation (egg) and implantation (endometrium). However, the incidence of luteal phase defects is difficult to assess because the definition is not standardized. Typically, the diagnosis is established by luteal phase endometrial dating; if the histologic development of the endometrium lags more than 2 days beyond the day of the cycle, it is diagnostic of a luteal phase defect. However, up to 30% of women with normal cycles meet this criterion. Another method involves measuring midluteal progesterone levels. If progesterone is less than 10 ng/mL, it suggests a luteal phase defect. This is not reliable because progesterone is intermittently secreted, and the serum progesterone level can change from 1 hour to the next in the same individual. Furthermore, the lack of properly validated tests places the existence of luteal phase defects and their association with subfertility in question. Lastly, as empiric treatment for unexplained infertility has developed, delaying treatment (see later: superovulation with IUI) for exact diagnoses has less importance. More sophisticated testing of endometrial proteins required for implantation (eg, integrins, glycodelin) may revive enthusiasm for making a specific diagnosis in the future.

The cause of ovulatory dysfunction has been previously discussed. All anovulatory patients should have determination of PRL and TSH levels—and, if necessary, androgen levels—to identify the cause of the ovulatory disturbance. Treatment should be directed toward the cause, which is discussed in greater detail later. It could be argued that all patients should have evaluation of early follicular cycle (days 2-4) FSH, LH, and estradiol to assess ovarian reserve (age).

### Pelvic Disorders

Pelvic disorders account for more than 30% of couples with the diagnosis of infertility. Uterine tube damage and adhesion formation are responsible for most pelvic pathologic processes causing infertility, whereas endometriosis is the primary pelvic disorder causing subfertility. The causes of tubal damage and adhesions include postinfectious state (pelvic inflammatory disease [PID]), endometriosis, and a history of pelvic surgery (especially surgery for ruptured appendicitis).

PID is defined as infection of upper genital tract structures and is usually caused by a sexually transmitted disease. The known initiating organisms are chlamydiae and Neisseria gonorrhoeae. The symptoms are variable but usually include lower abdominal pain, nausea, and vaginal discharge. However, in up to 30% of chlamydial infections, PID may be clinically inapparent and may remain undiagnosed until presenting with subfertility.

Endometriosis is the presence of endometrial glands and stroma outside of the uterus. There may be no manifestations other than infertility, or symptoms may progress to include severe pelvic pain, dysmenorrhea, and dyspareunia. The diagnosis is suspected if findings on surgical exploration show characteristic lesions. Lesions can be staged according to published criteria. Diagnosis is confirmed with biopsy of the peritoneal lesions. The disease occurs in approximately 3% to 10% of reproductive-age women and may be responsible for up to 25% to 35% of the female factors responsible for subfertility.

The pathogenesis of endometriosis is not completely known. A prominent theory (Sampson) involves retrograde menstruation. It is well established that menses can flow through the uterine tubes into the abdominal cavity. In fact, this phenomenon is thought to occur in almost all menstruating women. There is good evidence that the endometrial tissue subsequently invades and proliferates into the peritoneum. It is theorized that the immune system should normally dispose of the tissue and that altered immunity may result in implantation of this endometrial tissue outside the uterus in those women who subsequently develop endometriosis.

There is a strong association between adhesive disease and endometriosis. In these cases, the cause of subfertility is a result of distorted anatomy and consequently altered function. However, in mild cases of endometriosis, where only peritoneal lesions are identified and no anatomic distortion exists, the cause of infertility remains uncertain and controversial. There is evidence that the peritoneal fluid is altered in the presence of endometrial tissue with increased macrophages and inflammatory mediators. Several studies suggest that inflammatory changes result in adverse effects on folliculogenesis, ovum transport, fertilization, and implantation.

Tubal damage can be diagnosed with a hysterosalpingogram or surgical exploration. Hysterosalpingography involves the introduction of radiopaque contrast media into the pelvis through the cervix and then fluoroscopy, revealing an outline of contrast in the uterine cavity, uterine tubes, and peritoneal cavity. The diagnosis
of pelvic endometriosis can only be made by surgery, and most often the surgical procedure is laparoscopy. Diagnostic laparoscopy is usually done when there is a high suspicion of endometriosis based on the clinical history or adhesive disease based on a history of PID or pelvic surgery. Laparoscopy may also be performed, if all other tests are normal and the couple continues not to achieve a pregnancy.

**Male Factor Causes**

The male factor contributes in 40% to 50% of cases of diagnosed infertility, and all evaluations should include the male partner. The diagnostic test for male factor infertility is the semen analysis. Although this is a largely descriptive test (volume, sperm count, motility, and morphology), there is some correlation with pregnancy outcome. This should be used solely as a screening test. To understand the pathophysiology of male factors, it is important to review the physiology of spermatogenesis and the anatomy of the male reproductive tract as described in Chapter 12.

**Unexplained Infertility**

Approximately 15% to 20% of the couples diagnosed with infertility have no identifiable cause after a full investigation. The workup should include documentation of ovulation (regular menstrual cycles, progesterone levels, or LH testing), hysterosalpingography to verify patent fallopian tubes, and a semen analysis. The term unexplained implies that there is a potential explanation for the subfertility, but the cause has yet to be identified. The cause may be subtle abnormalities in folliculogenesis, sperm-ovum interactions, or defective implantation.

Several studies have evaluated the natural history of unexplained infertility. It is estimated that fecundity in younger couples (female partner under the age of 40) with unexplained infertility is 3% to 5% compared with 20% to 25% in the age-matched couples with normal fertility. Treatment involves methods that increase fecundability and are discussed later.

**MANAGEMENT OF THE INFERTILE COUPLE**

It is important to remember that in most couples, there is a chance for spontaneous conception. Recent studies estimate that the average probability for live birth without treatment is 25% to 40% during the 3 years after the first infertility consultation. This translates into a cycle fecundity rate of 0.7% to 1% per month. The presence of endometriosis, abnormal sperm, or tubal disease independently reduces the chance of spontaneous pregnancy and live birth by approximately 50% for each variable. Infertility for more than 3 years, female age over 30 years, and primary infertility were important negative prognostic factors.

Evaluation should focus on known causes of infertility or subfertility: ovulatory defects, pelvic disorders (tubal disease, endometriosis), and male factor issues.

**Ovulatory Disorders**

Treatment should be diagnosis-specific, if possible. For the female, this means that the cause of any ovulatory defect should be determined and specific treatment then instituted. This enhances outcome and decreases the risk of complications (spontaneous abortion and multiple gestation). This treatment may include the use of dopamine agonists (hyperprolactinemia), thyroid replacement (hypothyroidism), pulsatile GnRH (hypogonadotropic hypogonadism), or clomiphene citrate (for PCOS). The most common cause of anovulation is inappropriate feedback such as in PCOS. Ovulation in patients with PCOS can be induced with clomiphene citrate, a nonsteroidal agonist-antagonist of estrogen that blocks the hypothalamic-pituitary axis from feedback by circulating estrogens. As a result, there is increased gonadotropin release to stimulate follicular recruitment and ovulation. In addition, because PCOS is associated with insulin resistance, and elevated insulin directly has an impact on the ovary, insulin sensitizers such as metformin have been used to enhance ovulatory response in women with PCOS. Recently, a large multicenter randomized trial compared clomiphene to metformin and found clomiphene to be significantly more effective for ovulation induction and achieving a live birth.

**Pelvic Disorders**

In general, adhesive tubal lesions should be treated surgically. The location and extent of disease should, however, be evaluated. Patients with distal tubal occlusion—unless it is very mild—are most often better served by assisted reproduction (in vitro fertilization [IVF]). Other possible causes of infertility should also be examined. If a patient has a history of documented tubal disease, in addition to other abnormalities (ovulatory dysfunction or male factor infertility), or if they are over 35, the likelihood for successful surgical management decreases by approximately 50%, and consideration for avoiding surgery and moving directly to assisted reproduction is paramount. The exception to this rule is documentation of hydrosalpinges on ultrasound. The presence of hydrosalpinges that retain fluid when nondistended (ie, not seen only with hysterosalpingography) leads to a significant reduction in outcome with assisted reproductive therapy (ART). Prior removal or proximal occlusion of the tube to prevent contamination of the uterine cavity should be performed before ART is offered.

There are conflicting data in the literature concerning the appropriate treatment for mild endometriosis. A well-designed randomized trial from Canada evaluated the effect of surgical treatment on pregnancy outcome for patients diagnosed with mild endometriosis without anatomic distortion. It showed that pregnancy rates at 9 months postlaparoscopy were 27% in the surgically treated group compared with 18% in the untreated group. Severe endometriosis (disease that alters the pelvic anatomy or involves the ovary with endometriomas) should be surgically treated to restore normal pelvic anatomy. There appears to be no advantage to medical therapy for endometriosis in women seeking fertility.
Male Factor Infertility

Male factor infertility is discussed in Chapter 12. Like female partner treatment, therapy should be targeted, if possible, toward the cause of subfertility. Obstructive disease may be treated surgically. A prominent varicocele with a stress pattern on semen analysis (decreased motility with an increase in abnormal morphology) may suggest a need for surgical repair. Any endocrinologic abnormalities (while less common in the male) should be treated (e.g., prolactinoma). Unfortunately, beyond this point, most treatments require a combined approach very similar to that discussed below for unexplained infertility.

Unexplained Infertility

The treatment of unexplained infertility can be frustrating for the physician and the patient because the recommendations for therapy are not targeted toward a specific diagnosis. Although there are very limited evidence-based data to guide treatment, therapy should be directed toward increasing the fecundability rate. The two main treatments are superovulation plus intrauterine insemination (IUI) and IVF.

Supervovulation methods are designed to qualitatively improve the cycle and to hyperstimulate the ovary with rescue of more follicles (quantitative improvement). Administration of clomiphene citrate or of gonadotropins alone can be used for superovulation. However, higher success rates are observed when superovulation is combined with IUI of washed sperm (Table 13–8). IVF provides a higher fecundability rate. However, these procedures are significantly more costly and more invasive, and they should only be used after a trial (three or four cycles) of superovulation and IUI has failed. With older patients, aggressive therapy should be considered earlier in the treatment effort.

CONTRACEPTION

Approximately 50% of all pregnancies in the United States are unplanned. In adolescents and in women of older reproductive age, the unplanned pregnancy rate is higher, approaching 82% and 77%, respectively. This equates to 3.5 million unplanned pregnancies in the United States per year. The advent of oral contraceptives has meant that women have been able to postpone childbearing. However, approximately 50% of unplanned pregnancies are due to contraceptive failures. Possible causes of failure include lack of education, poor compliance, and side-effect profiles. In this section, we discuss the different methods of hormonal contraception. We shall discuss also the target population for the various modalities of contraception and their mechanisms, side-effects, and ways to decrease failure rates. At the end of the section, emergency contraception will be discussed briefly.

ORAL CONTRACEPTIVES

Combination Pills

In the United States, oral contraceptive pills are the most widely used method for contraception. There are two types of oral contraception: combination pills and progestin-only pills. The various hormones used in birth control pills are illustrated in Figure 13–17.

The development of oral contraceptive agents began with the isolation of progesterone. However, progesterone was very expensive and difficult to isolate. Ethisterone, a derivative of an androgen, was found to have progestin activity and was much easier to isolate than progesterone. With removal of carbon 19, the progestational activity was increased, and the new compound was termed norethindrone. When this hormone was administered to women, ovulation was inhibited. During the process of norethindrone purification, an estrogen contaminant was found. When this contaminant was removed, women would experience breakthrough bleeding. The estrogen was added back, thereby creating the first-generation combination birth control pill, which was approved by the Food and Drug Administration (FDA) in 1960.

Oral contraceptives can be divided into generations based on dose and type of hormone. The first-generation birth control pills contained more than 50 µg of ethinyl estradiol or mestranol and a progestin. The adverse events associated with high-dose estrogen, such as coronary thrombosis, led to development of the second-generation pill, which contained less than 50 µg of

ethinyl estradiol and progestins other than levonorgestrel derivatives. Next, attention was directed toward the progestin, which was thought to have adverse androgenic effects such as affecting lipid profiles and glucose tolerance. This led to the development of third-generation pills that contained both a lower dose of estrogen (20-30 μg of ethinyl estradiol) and newer progestins (gonanes: desogestrel or norgestimate). Indeed, studies have demonstrated a reduction in metabolic changes associated with these progestins, but limited data are available to show any actual reduction of cardiovascular events. Another recently developed progestin, drospirenone, has antimineralocorticoid and antiandrogenic activity in addition to its pharmacologic progestational effects. As an analog of spironolactone rather than androgen, it competitively binds to aldosterone receptors, and it may counteract the estrogen stimulation of the renin-angiotensin system, resulting in more weight stability and less water retention. A new combination oral contraceptive, Yasmin, which contains 3 mg drospirenone and 30 μg ethinyl estradiol, has been approved by the FDA and is prescribed for women with hyperandrogenism or other side-effects attributable to oral contraceptives. However, the relative antiandrogenic activity of drospirenone is small compared with cyproterone acetate or the therapeutic dose of spironolactone used for the treatment of hirsutism.
Contraceptives can be classified also based on formulas or schedules of administration. The theory behind phasic preparations was to further decrease the amount of total progestin administered in an attempt to reduce metabolic changes attributed to the progestin, thereby decreasing adverse effects. The traditional monophasic pill (eg, Loestrin) contains 30 μg of ethinyl estradiol and 1.5 mg of norethindrone. This dose is given every day for 3 weeks with a 1-week hormone-free interval. The progestin dose remains constant throughout the cycle. The second type is the biphasic pill (eg, Ortho-Novum 10/11), which contains 35 μg of ethinyl estradiol and either 0.5 or 1 mg of norethindrone. The 0.5 mg of norethindrone is administered in the first 10 days of the month, and the 1 mg is administered for the following 11 days. The last 7 days of the cycle are free of hormone. With this combination, there was a theoretical increase in breakthrough bleeding and an increased pregnancy rate. A meta-analysis revealed no difference, but limited data were available.

Because of concerns that this regimen might result in both breakthrough bleeding and pregnancies, another phasic formulation was developed. The triphasic pills (eg, Triphasil, Ortho-Novum 7/7/7) contain 0.5, 0.75, and 1 mg norethindrone combined with 35 μg ethinyl estradiol. Theoretically, this formulation improves cycle control. There are several other regimens, some of which alter estrogen doses to simulate the estrogen cyclic rhythm (Triphasil-30, Triphasil-40, Triphasil-30 μg ethinyl estradiol) and possibly decrease breakthrough bleeding. A meta-analysis comparing biphasic versus triphasic pills revealed that triphasic pills significantly improved cycle control. However, the progestins in each pill tested were different, and this could account for better cycle control rather than the phasic formulation. An additional meta-analysis was performed on triphasic versus monophasic pills to assess cycle control and metabolic effects. This analysis revealed no difference between the formulations. Therefore, there is little scientific rationale for prescribing phasic preparations in preference to the monophasic pill.

The pharmacologic activity of progestins is based on the progestational activity and bioavailability of each progestin as well as the dose. The relative potencies of the different progestins are levonorgestrel greater than norgestrel greater than norethindrone. The active estrogen component of oral contraceptives is ethinyl estradiol (even if mestranol is administered).

When the hormones are administered for 21 days of the cycle, there is enough progestin to inhibit rapid follicle growth for about 7 more days. Figure 13–18 demonstrates that during the steroid-free interval there is no rise in estrogen, indicating no follicular maturation. It is likely that pills missed after this time are responsible for some of the unintended pregnancies. Therefore, it is important that this interval not be extended.

Pharmacologic doses of progestin inhibit ovulation by suppressing GnRH pulsatility and possibly inhibiting release of pituitary LH. Progestins also impair implantation and produce thick, scanty cervical mucus that retards sperm penetration. These latter methods play a minor role in the mechanism of oral contraception.

Ethinyl estradiol helps prevent the selection of a dominant follicle by suppressing pituitary FSH. In addition to FSH suppression, ethinyl estradiol provides stability to the endometrium,
FIGURE 13-18 Progestin effects on steroidogenesis and ovulation. (Reproduced, with permission, from Brenner PF, et al. Serum levels of d-norgestrel, luteinizing hormone, follicle-stimulating hormone, estradiol and progesterone in women during and following ingestion of combination oral contraceptives containing d-norgestrel. Am J Obstet Gynecol. 1997;129:133.)

A randomized trial comparing continuous oral contraception with the traditional cyclic method revealed a significantly greater incidence of erratic bleeding with (overall) the same number of days of bleeding, albeit with a reduced volume of bleeding. New formulations have been developed for those who do not desire cyclic bleeding. This regimen involves 84 days of continuous hormone administration followed by a steroid-free interval of 1 week. This can easily be done with the traditionally packaged oral contraceptive pills.

A routine for daily administration improves compliance and contraceptive efficacy. Failure to take the pill at the same time every day and not understanding the package insert are associated with missing two or more pills during the cycle. To decrease failure rates, women should understand that if they forget to take the pill, they must use barrier prophylaxis.

Postpartum women who are not breast-feeding may begin combination oral contraceptives 3 weeks after delivery. For women who are breast-feeding, it is advised that institution of combination oral contraceptives be delayed until 3 months postpartum. The recommendation for this delay is due to decreased
milk letdown secondary to estrogen but may be waived once lactation is well established.

Noncompliance increases the incidence of unwanted pregnancies. Appropriate use of birth control is achieved 32% to 85% of the time in the general population. Teenagers have at most a 50% continuation rate, and 25% of pill users discontinue the practice in the first year. The efficacy of the oral contraceptive under conditions of perfect use is 0.1 failures per 100 woman-years (0.1 per 100 users). With typical use, the failure rate is 3%, with first-year failure rates approaching 7.3% to 8.5%. Side-effects contribute to noncompliance. The most common side-effect is breakthrough bleeding. Other unwanted symptoms include bloating, breast tenderness, nausea, and possibly headaches, weight gain, and depression. Some studies suggest that altering estrogen doses may improve symptoms. Failure rates may also be associated with concomitant use of drugs (eg, rifampin, hydantoins) that accelerate hormone metabolism.

### A. Other benefits

There are noncontraceptive benefits to the pill. These include reduced monthly blood loss (less iron deficiency) and less dysmenorrhea as well as reduced benign breast disease and mastalgia. Oral contraceptives also reduce the incidence of PID and ectopic pregnancies. Other significant benefits include a reduction in risk of ovarian cancer, endometrial cancer, and colorectal cancer. Oral contraceptive use also has cosmetic benefits; it can improve excess hair growth and acne (see PCOS). It is not unusual for the pill to be administered for noncontraceptive problems.

### B. Potential risks

In general, oral contraceptives have proved to be safe for most women, but the possibility of adverse effects has received much attention. Unfortunately, the literature is full of conflicting reports. Data concerning controversial adverse effects will be discussed in the following section.

Although the estrogen in combination oral contraceptives tends to increase triglycerides and total cholesterol, these levels are still within the normal range, and the contraceptives appear to increase HDL and decrease LDL. Progestins attenuate these effects, which suggest an adverse metabolic milieu. Although it is known that low HDL-LDL ratios are associated with cardiovascular events, the importance of lipid changes associated with birth control pills is unknown. To date there is no strong evidence of an increased incidence of myocardial infarctions in healthy nonsmoking oral contraceptive users. In patients with other cardiovascular risk factors such as hypertension—at least in Europe—there is an up to 12-fold increased risk of cardiovascular events. Women who are over 35 years of age and who smoke are at increased risk of cardiovascular events. This risk is amplified with use of the birth control pills. If more than 15 cigarettes per day are smoked, there is a relative risk (RR) of 3.3 for a cardiovascular event, compared with an RR of 20.8 with concomitant use of oral contraceptives. However, if a woman smokes fewer than 15 cigarettes per day, there is an RR of 2.0 for a cardiovascular event, compared with an RR of 3.5 with concomitant contraceptive use. Former smokers after 1 year have no significant increased risk. First-generation oral contraceptives (>50 µg ethinyl estradiol) imposed an RR for stroke (ischemic or hemorrhagic) of 5.8. With low-dose agents (<50 µg ethinyl estradiol), there appears to be no significant increased risk of stroke among healthy normotensive nonsmoking women. The RR associated with hemorrhagic stroke for hypertensive women is 10.2 to 14.2. Because the potential exists for adverse outcomes, women taking oral contraceptives should be screened regularly for cardiovascular risk factors to ensure safe administration.

The risk of deep vein thrombosis and pulmonary embolism is increased twofold to threefold with administration of the pill. The mechanism by which oral contraceptives enhance venous thrombosis is unknown, but there may be estrogen-related changes in coagulation parameters. These include increased clotting factors and activation of platelets and a decrease in protein S and fibrinolytic activity. However, these changes in measured serum clotting factors do not predict the occurrence of deep vein thrombosis. Genetic thrombophilias increase the risk of venous thrombosis. The prevalence of factor V Leiden in the general population is 5%. The incidence of deep vein thrombosis among this population is 60 per 100,000 per year, and with use of oral contraceptives, the incidence approaches 280 to 300 per 100,000 per year. The baseline incidence of deep vein thrombosis in women is approximately 3 per 100,000 per year, and with current oral contraceptive uses it is 9.6 to 21.1 per 100,000 per year. For comparison, during pregnancy, the incidence of deep vein thrombosis is 60 per 100,000 per year. Older age (≥40-44) increases the incidence two- to three-fold but does not affect the RR. There is no evidence that smoking has an effect on the incidence of deep vein thrombosis with oral contraceptive use. At this time, universal screening for thrombophilias is not cost effective. However, any history of deep vein thrombosis warrants a workup for thrombophilia.

The association of oral contraceptives and cancer risk has been evaluated for breast, cervical, and liver cancer. Observational studies investigating a possible association between oral contraceptive use and breast cancer have reported conflicting results. The most recent information is that oral contraceptive usage (current or past use) has no impact on the incidence of breast cancer—RR 1.0 (CI 95% 0.8-1.3)—among women 35 to 64 years of age. Several observational studies have linked oral contraceptive use with invasive cervical cancer, although it is not clear if this association is causally related. A recent study investigating the association between oral contraception use and cervical cancer revealed a nearly threefold increased risk among human papillomavirus carriers with 5 to 9 years of oral contraceptive use (RR 2.82; 95% CI 1.46-5.42). This evidence suggests that women taking oral contraceptives should be screened yearly with Pap smears to prevent cervical cancer. In the 1980s, there was an association between hepatocellular carcinoma in women under 50 years of age and oral contraceptive use. With further investigation there appears to be no increased risk of hepatic cancer with the use of oral contraceptives.

After discontinuation of oral contraceptives, the activity of the HPO axis gradually returns to a precontraceptive state. After a 2- to 4-week prolongation of the follicular phase, the LH peak is observed, which suggests that the suppressive effects of the oral contraceptive have dissipated and that cyclic menses will resume.

Contraindications to oral contraceptive administration are summarized in Table 13-9.
TABLE 13–9 Contraindications to combination oral contraceptive use.

Progestin Only

Progestin-only pills (Ortho Micronor, Nor-QD, 0.35 mg norethindrone; Ovrette, 0.075 mg levonorgestrel) are also available for contraception. The target population for administration of progestin-only contraception includes women with contraindications to estrogen, breast-feeding mothers, and older women.

The circulating levels of progestin following ingestion of progestin-only pills (minipill) are 25% to 50% of that following ingestion of estrogen-progestin oral contraceptive pills. Serum levels that peak 2 hours after administration are followed by rapid elimination (Figure 13–19). The peak levels of norethindrone and levonorgestrel vary (4–14 and 0.9–2 ng/mL, respectively), but 24 hours after pill ingestion, serum levels are 0.2 to 1.6 ng/mL and 0.2 to 0.5 ng/mL, respectively. Thus, there is no accumulation of progestin over time. Progestin-only administration results in lower steady state levels and a shorter half-life compared with concomitant administration with estrogen.

Owing to the lower levels of progestin in the progestin-only pill, there is less influence on the inhibition of ovulation and more impact of thickening cervical mucus (hostile environment) inhibiting sperm penetration. Sperm that are able to penetrate have decreased mobility. Progestins also alter the endometrial lining (inhibition of progesterone receptor synthesis and reduction in endometrial glandular development, preventing implantation) and perhaps inhibit the motility (number and motility of the cilia) of the uterine tube. LH peaks—as well as FSH peaks—are suppressed compared with pretreatment levels. The change in cervical mucus takes place 2 to 4 hours after the first dose. However, after 24 hours, thinning of the cervical mucus is evident, allowing

![FIGURE 13–19](image-url)
unimpaired sperm penetration, which is why it is critical to take the progestin-only pills at the same time every day.

The progestin-only pill should be started on the first day of menses. This pill should be taken at the same time every day. If administration is 3 hours late, a backup method should be used for 48 hours. If a pill is missed, a backup method should be used for 48 hours, and if two or more pills are missed, a backup method should be used for 48 hours due to rapid resumption of the cervical mucus effect. If no menses occur in 4 weeks, a pregnancy test is necessary. Progestin-only pills may be administered immediately postpartum.

The efficacy of progestin-only pills under conditions of perfect use is 0.3 to 3.1 failures per 100 woman-years (failure rates of 1.1%-9.6% in the first year) or 0.5 per 100 users. This efficacy rate is achieved only with careful compliance. The typical use is associated with a greater than 5% failure rate. Failure rates were lowest in women over 38½ years of age and those who were breast-feeding. The efficacy may also be influenced by body weight and by concomitant use of anticonvulsants. The major disadvantage is that the pill must be administered at the same time every day. As a result of even slight flexibility in the schedule, there is increased contraceptive failure.

The risks associated with progestin-only pills are minimal. Various studies have revealed no significant impact on lipids, carbohydrate metabolism, blood pressure, or the incidence of myocardial infarction and stroke. Furthermore, no adverse coagulation parameters have been associated with its use. There are almost no data on the association of progestin-only pills and endometrial, ovarian, cervical, or breast cancer. The major side-effect is breakthrough bleeding (40%-60%). Other side-effects include acne and persistent ovarian cysts. With discontinuation of the pill, menses resume with no impact on subsequent pregnancy rates or future fertility.

### CONTRACEPTION: LONG-ACTING CONTRACEPTIVES

The high rate of unintended pregnancies has led to the development of long-acting reversible contraceptive modalities. Interest in long-acting methods is increasing because they offer convenience, obviate problems of compliance, and thus offer higher efficacy. Most long-acting systems contain either combination or progestin-only hormones. The effectiveness of these hormones is prolonged, mostly due to the sustained system that results in a gradual release. The modes of administration include injectables, transdermal patches, subdermal rods, vaginal rings, and intracervical devices. The various types of long-acting contraceptives are discussed below.

#### Injectable Contraceptives

**A. Progestin only** Injectable progestins that contain medroxyprogesterone acetate (MPA, Depo-Provera) are beneficial when women have contraindications to estrogen, use antiepileptics, are mentally handicapped, or have poor compliance. Furthermore, there is good evidence that its use is safe in the presence of coronary artery disease, congestive heart failure, diabetes, tobacco use, and a history of venous thromboembolism. Other uses of MPA include treatment of metastatic endometrial or renal carcinoma.

Although most other long-acting contraceptives are sustained-release formulations, Depo-Provera (150 mg MPA) is provided as an aqueous microcrystalline suspension that gradually declines throughout the cycle (Figure 13–20). Pharmacologic levels (>0.5 ng/mL) are achieved within the first 24 hours and peak (at 2 ng/mL) within the first week after the injection. Serum concentrations are maintained at 1 ng/mL for approximately 3 months. Interestingly, estrogen concentration is in the early to midfollicular level (below 100 pg/mL) and persists for 4 months after the last injection. The serum concentration of MPA decreases to 0.2 ng/mL during the last 5 to 6 months (ovulation occurs when levels are <0.1 ng/mL). However, one study observed progesterone levels to rise after 3½ months.

The mechanism of action depends mainly on the ability of higher peaks of hormone to inhibit ovulation (LH surge). Like other progestins, MPA increases cervical mucus viscosity, alters the endometrium, and decreases the motility of the uterine tubes and uterus. FSH levels are minimally suppressed with Depo-Provera.

The manufacturer’s recommendation is to administer the agent every 3 months, starting within 5 days of the onset of menses and not to exceed 1 week. The agent is injected deep into the upper outer quadrant of the buttock or deltoid without massage to ensure slow release. If the subject is postpartum and not breast-feeding, Depo-Provera should be given within 3 weeks after delivery and if lactating within 6 weeks (Table 13–10).

Because compliance is an issue, the failure rate is minimal at 0 to 0.7 per 100 woman-years (0.3 per 100 users). Weight and use of concurrent medications do not affect the efficacy. However, continuation rates are poor at 50% to 60% because of the side-effect profile. The major dissatisfaction that leads to discontinuation is breakthrough bleeding, which approaches 50% to 70% in the first year of use. Other side-effects include weight gain (2.1 kg/y), dizziness, abdominal pain, anxiety, and possibly depression. Another disadvantage with the use of Depo-Provera is a delay in fertility after discontinuation. Ovulation returns when serum levels are less than 0.1 ng/mL. The time from discontinuation to ovulation is prolonged. Only 50% of patients ovulate at 6 months after discontinuing the medication, and although the agent does not cause infertility, achieving pregnancy may be delayed for more than 1 year. (The length of time for release at the injection site is unpredictable.) After the first year, 60% of women become amenorrheic, and at 5 years, the incidence of amenorrhea approaches 80%, which can be considered a potential benefit. Other benefits with use of MPA include prevention of iron deficiency anemia, ectopic pregnancy, PID, and endometrial cancer. In addition, Depo-Provera is a recommended contraceptive for women with sickle cell disease (decreased crisis) and seizure disorders (raises seizure threshold). Other therapeutic uses include dysmenorrhea and endometrial hyperplasia or cancer.
CHAPTER 13 Female Reproductive Endocrinology and Infertility

One major concern with use of Depo-Provera is the development of osteopenia, with possible advancement to osteoporosis later in life. Several observational studies have evaluated the potential impact on bone. A prospective trial revealed that current users, after 12 months of use, experience a mean BMD loss of 2.74%. However, on examining former users 30 months later, it was found that mean BMD was similar to that of nonusers, indicating that the loss is reversible and of minimal clinical importance. An ongoing multicenter study assessing BMD in users versus nonusers should clarify the impact of Depo-Provera on bone. BMD in adolescents has also been investigated because adolescence is a critical time in bone mineralization. A small prospective study revealed that BMD was decreased by 1.5% to 3.1% after 1 and 2 years of use in Norplant users compared to increases in BMD of 9.3% and 9.5% in controls. This is a potential concern and has also led to a prospective multicenter study investigating the use of Depo-Provera in adolescents. Although one possible cause is less exposure to estrogen, an alternative and perhaps not exclusive theory involves MPA-dependent glucocorticoid activity that impairs osteoblast differentiation. Other potential risks include an adverse lipid profile (increase in LDL, decrease in HDL) and a slightly increased risk of breast cancer. The association of breast cancer with use of Depo-Provera is minimal within the first 4 years of use, with no risk after 5 years of use. Paradoxically, MPA has been used for treatment of metastatic breast cancer.

B. Combination The development of monthly combination injectables (Lunelle) has responded to the erratic bleeding associated with Depo-Provera (Figure 13–21). The cycle control is similar to what is achieved with combined oral contraceptives. The monthly withdrawal bleeding occurs 2 weeks after the injection. The target populations are adolescents and women who have difficulty with compliance. Lunelle is an aqueous solution containing 25 mg of MPA and 5 mg of estradiol cypionate per 0.5 mL. In women who receive repeated administration of Lunelle, peak estradiol levels occur approximately 2 days after the third injection and are 247 pg/mL (similar to peak ovulatory levels). The estradiol level returns to baseline 14 days after the last injection (100 pg/mL); the drop in estradiol is associated with menstrual bleeding (2–3 weeks after the last injection). Peak MPA levels (2.17 ng/mL) occur 3½ days after the third monthly injection. The mean MPA level is 1.25 ng/mL. The level at day 28 of the cycle is 0.44 to 0.47 ng/mL (level needed for contraceptive

</table>

DMPA, depot medroxyprogesterone acetate; IUD, intrauterine device; MPA/E₂C, medroxyprogesterone acetate and estradiol cypionate; OCS, oral contraceptives.

Effect is 0.1-0.2 ng/mL. The earliest return of ovulation seen in women with multiple injections has been 60 days after the last dose. The mechanism of action is similar to that of combined oral contraceptives.

Lunelle is administered intramuscularly in the buttok or deltoid every month. The first injection should be given within the first 5 days of the menstrual cycle (Table 13–10). Even though pharmacokinetic analysis reveals a delay in ovulation, the manufacturer recommends a 5-day grace period. The failure rate is 0.1 per 100 woman-years. Neither body weight nor use of concomitant drugs appears to affect the efficacy. Although this contraceptive has the advantages of the oral contraceptives and is associated with better compliance, the continuation rate is only 55%. This may be due to its side-effect profile, which is similar to that of the combined oral contraceptives with the addition of monthly injections.

There are limited data on potential risks. The risk potential is probably similar to that of the combined oral contraceptives, with a potentially lower incidence of deep vein thrombosis secondary to the absence of the first-pass effect. On discontinuation of Lunelle, achieving pregnancy may be delayed for as long as to 3 to 10 months after the last injection.

Lunelle was approved for use in the United States in 2000. However, in October 2002, Lunelle was recalled from the market, due to plant manufacturing problems. Alternatives to Lunelle that are administered outside the United States are: Mesigyna, Perlutal, Yectames, and Chinese Injectable No 1.

Subdermal Implants

The Norplant package consists of six capsules (34 mm in length, 2.4 mm in diameter), with each capsule providing 36 mg of levonorgestrel (total 216 mg). The target population is women who have contraindications to or adverse side-effects from estrogen, women who are postpartum or breast-feeding, and adolescent mothers. This method provides long-term continuous contraception (approved for 5 years) that is rapidly reversible. The advantages, side-effects, risks, and contraindications are similar to those of oral progestins. The major disadvantage—not present with use of oral progestins—is the surgical insertion and removal of the rods. A newer system, Norplant II, contains two rods (4 cm in length, 3.4 cm in diameter) and releases 50 µg/d of norgestrel (approved for 3 years). The two-rod system has the same mechanism of action and side-effect profile as its predecessor. However, the rods are much easier and faster to insert and remove than the capsules.

Within the first 24 hours, serum concentrations of levonorgestrel are 0.4 to 0.5 ng/mL. The capsules release 85 µg of levonorgestrel per 24 hours for the first year (equivalent to the daily dose of progestin-only pills) and then 50 µg for the remaining 5 years. The
As a result, most women ovulate within 1 month after removal of Norplant. In addition, there are adequate hormone levels to inhibit ovulation for 2 more years, thereby inhibiting ovulation. However, given the low concentrations of progestin, there is no real effect on FSH. The estradiol levels achieve a steady state condition throughout the cycle (see later and Figure 13–22). After the seventh day of application, the progestin levels rapidly decline and undetectable serum levels are achieved after 96 hours. As a result, most women ovulate within 1 month after removal of the implants.

Norplant provides contraception in several ways. In the first 2 years, the levonorgestrel concentration is high enough to suppress the LH surge—most likely at the hypothalamic level—and thereby inhibits ovulation. However, given the low concentrations of progestin, there is no real effect on FSH. The estradiol levels approximate those in ovulatory women. In addition, there are adequate hormone levels to inhibit ovulation for 2 more years. With each consecutive patch, there is minimal accumulation of levonorgestrel or ethinyl estradiol. The amount of hormone delivered is not affected by the environment, activity, or site of application (abdomen, buttock, arm, torso). The adhesive is very reliable in a variety of conditions, including exercise, swimming, irregular serum peaks (often prolonged) and declines in serum estrogen levels that may contribute to erratic bleeding. By 5 years, more than 50% of the cycles are ovulatory. However, ovulatory cycles while using Norplant have been associated with luteal phase insufficiency. Other mechanisms of contraception are similar to oral progestins and include thickening of the cervical mucus, alterations of the endometrium, and changes in tubal and uterine motility.

The failure rate is 0.2 to 2.1 failures per 100 woman-years (0.9 per 100 users). Like oral progestins, body weight affects circulating levels and may result in more failures in the fourth or fifth year of use. Similar to oral progestins, the incidence of ectopic pregnancy among failures is increased to 20% (overall incidence is 0.28-1.3 per 1000 woman-years). The continuation rate (discontinuation rate of 10%-15% per year) is age-dependent and ranges from 33% to 78%. Menstrual disturbances are the most frequent side-effect; they approach 40% to 80%, especially in the first 2 years. Although the incidence of abnormal uterine bleeding is similar to that of Depo-Provera, a significant difference between these methods is that Norplant provides only a 10% amenorrhea rate at 5 years. Other reported side-effects include headache (30% indication for removal) and possibly weight gain, mood changes, anxiety, and depression—as well as ovarian cyst formation (eight-fold increase), breast tenderness, acne, galactorrhea (if insertion occurs on discontinuation of lactation), possible hair loss, and pain or other adverse reactions at the insertion site (0.8% of cases at discontinuation).

**Transdermal Patch**

The transdermal patch (Ortho Evra) is another approach to contraception. The thin 20-cm² patch is composed of a protective layer, a middle (medicated) layer, and a release liner that is removed prior to application. The system delivers 150 μg of norelgestromin (active metabolite of norgestimate) and 20 μg of ethinyl estradiol per day to the systemic circulation. The target population is similar to that described above for Lunelle. One advantage of this system over Lunelle is that there are no monthly injections, and as a result, there is greater autonomy for the patient. The patch is applied once a week for 3 consecutive weeks, followed by a patch-free week for monthly withdrawal bleeding. The patch should be changed on the same day each week. The mechanism of action, contraindications, and side effects are similar to what has been described in the section on oral contraceptives.

With use of the transdermal patch, the peak ethinyl estradiol and norelgestromin levels are 50 to 60 pg/mL and 0.7 to 0.8 ng/mL, respectively. Because of this unique delivery system, hormone levels achieve a steady state condition throughout the cycle (see later and Figure 13–22). After the seventh day of application, there are adequate hormone levels to inhibit ovulation for 2 more days. With each consecutive patch, there is minimal accumulation of norelgestromin or ethinyl estradiol. The amount of hormone delivered is not affected by the environment, activity, or site of application (abdomen, buttock, arm, torso). The adhesive is very reliable in a variety of conditions, including exercise, swimming,
humidity, saunas, and bathing. Complete detachment occurs in 1.8% of cases and partial detachment in 2.9% of cases.

The failure rate is 0.7 per 100 woman-years under conditions of perfect use. Body weight has not been shown to affect the efficacy. The compliance with perfect use ranges from 88.1% to 91% among all age groups. This is significantly different from what is achieved with oral contraceptives (67%-85%), especially with women under 20 years of age. The side-effect profile is similar to those of oral contraceptives, except that there is slightly more breakthrough bleeding with the transdermal patch in the first 1 to 2 months (up to 12.2% vs 8.1%) and less breast tenderness (6.1% vs 18.8%). The incidence of skin reaction was 17.4%, characterized as mild in 92%, resulting in discontinuation in under 2%.

**Vaginal Rings**

Since the early 1900s, it has been recognized that the vagina is a place where steroids can be rapidly absorbed into the circulation. A study in the 1960s revealed that silicone rubber pessaries containing sex steroids would release the drug at a continuous rate. These studies led to the development of contraceptive vaginal rings.

As with oral contraceptives, there are combination and progestin-only formulations. Several progestin-only rings have been introduced since the 1970s. However, they were associated with significant menstrual disturbances. More recently, combination types have been developed. The most recent (2002) FDA-approved vaginal ring is a combination type called the NuvaRing.

The NuvaRing is made of ethylene vinyl acetate that provides 0.015 mg of ethinyl estradiol and 0.120 mg of etonogestrel per day. Maximum serum concentrations are achieved within 1 week after placement. The ring is designed to be used for 21 days and then removed for 1 full week to permit withdrawal bleeding. This device is capable of inhibiting ovulation within 3 days after insertion. After removal, the time to ovulation is 19 days. The mechanism of action, contraindications, and risks are similar to those of oral contraceptives. However, when assessing systemic exposure, use of the vaginal ring allows for 50% of the total exposure to ethinyl estradiol (15 μg in the ring compared with a 30-μg ethinyl estradiol-containing oral contraceptive).

The failure rate is similar to that reported with oral contraceptives. The continuation rate is 85.6% to 90%. Irregular bleeding is minimal (5.5%), and overall, the device is well tolerated, with an associated 2.5% discontinuation rate. Side-effects are similar to those of oral contraceptives, but cycle control appears to be improved. The reported incidence of vaginal discharge is 23% versus 14.5% with oral contraceptives. The ring does not appear to interfere with intercourse (1%-2% of partners reported discomfort); however, the device can be removed for 2 to 3 hours during intercourse without changing efficacy.
Intrauterine Devices

Intrauterine devices (IUDs) are another modality of contraception that has been used clinically since the 1960s. Historically, these devices were made of plastic (polyethylene) impregnated with barium sulfate to make them radiopaque. Several other devices were subsequently developed, including the Dalkon Shield. After the introduction of the Dalkon Shield, an increase in pelvic infections was observed secondary to its multifilament tail. Furthermore, tubal infertility and septic abortions were increasing, and massive litigation occurred as a result. Consequently, even though the modern IUD has negligible associated risk, the use of IUDs in the United States is minimal—less than 1% of married women.

Currently, two types of IUDs are used in the United States: the copper- and the hormone-containing devices. The most recent FDA-approved intrauterine system contains levonorgestrel (Mirena) and is approved for 5 years of use. Several studies have demonstrated that these devices are unlike the Dalkon Shield and are very safe and efficacious. The target population is women who desire highly effective contraception that is long-term and rapidly reversible.

The copper (TCu-380A) IUD is a T-shaped device. The mechanism of action is mostly spermicidal due to the sterile inflammatory reaction that is created secondary to a foreign body in the uterus. The abundance of white blood cells that are present as a result kills the spermatozoa by phagocytosis. The amount of dissolution of copper is less than the daily amount ingested in the diet. However, with release of copper, salts are created that alter the endometrium and cervical mucus. Sperm transport is significantly impaired, limiting access to the oviducts.

There are two hormone-containing intrauterine devices: the progesterone-releasing device (Progestasert) and the levonorgestrel-releasing device (Mirena). The Progestasert contains progesterone, which is released at a rate of 65 mg/d (approved for 1 year). This diffuses into the endometrial cavity, resulting in decidualization and atrophy of the endometrium. Serum progesterone levels do not change with the use of Progestasert. The main mechanism of action is to impair implantation. Mirena contains 52 mg of levonorgestrel, which is gradually released at a rate of 20 µg/d (approved for 5 years). Unlike Progestasert, systemic absorption of levonorgestrel inhibits ovulation about half the time. Although women may continue to have cyclic menses, over 40% have impaired follicular growth, with up to 23% developing luteinized unruptured follicles. Other mechanisms of action are similar to those described for Progestasert and the progestin-only pills. Mirena has the added advantage of significantly decreasing menstrual flow and has been used to treat menorrhagia.

The IUD should be placed within 7 days after onset of the menstrual cycle or at any time postpartum. Protection begins immediately after insertion. The failure rates after the first year of use are 0.5% to 0.8% for the TCu-380A, 1.3% to 1.6% for Progestasert, and 0.1% to 0.2% for Mirena. The expulsion rate is approximately 10%.

If a woman becomes pregnant with an IUD in place, the incidence of an ectopic pregnancy is 4.5% to 25%. The incidence of ectopic pregnancies with IUDs varies depending on the type of device. With Progestasert, the ectopic rate is slightly higher (6.80 per 1000 woman-years), most likely because its mechanism of action is limited to inhibiting implantation in the endometrium—in contrast to the copper or levonorgestrel IUD (0.2-0.4 per 1000 woman-years), both of which also interfere with conception.

The continuation rate range for the current IUDs is 40% to 66.2% (Mirena). The side-effects of the copper IUD include dysmenorrhea and menorrhagia. The most common adverse effect associated with the hormone-containing devices is erratic, albeit significantly less, bleeding. In fact, 40% of women experienced amenorrhea at 6 months and 50% at 12 months. The incidence of spotting in the first 6 months was 25% but decreased to 11% after 2 years. Other reported side-effects of levonorgestrel include depression, headaches, and acne. There is a tendency to develop ovarian cysts early after insertion with the levonorgestrel-containing device that resolves after 4 months of use.

The nominal risks associated with IUD use include pelvic infection (within 1 month after insertion), lost IUD (ie, perforation into the abdominal cavity; 1:3000), and miscarriage. There is no association between IUD use and uterine or cervical cancer. Contraindications to IUD use are active genital infection and unexplained bleeding.

**EMERGENCY CONTRACEPTION**

Postcoital contraception is a method that may be used by a woman who believes her contraceptive method has failed or who has had unprotected intercourse and feels that she may be at risk for an unintended pregnancy. The first study to evaluate the efficacy of emergency contraception with hormones was in 1963. Subsequently, several studies have been performed with various contraceptives that paved the way for more widespread use. In 1997, the FDA approved the use of high-dose oral contraceptives for postcoital contraception. Since then, pharmaceutical companies have marketed specific packaging for the use of emergency contraception. Other methods, including mifepristone (RU-486) and the IUD have also been effective for postcoital contraception.

Similar to the formulas of oral contraception, there are both combination and progestin-only types of emergency contraception. The combination method (Yuzpe regimen) entails administration of two doses of two tablets (Ovral: 50 μg ethinyl estradiol, 0.5 mg norgestrel) 12 hours apart (total: 200 μg ethinyl estradiol, 2 mg norgestrel). Other oral contraceptives may be used with adjustment in the number of pills for equivalence (ie, two doses of four tablets: any second-generation oral contraceptive 12 hours apart). The specific medication (Preven) that is FDA approved and marketed for postcoital contraception contains two doses of four tablets (ethinyl estradiol 50 μg, levonorgestrel 0.25 mg) 12 hours apart. The progestin-only method involves two doses of 10 pills (Ovyrette 0.075 mg) 12 hours apart (Plan A). The marketed form (Plan B) contains two doses of one tablet (levonorgestrel 0.75 mg) 12 hours apart.

Following a single oral dose of 0.75 mg of levonorgestrel, the serum concentration peak (5-10 ng/mL) was at 2 hours with a rapid
decline during the first 24 hours. The mechanism of action is uncertain, but levonorgestrel most likely inhibits ovulation and alters the endometrium to prevent implantation. Studies have shown decreased sperm recovery from the uterine cavity, possibly due to thickened cervical mucus, or the alkalization of the intrauterine environment. Others have shown that changes in other factors, such as integrins, can alter endometrial receptivity. The mode of action likely depends on the timing of intercourse relative to ovulation and to the administration of emergency contraception.

Maximum efficacy is achieved if the first dose is administered within 72 hours after intercourse and repeated in 12 hours. Combination formulas have a failure rate of 2% to 3%, and progestin-only preparations have a failure rate of 1%. Emergency contraception effectively reduces the rate of unintended pregnancies from 8% to 2%, a 75% reduction. However, with increasing time since unprotected intercourse, the efficacy changes from 0.4% to 1.2% to 2.7% for the first, second, or third 24-hour period after unprotected intercourse. For maximum efficacy, emergency contraception may be prescribed in advance so women will already have the correct dosing. No increase in risk-taking behavior has been noted with this strategy.

Significant nausea or emesis (51.7%) is associated with use of emergency contraception, although it is substantially less with progestin-only formulations. An anemicetic should be administered 1 hour before each treatment. If a patient vomits within 1 hour after ingestion, additional pills need to be administered.

Contraindications to emergency contraception with the combination regimen are possibly the same as those described for oral contraceptives; for progestin-only pills, there are no contraindications. Emergency contraception should be an optional function of the rape management protocol.

Lowercase letters for genes, for example, Sry, Sox9, Fgf9 are used to indicate the mouse homologue of the human gene where a particular function has not yet been demonstrated in humans.
Advances in developmental and cell biology, molecular genetics, experimental embryology, steroid biochemistry, and methods of evaluation of the interaction between the hypothalamus, pituitary, and gonads as well as behavioral science have helped clarify problems of sexual determination and differentiation. Anomalies may occur at any stage of intrauterine development of the hypothalamus, pituitary, gonads, and genitalia and lead to gross ambisexual development or to subtle abnormalities that do not become manifest until sexual maturity is achieved.

**HUMAN SEX DIFFERENTIATION**

**Chromosomal Sex**

The normal human diploid cell contains 22 autosomal pairs of chromosomes and two sex chromosomes (two Xs, or one X and one Y). When arranged serially and numbered according to size and centromeric position, they are known as a karyotype. Advances in the techniques of staining chromosomes permit positive identification of each chromosome by its unique *banding* pattern. A technique called fluorescence in situ hybridization (FISH) is particularly useful in identifying quickly both sex chromosomes, mosaicism and structural abnormalities involving the sex chromosomes, the presence or absence of SRY (the testes determining gene on the Y chromosome), and other deleted genes (Figure 14–1). High-resolution chromosome banding and painting techniques provide precise identification of each chromosome.

Studies in animals as well as humans with abnormalities of sexual differentiation indicate that the sex chromosomes (the X and Y chromosomes) and the autosomes harbor genes that influence sex determination and differentiation by causing the bipotential gonad to develop either as a testis or as an ovary. Two intact and normally functioning X chromosomes, in the absence of a Y chromosome or its SRY gene, lead to the formation of an ovary under normal circumstances, whereas a Y chromosome (whose SRY gene is intact) or the translocation of SRY, the testis-determining gene on the short arm of the Y chromosome, to an X chromosome or autosomal leads to testicular organogenesis.

In humans, there is a marked discrepancy in size between the X and Y chromosomes. Gene dosage compensation is achieved in all persons with two or more X chromosomes in their genetic constitution by partial inactivation of all X chromosomes except one. This phenomenon is thought to be a random process (except when a structurally abnormal X chromosome is present) that occurs in each cell in the late blastocyst stage of embryonic development, during which either the maternally or the paternally derived X chromosome undergoes heterochromatinization. A result of this epigenetic process is formation of an X chromatin body (Barr body) in the interphase cells of persons having two or more X chromosomes. In patients with two or more X chromosomes, the maximum number of Barr bodies (partially inactivated X chromosomes) seen in interphase cells will be one less than the number of X chromosomes in the karyotype. A gene termed *XIST* (X-inactive specific transcripts) is located in the X inactivation center at Xq13.2 on the paracentromeric region of the long arm of the X chromosome. *XIST* is expressed only by the inactive X chromosome. The *XIST* gene encodes a large RNA that appears to coat the X chromosome and facilitates inactivation of selective genes on the X chromosome.

The distal portion of the short arm of the X chromosome escapes inactivation and has a short (2.5-megabase [mb]) segment homologous to a segment on the distal portion of the short arm of the Y chromosome (Figures 14–2 and 14–3). This segment is called the pseudoautosomal region (PAR); it is these two limited regions of the X and Y that pair during meiosis, undergo obligatory chiasm formation, and allow for exchange of DNA between these specific regions of the X and Y chromosomes. At least 10 genes have been localized to the pseudoautosomal region on the short arm of the X and Y chromosomes. Among these are a gene whose deletion results in the neurocognitive defects observed in Turner syndrome and a gene for short stature, *SHOX* (short stature homeobox gene), which is expressed in bone. A mutation or deletion of *SHOX* on either the X or Y chromosome is associated with "idiopathic" short stature as well as dyschondrosteosis (Leri-Weill syndrome). Homozygous mutations of this gene are associated with a more severe form of short stature, Langer mesomelic dwarfism. A pseudoautosomal region has also been described for the distal ends of the long arms of the X and Y chromosomes.

**FIGURE 14-1** FISH (fluorescent in situ hybridization) for SRY in metaphase and interphase cells. Image illustrates localization of the SRY probe on the distal short arm of the Y chromosome (Yp11.3) in spectrum orange. The probe for the centromere region of the X chromosome is shown in spectrum green. Note the presence of both probes in the interphase cell below. (Reproduced, with permission, from Grumbach MM, Hughes IA, Conte FA. Disorders of sex determination. In: Larsen PR, et al, eds. Williams Textbook of Endocrinology. 10th ed. WB Saunders; 2003.)
chromosomes (see Figures 14–2 and 14–3). The pseudoautosomal region of the long arms of the X and Y chromosomes contains genes that are mostly growth factors and signaling molecules. The Y chromosome (see Figure 14–3) represents only 2% of the human genomic DNA and is about 60 mb in length. It is unique in that it contains few active genes compared to the X and autosomal chromosomes and has a large apparently noncoding heterochromatic region. It contains at least two genes affecting growth, the SHOX gene in the PAR and the growth control gene on the Y chromosome (GCY). The euchromatic region of the short arm of the Y chromosome contains the SRY gene (the male determining factor) distal to the PAR region at Yp1.3. The short arm of the Y chromosome contains genes that when deleted produce the phenotype stigma of Turner syndrome. The pericentromeric region of the Y is the locus for the TSPY (testis-specific protein Y encoded) genes which predispose to gonadoblastoma formation in the presence of dysgenetic testicular development. The PRKY gene is homologous to a gene PRKX (protein kinase X linked) on the X chromosome and is the locus for Y to X translocation observed in 46,XX SRY-positive males. The euchromatic region of the long arm of the Y chromosome has genes that when deleted result in azoosperma.

**Genes involved in organogenesis of the bipotential gonad**

WT1 Heterozygous mutations and deletions of the Wilms tumor gene (WT1) located on 11p13 result in urogenital malformations
as well as Wilms tumor. Knockout of the \( \text{WT}_1 \) gene in mice results in apoptosis of the metanephric blastema and as a consequence, absence of the kidneys and gonads. Thus, \( \text{WT}_1 \), a transcriptional regulator, appears to act on metanephric blastema early in urogenital development (Figure 14-4A). Dominant-negative point mutations of \( \text{WT}_1 \) in human beings results in the Denys-Drash and Frasier syndromes, whereas a contiguous deletion of the gene and surrounding DNA results in Wilms tumor, aniridia, ambiguous genitalia, and mental retardation—the WAGR syndrome.

**SF-1** Steroidogenic factor-1 (SF-1) is a nuclear receptor involved in transcriptional regulation of many genes, including those that are involved in gonadal development, adrenal development, steroid

---

**FIGURE 14-4A** Major genes involved in sex determination from the intermediate mesoderm to the bipotential gonad. (DMRT1, doublesex and mab-3-related transcription factor 1; PGC, primordial germ cell [arise from an extragonadal site]; SF-1, steroidogenic factor 1; SOX9, SRY-like HMG-box 9; \( \text{WT}_1 \), Wilms tumor suppressor gene-1) The bipotential gonad contains the precursor cells which differentiate into the supporting cells, steroid hormone-producing cells, and germ cells as shown.
synthesis, and reproduction (see Figure 14-4A). SF-1 is located on 9q33 and is expressed in the urogenital ridge as well as in steroidogenic organs. SF-1 is required for the synthesis of testosterone in Leydig cells; in Sertoli cells it regulates the anti-Müllerian hormone (AMH) gene. Homozygous knockout of the gene encoding SF-1 (SF-1 is the mouse homologue of mammalian SF-1) in mice results in apoptosis of the cells of the genital ridge that give rise to the adrenals and gonads and thus absence of gonadal and adrenal gland morphogenesis in both males and females. This gene has a critical role in the formation of all steroid-secreting glands (ie, adrenals, testes, and ovaries). Initial studies in humans with SF-1 mutations identified individuals with adrenal insufficiency, a 46,XY karyotype, complete gonadal dysgenesis, and the presence of müllerian derivatives, similar to the mouse phenotype. Subsequently, the spectrum of affected patients has included a range of 46,XY disorders of sexual development without adrenal insufficiency including hypospadias, anorchia, micropenis, complete gonadal dysgenesis, infertility in otherwise normal males, and ovarian failure in 46,XX females.

**DMRT1** Haploinsufficiency of DMRT1 (double sex Mab3-related transcription factor gene 1)—a gene related to double sex in drosophila and Mab3 in Caenorhabditis elegans is a candidate for the abnormality in testis organogenesis in patients with 9p deletions (see Figure 14-4A). 46,XY patients invariably have the stigmata of the 9p syndrome (mental retardation, trigonocephaly, upslanting palpebral fissures, etc), as well as female or ambiguous external genitalia and Müllerian structures associated with streak gonads or dysgenetic testes. Recent data suggest that ovarian function may either be compromised or normal in 46,XX females with the 9p syndrome. Ambiguous genitalia has also been reported in 46,XY patients with deletions of 10q. However, as yet a specific mutant gene(s) causing this DSD has not been identified on the 10q region.

**Genes involved in testicular determination (Figure 14-4B)**

**SRY** In studies of 46,XX males with very small Y-to-X translocations, a gene was localized to the region just proximal to the pseudoautosomal boundary of the Y chromosome (Yp11.3) (see Figure 14-3) which has been named SRY. Deletions or mutations of the human SRY gene occur in about 15% to 20% of 46,XY females with complete XY gonadal dysgenesis and 90% of 46,XX males have a Y to X translocation which includes the SRY gene.

**Postulated representation of the cascade of genes involved in mammalian gonadal determination**

**FIGURE 14-4B** Opposing gene signals (differential activation) determines fate of primordial gonad as a testis or ovary. RSPO1, respondin 1; WNT4, human homolog of Drosophila wingless gene; FOXL2, forkhead box L2; β-catenin, key-regulated effector of the WNT-signaling pathway. DAX-1 (DSS-AHC-critical region on the X chromosome gene 1) RSPO1 activates the WNT4/β-catenin canonical-signaling pathway which inhibits SOX9 expression and promotes ovarian differentiation. SRY upregulates SOX9 by binding to testicular enhancing elements in the SOX9 gene (TESCO), and both SRY and SOX9 (in mice) inhibit the β-catenin canonical-signaling pathway and promote Sertoli cell and consequent testicular development. A feed-forward loop involving SF-1 and FGF-9 has been demonstrated in mice which maintains SOX9 expression. FOXL2 "knockout" in mice causes gonadal sex reversal, i.e., ovary to testes suggesting that FOXL2 inhibits SOX9 expression. No human homozygous FOXL2 null mutations have been reported as yet. Duplication of DAX1 or WNT4 results in inhibition of testicular development and atypical genitalia—dysgenetic 46,XY DSD. MAP3K4, mitogen-activated protein kinase 4; CBX2, chromobox homologue 2. It has been suggested that CBX2 is upstream of SRY. More complete understanding of the exact function of MAP3K4 remains to be elucidated.
Compelling evidence that \textit{SRY} is the testis-determining factor is the observation that transfection of the \textit{Sry} gene into 46,XX mouse embryos results in transgenic 46,XX mice with testes and male sex differentiation.

The \textit{SRY} gene encodes a DNA-binding protein that has an 80 amino acid domain similar to that found in high-mobility group (HMG) proteins. This domain binds to DNA in a sequence-specific manner (A/TAACAAT). It bends the DNA and thus is thought to facilitate interaction between DNA-bound proteins to affect the transcription of downstream genes. The human \textit{SRY} gene has no intron; two nuclear localization sites, calmodulin and importin B are critical for the function of the gene. In mice, Sry facilitates the upregulation of \textit{Sox9} by binding to multiple enhancing elements in the \textit{Sox9} gene and along with \textit{Sf-1} establishes a feed-forward pathway resulting in upregulation of \textit{Sox9} and its continued expression in Sertoli cells. A feed-forward loop involving \textit{Sox9} and \textit{Fgf9} has also been demonstrated in the mouse but not yet in the human gonad. Both \textit{Sry} and \textit{Sox9} in mice appear to inhibit the Rspo1 (R-spondin 1)-\textit{Wnt4}-\beta-catenin-FOXL2 signaling pathway, facilitating Sertoli cell induction and testicular organogenesis and inhibiting ovarian development (see Figure 14–4B). In the absence of Sry, the \textit{Wnt4}-\beta-catenin canonical pathway is stabilized and \textit{Sox9} is suppressed which results in ovarian development. Hence, it appears that \textit{Sry} and \textit{Sox9} are repressors of a major ovarian determining pathway—\textit{Rspo1-Wnt4-\beta-catenin}—which induces ovarian development along with the downstream gene—\textit{Fox L2} and other genes yet to be defined, as well as germ cells which are essential for ovarian development (but not testicular differentiation). Duplications of \textit{DAX1} or \textit{WNT4} in humans repress testicular development presumably by preventing the repression of \textit{\beta-catenin} on its downstream gene FOXL2 by \textit{SRY} and \textit{SOX9}. Ovarian determination is a genetically controlled pathway and not, as previously though, a default pathway.

Most of the mutations thus far described in 46,XY females with gonadal dysgenesis have occurred in the nucleotides of the \textit{SRY} gene encoding the DNA-binding region (the HMG box) of the \textit{SRY} protein. Mutations that affect DNA bending as well as nuclear transportation of the \textit{SRY} protein have also been implicated in defective testicular development.

\textbf{SOX9} SOX9 has an HMG box that is more than 60\% homologous to that of \textit{SRY}. It is localized to 17q24.3-q25.1 and is expressed in the developing sex cords and, thereafter, in the Sertoli cells (see Figure 14–4B). It is also expressed in cartilage. Mutations in one allele of the \textit{SOX9} gene can result in a bone abnormality called campomelic dysplasia (CMPD) and XY gonadal dysgenesis with ambiguous genitalia in affected 46,XY males. Duplication of the \textit{SOX9} gene both in humans and mice results in sex reversal in XX individuals who are \textit{SRY} negative. It appears that \textit{SOX9} is the critical gene acting downstream of \textit{SRY} for Sertoli cell differentiation and consequent testicular development.

\textbf{DHH} \textit{Desert hedgehog} (DHH), a gene that codes for a signaling molecule located on chromosome 12q13.1 in humans, is an important gene in mammalian testes organogenesis and function. Mutations in \textit{DHH} have been reported in individuals with 46,XY gonadal dysgenesis.

\textbf{GATA4} GATA4 is a transcription factor which interacts with other proteins including SF-1 and FOG2 to regulate the expression of \textit{SRY}. Recently, a heterozygous missense mutation has been described affecting three male siblings and resulting in 46,XY DSD and congenital heart disease.

\textbf{Genes involved in ovarian determination} \textbf{DAX1} A mutation or deletion of \textit{DAX1}, which encodes a transcription factor, results in X-linked adrenal hypoplasia congenita and hypogonadotropic hypogonadism in 46,XY males (see Figures 14–2, 14–4B). Deletion or mutation of the \textit{DAX1} gene in 46,XY individuals has not resulted in an abnormality of testicular differentiation in humans. However, XY gonadal dysgenesis has been reported in individuals with duplications of Xp21, a locus that contains the \textit{DAX1} gene on the X chromosome. Duplication of the \textit{DAX1} gene appears not to affect ovarian morphogenesis and function in 46,XX females. Thus, \textit{DAX1} dosage plays a critical role in testicular development and function (see Figure 14–4B).

\textbf{WNT4} WNT4 is a signaling molecule encoded by a gene located on the short arm of chromosome region 1 (1p35). Duplication of \textit{WNT4} has been associated with dysgenetic testicular development and ambiguous genitalia in 46,XY, \textit{SRY}, positive individuals. Testis development is inhibited likely as a result of upregulation of \textit{DAX1} and stabilization of \textit{\beta-catenin-FOXL2} which would inhibit \textit{SOX9} expression in the developing gonad. 46,XY patients who have duplications of \textit{WNT4} exhibit a heterogeneous phenotype varying from cryptorchidism alone to female external genitalia. \textit{WNT4} is expressed in the primordial ovary and is an essential signal for ovarian determination (see Figure 14–4B). In mice, \textit{Wnt4} expression in the ovary prevents the migration of steroid (androgen)-producing cells into the ovary, restrains the development of a testis-specific blood vessel (the coelomic vessel), and is critical for the development of the Mullerian ducts and the maintenance of germ cells.

A 46,XX female with absent Mullerian structures (atypical Mayer-Rokitansky-Küster-Hauser syndrome) has been reported who had a loss of function mutation in the \textit{WNT4} gene. Her phenotype was similar to that described in \textit{Wnt4}-mutated mice. She had unilateral renal agenesis as well as clinical signs of androgen excess as manifested by severe acne requiring antiandrogen therapy. Wolffian duct development was not ascertained. Two other similar patients have been reported.

\textbf{RSPO1 (R-spondin 1)} \textit{RSPO1} (R-spondin 1), a gene located in 1p34.3, appears to stabilize the expression of \textit{WNT4-\beta-catenin-FOXL2} and thus promotes ovarian determination (see Figure 14–4B). Mutations in \textit{RSPO1} cause 46,XX females to develop testes and male sexual development, as well as palmpoplantar hyperkeratosis and a predisposition to squamous cell carcinoma of the skin. The fact that a mutation in \textit{RSPO1} can redirect gonadal development in a 46,XX individual from an ovary to a testes suggests that it is a critical determinant in ovarian determination in humans.

\textit{FOXL2} is a putative forkhead transcription factor, which does not cause a DSD in human. Heterozygous \textit{FOXL2} mutations in affected 46,XX human females causes premature ovarian failure with or without blepharophimosis. However, induced FoxL2 deletions in the ovary of the mouse lead to transdifferentiation of the ovary into testes.
A 46,XY phenotypic female with normal ovaries and a mutation in the CBX2 (chromobox homolog 2) gene, the human homolog of mouse m33, an ortholog of the Drosophila Polycomb gene, has recently been reported. It was postulated that this gene is upstream of SRY and that mutations in this gene prevent the repression of the ovarian gene pathway presumably by decreasing SRY/SOX9 expression enabling the expression of RSPO1-WNT4-β-catenin-FoxL2 and other ovarian determining genes.

Our lack of complete understanding of ovarian and testicular determination is illustrated in the study by Dumic et al who reported a familial cohort of 46,XY females. A 46,XY female was reported to have undergone spontaneous menarche and given birth to a 46,XY daughter with gonadal dysgenesis. Studies in this cohort have uncovered a mutation in a gene not previously known to be involved in the sex determination cascade—mitogen-activated protein kinase kinase kinase 4 (MAP3K4). Mutations in this gene involved in the mitogen-activated protein kinase signaling pathway cause a striking decrease in the expression of Sry and Sox9 in the developing mouse gonad resulting in sex reversal. Recently, mutations in MAP3K1 have been reported to 46,XY DSD leading to either partial or complete gonadal dysgenesis. Further studies in humans will be necessary to elucidate the exact mechanism which allows for repression of testicular development and the genesis of an apparently normal functioning ovary in SRY positive 46,XY individuals.

**TESTICULAR AND OVARIAN DIFFERENTIATION (FIGURE 14–5)**

The mammalian gonad forms on the surface of the mesonephros within the genital ridge as a result of proliferation of the coelomic epithelium. Until the 12-mm stage (~42 days of gestation), the embryonic gonads of males and females are indistinguishable. By 42 days, 300 to 1300 primordial germ cells have seeded the undifferentiated gonad from their extragonadal origin in the yolk sac dorsal endoderm. These large cells are the progenitors of oogonia and spermatogonia; lack of these cells is incompatible with further ovarian differentiation but not testicular differentiation. The undifferentiated gonad also contains supporting cells and steroidogenic cells. Under the influence of SRY/SOX9 and other genes that encode male sex determination, the gonad begins to differentiate as a testis at 43 to 50 days of gestation. The supporting cells differentiate into pre-Sertoli cells which organize into seminiferous tubules and surround the germ cells which undergo mitotic arrest. Leydig cells derived from steroidogenic cells are apparent by about 60 days, and differentiation of male external genitalia occurs by 65 to 77 days of gestation.

In the undifferentiated gonad destined to be an ovary, lack of further differentiation persists. At 77 to 84 days—long after differentiation of the testis in the male fetus—a significant number of germ cells enter meiotic prophase to characterize the transition of oogonia into oocytes, which marks the onset of ovarian differentiation from the undifferentiated gonads. The supporting cells become granulosa cells and steroidogenic cells become theca cells. Germ cell meiosis in the developing ovary is induced by retinoic acid signaling. Sry induces an enzyme which metabolizes retinoic acid to an inactive product and prevents meiosis of germ cells in the developing testis. Primordial follicles (small oocytes surrounded by a single layer of flat granulosa cells and a basement membrane) are evident after 90 days. Preantral follicles are seen after 6 months, and a population of fully developed oocytes with fluid-filled cavities and multiple layers of granulosa cells are present by approximately 11 years of age.
present at birth. As opposed to the testes, there is little evidence of hormone production by the fetal ovary.

**Differentiation of Genital Ducts (Figure 14–6)**

By the seventh week of intrauterine life, the fetus is equipped with the primordia of both male and female genital ducts. The Müllerian ducts, if allowed to persist, form the uterine (fallopian) tubes, the corpus and cervix of the uterus, and the upper third of the vagina. The Wolffian ducts, on the other hand, have the potential for differentiating into the epididymis, vas deferens, rete, corpus and cervix of the uterus, and the upper third of the primordia of both male and female genital ducts. The Müllerian ducts undergo apoptosis under the influence of AMH, a dimeric glycoprotein secreted by fetal Sertoli cells. AMH acts locally to cause Müllerian duct regression ipsilaterally. Müllerian duct regression is the earliest indicator of male sex differentiation.

The gene for AMH encodes a 560 amino acid protein, whose carboxyl terminal domain shows marked homology with transforming growth factor-β (TGF-β) and the B chain of inhibin and activin. The gene is localized to the short arm of chromosome 19. AMH is secreted by human fetal and postnatal Sertoli cells and is used as a marker for the presence of these cells. SF-1 (an orphan nuclear receptor) in combination with WTI, SOX9, and GATA4 (Figure 14–7), regulates AMH gene expression. The human AMH receptor gene maps to the q13 band of chromosome 12. The receptor is similar to other type II receptors of the TGF-β family.

The differentiation of the Wolffian duct is mediated by testosterone (T) secretion from the testis. SF-1 regulates steroidogenesis by the Leydig cell in the testes by binding to the promoter of the genes encoding P450 side chain cleavage enzyme (P450scc) and 17α-hydroxylase (P450c17). In the presence of an ovary or in the absence of a functional fetal testis, Müllerian duct differentiation occurs, and the Wolffian ducts involute (see Figure 14–6).

**Differentiation of External Genitalia (Figure 14–8)**

Up to the eighth week of fetal life, the external genitalia of both sexes are identical and have the capacity to differentiate into the genitalia of either sex. Female sex differentiation occurs in the presence of an ovary or streak gonads or if no gonad is present (see Figure 14–8). The fetal ovary does not secrete sex steroids during gestation or AMH during the critical period of female differentiation of the genital ducts and external genitalia. Studies in the past have indicated that the fetal adrenal gland is 3β-HSD-2 (3 beta-hydroxysteroid dehydrogenase-2) deficient and secretes primarily DHEA-S (dehydroepiandrosterone sulfate) until late in gestation. DHEA-S is converted by the placenta to DHEA which is metabolized to T. T is aromatized to estrogen, thereby preventing the exposure of the female external genitalia to high levels of T/dihydrotestosterone (DHT). Placental aromatase activity is low from 8 to 12 weeks of gestation but increases markedly after the first trimester (Figure 14–9). Recent studies indicate that the normal female genitalia are protected from androgen exposure early in gestation (8–12 weeks), a stage when placental aromatase activity is relatively low. Sex differentiation of the external genitalia is occurring by the transient expression of 3β-HSD-2 in the fetal adrenal, resulting in cortisol secretion, and consequently relative suppression of both adrenocorticotropic hormone (ACTH) and DHEA-S secretion with a resultant decrease in placental testosterone synthesis and secretion. Adrenally derived androgen levels appear to be the same during this period in both males and females. After 12 weeks of gestation, 3β-HSD-2 activity diminishes in the fetal adrenal which leads to an increase in ACTH and DHEA-S secretion. Testosterone is now converted by the increased placental aromatase to estrogen. In addition, androgen receptor activity diminishes in the labioscrotal folds, and excess androgen exposure after 12 to 14 weeks gestation results in only clitoromegaly, but not labioscrotal fusion. Thus, the transient expression of 3β-HSD-2 and the consequent ability of the fetal adrenal gland to transiently synthesize cortisol, as well as the decrease in androgen receptor activity in genital skin protects the female external genitalia from masculinization during the window of dimorphic differentiation of the external genitalia.

Differentiation of the external genitalia along male lines depends on the action of DHT, the 5α-reduced metabolite of T. In the male fetus, T is secreted by the Leydig cells, autonomously at first and later under the influence of human chorionic gonadotropin (hCG), and later fetal pituitary luteinizing hormone (LH). Masculinization of the external genitalia and urogenital sinus of the fetus results from the action of DHT, which is synthesized from T in the target cells by the enzyme 5α-reductase-2 as well as possibly secreted by the testes via the backdoor pathway (Figure 14–10). This pathway was first found in marsupials and then implicated in patients with P450 oxidoreductase (POR) deficiency. This backdoor pathway synthesizes DHT, a nonaromatized androgen, without utilizing T as a precursor. This pathway may play a significant role in male differentiation; however, further studies are necessary to define this.

DHT (as well as T) is bound to a specific protein receptor in the nucleus of the target cell (Figure 14–11). The transformed steroid-receptor complex dimerizes and binds with high affinity to specific DNA domains, initiating DNA-directed, RNA-mediated transcription. This results in androgen-induced proteins that lead to differentiation and growth of the cell. The gene that encodes the intracellular androgen-binding protein has been localized to the paracentromeric portion of the long arm of the X chromosome (see Figure 14–2). Of note, an X-linked gene controls the androgen response of all somatic cell types by specifying the androgen receptor protein. As noted previously, there is a decrease in androgen receptor activity in the labioscrotal folds after 12 to 14 weeks so that even with intense T/DHT stimulation, labioscrotal fusion does not occur although growth of the genital tubercle can continue resulting in clitoromegaly in females and penile enlargement in males.

Incomplete masculinization of the male fetus results from (1) impairment in the synthesis or secretion of fetal T and/or DHT (3α-HSD-3 deficiency) or the conversion of T to DHT
FIGURE 14-6 Embryonic differentiation of male and female genital ducts from Wolffian and Müllerian primordia. A. Indifferent stage showing large mesonephric body. B. Female ducts. Remnants of the mesonephros and Wolffian ducts are now termed the epoophoron, paroophoron, and Gartner duct. C. Male ducts before descent into the scrotum. The only Müllerian remnant is the testicular appendix. The prostatic utricle (vagina masculina) is derived from the urogenital sinus. (Modified from Corning HK, Lehrbuch der Entwicklungsgeschichte des Menschen, JF Bergmann, Munich, 1921; and Wilkins L. The diagnosis and treatment of endocrine disorders. In: Charles C, ed. Childhood and Adolescence. 3rd ed. Thomas Publishers; 1965.)

**Testosterone converted to Aromatase (CYP19)**

**AR**

**Cortisol**

**ACTH**

**FIGURE 14–9** Sex differentiation of the external genitalia of males is induced by dihydrotestosterone (DHT) which is synthesized in the cells of the external genitalia from fetal testicular testosterone by the enzyme Salpha-reductase-2. DHT may also be produced via the "back door pathway". Male differentiation of the external genitalia occurs from 8 to 12 weeks of gestation when aromatase activity of the liver and placenta is relatively low. During this critical window of dimorphic sexual differentiation, the fetal adrenal transiently expresses 3β-HSD-2, resulting in adrenal secretion of cortisol and a consequent downregulation of fetal ACTH and T precursor (DHEA-S) secretion from the fetal adrenal as well as putative adrenal testosterone secretion. Thus, the female external genitalia are protected from T/DHT exposure and virilization during this period when aromatase activity is low. After 12 weeks of gestation, 3β-HSD-2 activity in the adrenal is extinguished until 24 weeks of gestation resulting in an increase in DHEA-S (T precursor) from the fetal adrenal. However, increased placental aromatase activity and a decrease in androgen receptor activity in the labioscrotal folds of 46,XX females occurs so that excess T/DHT exposure after 12 weeks of gestation results only in clitoromegaly. (Modified from Hanley NA, Arlt W. The human fetal adrenal cortex and the window of sexual differentiation. Trends Endocrinol Metab. 2006;17:391.)

(5α-reductase-2 deficiency, (2) deficient or defective androgen receptor activity, or (3) defective production and local action of AMH.

**PSYCHOSEXUAL DIFFERENTIATION**

Psychosexual differentiation can be classified into four broad categories: (1) gender identity, defined as the identification of self as either male or female; (2) gender role (ie, those aspects of behavior in which males and females differ from one another in one’s culture at this time); (3) gender orientation, the choice of sexual partner; and (4) cognitive differences.

For much of the past 50 years, the prevailing dogma has been that newborns are born psychosexually neutral and that gender identity is imprinted postnatally by words, attitudes, family dynamics, and comparisons of one’s body with that of others. Gender identity had been hypothesized to be neutral at birth and not established until 12 to 18 months of age. During the last decade, this hypothesis has been rigorously challenged. It has become evident that prenatal exposure to T/DHT and possibly genes on the Y chromosome can influence gender identity in the individual with a DSD. A growing body of evidence indicates that gender identity is more plastic than previously thought. If, at puberty, discordant secondary sexual characteristics are allowed to mature, some individuals, especially those with 5α-reductase deficiency, 45,X/46,XY mosaicism, or 17β-HSD-3 deficiency, have had doubts about their gender identity and have chosen to change their assigned sex from female to male. However, in general, it has been demonstrated that most patients with DSD (except for those mentioned above) will accept their gender assignment even when it is not concordant with their sex chromosome constitution—a phenomenon which underscores both the complexity and plasticity of the processes that determine gender identity. This suggests that androgens have a facultative and not a deterministic role in gender identity. Androgens have a significant effect on childhood play behavior, maternal interest, and sexual orientation. It is apparent that both genes and hormones (nature) and environment and experience (nurture) are critical factors in the development and maintenance of gender identity. Further studies on patients with ambiguous genitalia, including long-term outcomes of the factors influencing gender identity, gender role, and sexual activity in DSD patients, are critical to furthering our understanding of the multifaceted complexities of the differentiation of gender identity and to support more evidence-based guidelines for decisions about sex assignment.

**CLASSIFICATION AND NOMENCLATURE OF DISORDERS OF SEX DETERMINATION (AND DIFFERENTIATION) (TABLE 14–1)**

An International Conference on Management of Intersex was held in Chicago, Illinois, in 2005 because of ethical issues and patient
The enzymatic pathway of testosterone synthesis in the adrenal and testes is shown in blue on the left. A backdoor pathway first described by Wilson and Aucus from studies in marsupials is shown on the right. This pathway utilizes 17-OH progesterone to synthesize dihydrotestosterone independent of testosterone synthesis. The backdoor pathway as well as traditional testosterone synthesis by the fetal testes may be essential for normal male external genitalia differentiation. It has been suggested that virilization in 46,XX individuals with CAH (such as 21-hydroxylase, 11-hydroxylase, P450 oxidoreductase, and possibly 3β-HSD-2 deficiency) who have elevated levels of 17-OH progesterone in utero may involve DHT synthesis via the backdoor pathway. The fetal adrenal is relatively 3β-HSD-2 deficient from 12 to 24 weeks of gestation and DHEA-S is primarily secreted and converted in the liver to 16-OH DHEAS. DHEA-S is converted by placental sulfatase to DHEA which then is metabolized to T and subsequently to estradiol by placental aromatase. Similarly, 16OHDHEAS is aromatized to estriol. Androstenedione can be directly converted to estrone by (3α-HSD-3 (AKRcs), 3α,4α-reductase, cytochrome b5; 3β-HSD-1, 3β-hydroxysteroid dehydrogenase type 1; 3β-HSD-2, 3β-hydroxysteroid dehydrogenase type 2; 17β-HSD-1, 17β-hydroxysteroid dehydrogenase type 1; 17β-HSD-3, 17β-HSD-3, 17β,20α-hydroxysteroid dehydrogenase type 3; CY17, CYP21, 21 hydroxylase; CYP11B1, 11 hydroxylase; DHEA, dehydroepiandrosterone; P450scc, P450 side chain cleavage; POR, P450 oxidoreductase; STAR, steroidogenic acute regulatory protein; Sulf2A1, sulfatase).
concerns about the venerable but antiquated terms *intersex*, *pseudohermaphrodite*, *true hermaphrodite*, and so forth, which were perceived by patients as pejorative. A new nomenclature was proposed and accepted. The term, disorders of sexual development (DSD), connoting all conditions in which chromosomal, gonadal, or anatomic sex are atypical, was coined. (See Lee PA et al for the complete consensus statement.)

DSDs are the result of abnormalities in complex processes that originate in genetic information on the X and Y chromosomes as well as on the autosomes. A 46,XY DSD (previously male hermaphrodite) is one whose gonads are exclusively testes in origin but whose genital ducts or external genitalia (or both) exhibit incomplete masculinization. A 46,XX DSD (previously female hermaphrodite) is a person whose gonadal tissue is exclusively...

*aThese terms are previous terminology and are no longer recommended; they should be abandoned. They are listed in parentheses during this transition period.*

*bIn pregnant patient with CAH whose disorder is poorly controlled or who is noncompliant especially during the first trimester.*

*cThe patient reported had strikingly elevated gonadotropins in infancy and only sparse primordial follicles on biopsy at 4 years of age suggesting gonadal dysgenesis.*

Klinefelter syndrome is one of the most common forms of primary hypogonadism and infertility in males. Surveys of the prevalence of 47,XXY fetuses by karyotype analysis of unselected newborn infants indicate a prevalence of about 1:700 newborn males. However, there is a striking disparity between the prevalence diagnosed at birth by karyotype screening and the frequency of Klinefelter syndrome identified in adults. It has been estimated that only 25% of individuals with Klinefelter syndrome are diagnosed during life and less than 10% in childhood. This most likely is due to the broad spectrum of phenotypes, testicular function, and psychosocial status found in patients with this syndrome. Ninety percent of affected patients have a 47,XXY sex chromosome constitution and an X chromatin-positive buccal smear, the rest demonstrate a variety of sex chromosome constitutions, including mosaicism. Virtually all of these variants have at least two X chromosomes and a Y chromosome in common, except for the rare group that has only an XX sex chromosome complement (3%-4%).

Hormonal levels are variable, and T levels may be in the low-normal to normal range. In addition, variability in phenotype can result in part from sex chromosome mosaicism with a normal XY cell line as well as variability in androgen sensitivity. The androgen receptor is a ligand-dependent transcription factor that has a polymorphism involving CAG (glutamine) trinucleotide repeats. The longer the length of the CAG repeat, the less the transactivation activity of the ligand-bound receptor. In a study of 35 patients with Klinefelter syndrome, the one genetic factor affecting phenotype was the CAG repeat length of the functional androgen receptor. The repeat lengths correlated inversely with penile length, a T-sensitive organ. Neither an effect of parental origin of the X chromosome (imprinting) nor evidence of skewed X chromosome inactivation affected the phenotype. In a study of 77 patients with Klinefelter syndrome, preferential inactivation of the shorter CAG allele was detected.

The most consistent feature of Klinefelter syndrome is small atrophic testes due to seminiferous tubule dysgenesis and consequent azospermia. Tall stature is common in Klinefelter syndrome, reflecting the presence of three SHOX genes. Adult males with a 47, XXY karyotype tend to be taller than average, with adult height close to the 75th percentile, mainly because of the disproportionate length of their legs, which is present prepuber tally. Untreated adult males, especially those with subnormal sex steroid levels, are at increased risk of osteoporosis. In addition, individuals with Klinefelter syndrome have an increased prevalence of mild diabetes mellitus, autoimmune thyroid disorders, early tooth decay, varicose veins, stasis dermatitis, cerebrovascular disease, chronic pulmonary disease, deep vein thrombosis, carcinoma of the breast, midline germ cell tumors, and Hodgkin lymphoma. The data on carcinoma of the breast are controversial. There were no cases in a cohort of 696 men with Klinefelter syndrome from the Danish cytogenetic register; however, 7 of 93 men with breast cancer in a Swedish study had Klinefelter syndrome. Life expectancy is reduced by about 2.1 years over controls, with a lower death rate than expected from ischemic heart disease and prostate cancer.

Patients with Klinefelter syndrome may have delayed adolescence although a recent study suggested that the onset of puberty and early progression were relatively normal. There is an increased risk of malignant extragonadal germ cell tumors in the central nervous system, mediastinum, and sacral region. The germ cell tumors often secrete hCG and cause sexual precocity in the affected prepubertal individual. Accordingly, we recommend that boys with hCG-secreting midline germ cell tumors have a karyotype analysis.

The testicular lesion is progressive and gonadotropin dependent. Gonadal germ cells become depleted at an accelerated rate after the onset of puberty, and there appears to be a maturation arrest of spermatogenesis. The testes are characterized in the adult by extensive seminiferous tubular hyalinization and fibrosis, absent or severely deficient spermatogenesis, and pseudodenomatous clumping of the Leydig cells. Although hyalinization of the tubules is usually extensive, it varies considerably from patient to patient and even between testes in the same patient. Azoospermia is the rule; patients reported to be spontaneously fertile invariably have been 46,XY/47,XXY mosaics. Using surgical techniques, sperm has been found in 50% of the nonmosaic patients with Klinefelter syndrome. In biopsied testes of patients with 47,XXY Klinefelter syndrome, only a minor fraction of tubules contain germ cells. FISH analysis revealed that the spermatocytes were euploid, suggesting that the spermatogonia that undergo mitosis have only one X chromosome thus allowing for progression in cell differentiation and the ability to engage in meiosis. Intracytoplasmic sperm injection (ICSI) with sperm retrieved surgically from testes (TESE) of patients with Klinefelter syndrome has been used with success for ovum fertilization. Using ICSI, most infants born to fathers with Klinefelter syndrome have had normal karyotypes. However, there is an increased incidence of sex chromosome and autosomal aneuploidy, possibly related to the assisted fertility technique (ART). Preimplantation genetic diagnosis (PGD) is recommended. However, the potential risk to the embryo of PGD...
must be weighed against the risk of chorionic villus biopsy or amniocentesis in the event of a successful pregnancy.

Nondisjunction during the first or second meiotic division of gametogenesis plays an important role in the genesis of a 47,XXY karyotype. Fifty-three percent of cases appear to result from paternal nondisjunction at the first meiotic division, 34% from meiotic nondisjunction during the first maternal meiotic division, and 9% from nondisjunction at the second meiotic division. Only 3% of patients appear to have arisen from postzygotic mitotic nondisjunction. Early studies suggested that parental age was a factor in the etiology of Klinefelter syndrome, but in a study of 228 patients, no association with advanced parental age was found.

Diagnosis: Klinefelter syndrome is suggested by the classic phenotype and hormonal changes. It is confirmed by the finding of an X chromatin-positive buccal smear or an FISH analysis which demonstrates an XXY constitution or the demonstration of a 47,XXX karyotype in blood, skin, or gonads. After puberty, levels of serum gonadotropins especially follicle-stimulating hormone (FSH) are raised. The T production rate, the total and free levels of T, and the metabolic clearance rates of T and estradiol tend to be low, whereas plasma estradiol levels are relatively normal or high for a male. Testicular biopsy reveals the classic findings of hyalinization of the seminiferous tubules, severe deficiency of spermatogonia, and pseudoatrophic clumping of Leydig cells.

Hormonal evaluation in the newly diagnosed patient with Klinefelter syndrome should include plasma LH and FSH by immunochemiluminescence (ICMA). These levels are usually in the normal range prior to the onset of puberty. Thereafter, a rise in FSH and subsequently LH is usually observed. A plasma estradiol and T by liquid chromatography-tandem mass spectrometry (LCMSMS) should be obtained. In the adolescent or postadolescent patient, a bone density is indicated to determine whether the patient has osteopenia/osteoporosis and requires therapy for this.

Treatment: Treatment in adolescents and adults with Klinefelter syndrome should be directed toward health maintenance and the options for fertility (eg, cryopreservation of sperm from ejaculate in adolescence or TESE in older patients, T replacement if necessary, and prevention of osteopenia/osteoporosis and deep vein thrombosis). Klinefelter patients are born with spermatogonia, and testicular failure is progressive beginning at puberty. Obtaining ejaculated sperm in early adolescence for cryopreservation, if possible, might obviate the need for TESE at a later time. Although several studies have reported that sperm have been found in 8% of ejaculated serum samples from nonmosaic 47,XXY patients, a recent study reported lack of sperm in samples from 13 patients less than 20 years of age. Because of the progressive nature of testicular failure which occurs after the onset of puberty, surgical sperm retrieval is less successful with advancing age. T therapy in the hypogonadal patient will enhance secondary sexual characteristics and sexual performance, increase muscle mass, prevent or help ameliorate osteopenia/osteoporosis and prevent the development of gynecomastia. If T deficiency is evident in adolescence, therapy with T enanthate in oil at a dose of 50 mg intramuscularly monthly may be initiated. Alternatively, testosterone by patch or gel may be used. The plasma concentration of T can be assessed midway between injections, and the doses gradually increased to attain a level in the mid-normal range for stage of development and/or age.

In the adult patient, transdermal T by patch or gel can be used for replacement therapy. T levels can be assessed 1 week after the start of therapy and adjusted to maintain levels in the mid-normal range for age. Patients should be informed of the possibility of deep vein thrombosis and the T discontinued if the hematocrit rises above 54% because of the risk of hypercoagulability associated with elevated hematocrit levels. If gynecomastia is present and is not ameliorated by T therapy, surgical reduction is required if it is psychologically disturbing to the patient.

Early diagnosis with remedial therapy for speech and behavior problems, counseling for the patient and parents, as well as support group services appears to improve the well being and overall quality of life in patients diagnosed with Klinefelter syndrome.

**Variants of Chromatin-Positive Seminiferous Tubule Dysgenesis**

**Variants of Klinefelter syndrome** Variants of Klinefelter syndrome include 46,XY/47,XXY mosaics as well as patients with multiple X and Y chromosomes. With increasing numbers of X chromosomes in the genome, both mental retardation and other developmental anomalies such as radial or synostosis become prevalent.

**46,XX males (46,XX testicular DSD)** Phenotypic males with a 46,XX karyotype have been described since 1964; the incidence of 46,XX males is approximately 1:20,000 births. In general, these individuals have a male phenotype, male psychosocial gender identity, and testes with histologic features similar to those observed in patients with a 47,XXY karyotype. At least 10% of patients have hypospadias or ambiguous external genitalia, primarily those patients who are SRY negative. 46,XX males have normal body proportions and a mean final height that is shorter than that of patients with a 47,XXY sex chromosome constitution or normal males but taller than that of normal females. There is a higher incidence of undescended testes in 46,XX males than in 47,XXY patients. As in 47,XXY individuals, T levels are low or low-normal, gonadotropins are elevated, and spermatogenesis is impaired postpubertally. Gynecomastia is more frequent than that observed in 47,XXY males.

Males with a 46,XX karyotype have acquired one X chromosome from each of their parents. Approximately 90% of XX males have a Y chromosome–specific DNA segment from the distal portion of the Y short arm translocated to the distal portion of the short arm of the paternal X chromosome. This translocated segment is variable in length but always includes the SRY gene, which encodes testis-determining factor as well as the pseudoautosomal region of the Y chromosome. Thus, in at least 90% of XX males, an abnormal X-Y terminal exchange during paternal meiosis has resulted in two products: an X chromosome with an SRY gene and a Y chromosome deficient in this gene (the latter would result in a female with XY gonadal dysgenesis). Fewer than 10% of XX males tested have lacked Y chromosome–specific DNA sequences (including the SRY gene) and the pseudoautosomal region of the Y chromosome. These XX, SRY-negative males tend to have hypospadias and may have relatives with ovotesticular DSD.
The finding of XX males who lack any evidence of Y chromosome–specific genes suggests that testicular determination—and, thus, male differentiation—can occur in the absence of a gene or genes from the Y chromosome. This could be a result of (1) mutation (upregulation) or duplication of a downstream autosomal gene involved in male sex determination (eg, SOX9) which if duplicated in a 46,XX individual causes sex reversal both in mice and humans; or (2) mutation, deletion, or aberrant inactivation of a gene sequence, which causes repression of testis determination. Two families with multiple 46,XX phenotypically normal males who had palmar-plantar hyperkeratosis and a predisposition to squamous cell carcinomas have been reported. All affected males had a homozygous deletion of 2700 base pairs of the \textit{R-spondin1} gene. \textit{RSPO1}, an ovary-determining gene, has no role in testes determination as evidenced by the description of a 46,XY male with a homozygous mutation of \textit{RSPO1} who had normal testicular function; or (3) circumscribed Y chromosome mosaicism (eg, occurring only in the gonads); (4) A 46,XX SRY negative male has recently been described with a mutation in SOX3. SOX3 is a member of the SRY HMG box family of genes and is found on the X chromosome at Xp26-27. This mutation is postulated to cause aberrant expression of SOX3 in gonadal primordia and thereby upregulating SOX9 expression resulting in testicular determination.

**SYNDROME OF GONADAL DYSGENESIS: TURNER SYNDROME AND ITS VARIANTS**

**Turner Syndrome: 45,X Gonadal Dysgenesis**

One in 2000 to 2500 newborn females have an absence of a second sex chromosome (either an X or Y), a structural rearrangement of the X chromosome, and/or mosaicism. Patients with a 45,X karyotype represent approximately 50% of all patients with X chromosome abnormalities. It has been estimated that 99% of 45,X fetuses do not survive beyond 28 weeks of gestation probably related to congenital heart anomalies, and 15% of all first-trimester abortuses have a 45,X karyotype. In about 70% to 80% of 45,X individuals, the X chromosome is of maternal origin.

The cardinal features of 45,X gonadal dysgenesis are a variety of somatic anomalies, sexual infantilism at puberty secondary to gonadal dysgenesis, and short stature. Patients with a 45,X karyotype can be recognized in infancy, usually because of lymphedema of the extremities and loose skin folds over the nape of the neck. In later life, the typical patient is often recognizable by her distinctive facies in which micrognyhia, epicanthal folds, prominent low-set ears, a fish-like mouth, and ptosis are present to varying degrees. The chest is shield-like, and the neck is short, broad, and webbed (40% of patients). Additional anomalies associated with Turner syndrome include renal abnormalities (30%), pigmented nevi, cubitus valgus, congenital hip subluxation, a tendency to keloid formation, lymphedema of the lower extremities or puffiness of the dorsum of the hands and feet, short fourth metacarpals and metatarsals, Madelung deformity of the wrist, scoliosis, and recurrent otitis media, which may lead to conductive hearing loss. The high prevalence of otitis media is a consequence of an abnormal relationship between the Eustachian tube and the middle ear. Sensorineural hearing loss increases with age and is present in 61% of women with Turner syndrome over 35 years of age. All patients should have routine periodic auditory screening.

Patients with Turner syndrome have an increased prevalence of cardiovascular anomalies. The incidence of bicuspid aortic valves diagnosed by echocardiography has varied between 9% and 34%. A bicuspid aortic valve is a risk factor for subacute bacterial endocarditis. With age there is an increased tendency for a stenotic and/or insufficient aortic valve. Coarctation of the aorta is present in 10% of patients, especially individuals with a webbed neck. Bicuspid aortic valves, coarctation, aortic dilation, and hypertension are critical risk factors for aneurysm formation and death due to aortic rupture. Thus, all patients with Turner syndrome should have a complete cardiac evaluation by a cardiologist at diagnosis as well as periodic follow-up echocardiography or magnetic resonance imaging (MRI) as necessary to monitor aortic diameter and cardiovascular status. Routine intravenous urography or renal sonography is indicated to detect a surgically correctable renal abnormality. The most common renal anomalies are a horseshoe kidney, duplication of the renal pelvis and ureter, and hydronephrosis secondary to uteropelvic obstruction. Complete absence of a kidney and gross renal ectopia have been reported. The internal ducts as well as the external genitalia of these patients are invariably female except in rare patients with a 45,X karyotype, in whom a Y-to-autosome or Y-to-X chromosome translocation or cryptic mosaicism for a Y-containing cell line has been found.

Short stature is an invariable feature of the syndrome of gonadal dysgenesis. Mean final height in 45,X patients is 143 cm, with a range of 133 to 153 cm. Short stature found in patients with the syndrome of gonadal dysgenesis is not due to a deficiency of growth hormone (GH), insulin-like growth factor I (IGF-I), sex steroids, or thyroid hormone. It is related, at least in part, to haploinsufficiency of the \textit{SHOX} gene in the pseudoautosomal region of the X and Y chromosome (see earlier sections). The administration of high-dose recombinant human GH leads to an increase in final height.

Gonadal dysgenesis is a cardinal feature of patients with a 45,X chromosome constitution. The gonads at adolescence are typically streak-like and usually contain only fibrous stroma arranged in whorls. Longitudinal studies of both basal and gonadotropin-releasing hormone (GnRH)-evoked gonadotropin secretion in patients with gonadal dysgenesis indicate a lack of feedback inhibition of the hypothalamic-pituitary axis by the dysgenetic gonads in affected infants and adolescents (Figure 14–12). Plasma and urinary gonadotropin levels, particularly FSH levels, are high during early infancy and after 9 to 10 years of age. Because ovarian function is impaired, puberty does not usually ensue spontaneously; sexual infantilism is a hallmark of this syndrome. Rarely, patients with a 45,X karyotype may undergo spontaneous pubertal maturation, menarche, and even pregnancy. It has been suggested that measurable levels of inhibin B may indicate the presence of functional follicles and the possibility of spontaneous pubertal development while low levels of AMH might herald ovarian failure. A variety of other disorders are associated with this...
syndrome, including obesity, nonosteoporotic fractures in childhood and osteoporotic fractures in adulthood, congenital dislocation of the hip, type 2 diabetes mellitus, an increased number of melanocytic nevi but no increase in melanoma, orthodontic problems, Hashimoto thyroiditis, rheumatoid arthritis, inflammatory bowel disease, intestinal telangiectasia with bleeding, hypertension, coeliac disease, ischemic heart disease, stroke, and anorexia nervosa. Abnormal liver enzymes with elevation of transaminases, alkaline phosphatase, and gamma-glutamyl transferase have been reported in more than 50% of adults. Most patients with Turner syndrome have normal intelligence. Only a small percentage of patients have significant developmental delay. However, 70% have learning disabilities involving spatial relationships, nonverbal problem-solving, and attention. Early testing and remediation is recommended, as well as psychologic support.

Diagnosis: Phenotypic females with the following features should have a karyotype analysis: (1) short stature (>2.5 standard deviations [SDs] below the mean value for age) with or without somatic anomalies associated with the syndrome of gonadal dysgenesis; and (2) delayed adolescence with an increased concentration of plasma FSH; (3) patients with clinical findings suggestive of Turner syndrome (eg, lymphedema of hands or feet, left-sided cardiac anomalies, characteristic facies, short fourth metacarpals, etc).

The initial evaluation of a patient with Turner syndrome should include karyotype analysis as well as FISH of 200 cells to rule out mosaicism or the presence of a Y chromosome in individuals with a 45,X karyotype and in those in whom a small nonidentifiable marker chromosome is present. A renal ultrasound is indicated to rule out surgically correctable anomalies. A cardiac evaluation with echocardiogram or MRI should be done to evaluate aortic size and rule out coarctation of the aorta or an anomaly of the aortic valve. Besides routine chemistries, gonadotropins, AMH (provides an estimate of the number of antral follicles), and inhibin B should be assessed in order to determine the status of the gonads. Periodic assessment of the cardiac status, especially in those with bicuspid aortic valves and/or hypertension, is indicated throughout the lifetime of the patient. Other systems which need periodic evaluation include: (1) thyroid function studies, (2) assessment of tissue transglutaminase activity for celiac disease, (3) hearing evaluation, (4) orthodontics, and (5) psychosocial and school performance issues. In view of the increased incidence of specific learning defects involving spatial relationships, executive skills, and so forth, it is prudent to evaluate these functions at 4 to 5 years of age so that appropriate remedial therapy can be undertaken as early as possible if warranted.

At adolescence, in addition to the continuing above assessments, lipids, fasting glucose and insulin, and liver function should be assessed. Psychosocial and educational issues should continue to be addressed with the patient and the parents.

Treatment: Maximizing growth and hormone replacement at puberty in order to engender an orderly progressive development of secondary characteristics at a time concordant with peers are two of the main goals of therapy in patients with Turner syndrome. Individuals with Turner syndrome treated with recombinant GH (0.375 mg/kg/wk divided into seven once-daily doses (maximum dose 15-18 mg/wk), with or without oxandrolone (0.0625 mg/kg/d by mouth), have an increase in the rate of growth that is sustained and results in a mean increase in height of 7 to 10 cm after 3 to 7 years of therapy. The serum IGF-1 level should be followed and the dose titered to maintain the IGF-1 level below the upper limit of normal for age. Beginning GH therapy earlier (as soon as growth failure is evident) in childhood allows for a longer duration of therapy which results in a greater gain in height and fosters initiation of estrogen replacement at an age commensurate with normal puberty. Before initiation of GH therapy, a thorough analysis of the costs, benefits, and possible side-effects must be discussed with the parents and the child. Significant side effects include: (1) the accelerated onset of diabetes mellitus in the pre-diabetic, (2) pseudotumor cerebri, (3) slipped femoral epiphysis, and (4) unknown long-term side effects. The influence of the gain in height on any of the quality of life parameters in individuals

FIGURE 14-12 Diphasic variation in basal levels of plasma follicle-stimulating hormone (FSH) (ng/mL-LER 869) in patients with a 45,X karyotype (solid triangles) and patients with structural abnormalities of the X chromosome and mosaics (solid circles). Note that mean basal levels of plasma FSH in patients with gonadal dysgenesis are in the castrate range before 4 years and after 10 years of age. (Reproduced with permission from Conte FA, Grumbach MM, Kaplan SL. A diphasic pattern of gonadotropin secretion in patients with the syndrome of gonadal dysgenesis. J Clin Endocrinol Metab. 1975;40:670.)
with Turner syndrome treated with GH has been questioned by some. There is no synergistic effect of combined estrogen replacement and GH therapy on final height in this disorder. However, in a recent study, percutaneous estrogen administration for pubertal induction was associated with a 2.1 cm greater adult height than oral estrogen administration. These data suggest that, as observed in adult women, oral estrogens decrease the plasma concentrations of IGF-1 and suppress IGF-1’s metabolic effects. Estrogen replacement therapy is usually initiated after 11 to 13 years of age.

Increasingly, transcervical estrogen administration by patch or gel, which avoids first pass through the liver, is the treatment of choice. After the first 18 to 24 months of estrogen therapy, medroxyprogesterone acetate (4–5 mg) or conjugated estrogens (0.3 mg or less) or ethinyl estradiol (3–5 μg) can be given orally for the first 21 days of the calendar month. Thereafter, the dose of estrogen is gradually increased over the next several years to 1.25 mg of conjugated estrogens or 10 μg of ethinyl estradiol daily for the first 21 days of the month. The minimum dose of estrogen necessary to initiate and maximize uterine development, secondary sexual characteristics, and menses, as well as to prevent osteoporosis should be administered. After the first 18 to 24 months of estrogen therapy, medroxyprogesterone acetate (5 mg) or a comparable progestin is given on the tenth to twenty-first days of the month to ensure physiologic menses and to reduce the risk of endometrial carcinoma, which is associated with unopposed estrogen stimulation.

We recommend a transition program when transferring adolescent or young adult patients to an adult caregiver. Ideally, this program will introduce the patient to the physicians who will be involved in her future care, which may include an internist, endocrinologist, reproductive endocrinologist, ENT specialist, adult cardiologist, and psychologist.

Many of the morbidities that contribute to the decrease in lifespan are detectable with comprehensive medical surveillance and are amenable to medical and/or surgical therapy. Protocols for the management of the adult Turner syndrome patient have been published (see Gravholt et al; Bondy et al; Conway in reference list at the end of this chapter). Individuals with Turner syndrome by nature are very maternal. They should be reassured about their sexual function and informed about their potential for maternity with donor eggs and in vitro fertilization in an age-appropriate manner. The success rate of ovum donation is 40% per treatment cycle, and only 50% of pregnancies achieve a live birth due to a high miscarriage rate. In one study, 38% of patients had pregnancy associated hypertensive problems. There is an increased risk of aortic dissections during pregnancy. Thus, all women with Turner syndrome who desire a pregnancy should have a careful, complete cardiac evaluation prior to egg implantation and close continued monitoring if pregnancy ensues. We recommend caesarian delivery to avoid the increased stress to the cardiovascular system associated with labor and because of the risk of cephalopelvic dystocia in these women.

**X Chromatin–Positive Variants of the Syndrome of Gonadal Dysgenesis**

Patients with structural abnormalities of the X chromosome (deletions and additions) and sex chromosome mosaicism with a 45,X cell line may manifest the somatic as well as the gonadal features of the syndrome of gonadal dysgenesis. Evidence suggests that genes on both the long and short arms of the X chromosome control gonadal differentiation, whereas genes primarily on the short arms of the X prevent the short stature and somatic anomalies that are seen in 45,X patients (see Figure 14–2). In general, 45,X/46,XX mosaicism modifies the 45,X phenotype toward normal and can even result in normal gonadal function and fertility. Patients with duplication of the long arms of the X chromosome and deletion of the short arm—the so-called Xq isochromosome—appear to have an increased prevalence of autoimmune thyroiditis, type 2 diabetes, and inflammatory bowel disease in comparison to those with a 45,X karyotype. Patients with a 46,X,X (ring) cell line in their karyotype may manifest mental retardation and congenital anomalies not usually associated with Turner syndrome. These abnormalities are related to lack of inactivation of small ring X chromosomes and, hence, functional disomy for genes on the ring X chromosome and the normal X chromosome.

**X Chromatin–Negative Variants of the Syndrome of Gonadal Dysgenesis**

These patients usually have mosaicism with a 45,X and a Y-bearing cell line—45,X/46,XY; 45,X/47,XXX; 45,X/46,XY/47,XXX—or perhaps a structurally abnormal Y chromosome. They range from phenotypic females with the features of Turner syndrome to patients with ambiguous genitalia to completely normal-looking males with few stigmas of Turner syndrome and short stature. The variations in gonadal differentiation range from bilateral streaks to bilateral dysgenetic testes to apparently normal testes, and there may be asymmetric development (eg, a streak on one side and a dysgenetic testis or, rarely, a normal testis on the other side)—sometimes called mixed gonadal dysgenesis. The development of the external genitalia and of the internal ducts correlates with the degree of testicular differentiation and the capacity of the fetal testes to secrete AMH and T.

The risk of gonadal tumors is greatly increased in patients with 45,X/46,XY mosaicism and streak or dysgenetic gonads; hence, prophylactic removal of streak gonads or dysgenetic undescended testes in this syndrome is indicated. Breast development at or after the age of puberty in these patients is commonly associated with a gonadal neoplasm, usually a gonadoblastoma. Pelvic sonography, computed tomography (CT), or MRI may be useful in screening...
for neoplasms in these patients. Gonadoblastomas are calcified and so may be visible even on a plain film of the abdomen.

**Diagnosis:** The diagnosis of 45,X/46,XY mosaicism can be established by the demonstration of both 45,X and 46,XY cells in blood, skin, or gonadal tissue. In some mosaics, a marker chromosome is found that is cytogenetically indistinguishable as X or Y. In these cases, either FISH or molecular analyses with X- and Y-specific probes is indicated to definitively determine the origin of the marker chromosome, because gonadoblastomas have been reported in patients with deleted Y chromosomes—even those with deletions of the SRY gene. Ninety percent of patients with 45,X/46,XY mosaicism ascertained by amniocentesis have normal male genitalia and normal testicular histology. Thus, the ambiguity of the genitalia invariably described in patients with 45,X/46,XY mosaicism is due to ascertainment bias. We have observed a short 30-year-old male with documented 45,X/46,XY mosaicism who has normal male genitalia and is fertile.

**Treatment:** The decision regarding the sex of rearing in this variant of the syndrome of gonadal dysgenesis should be based on the age at diagnosis and the potential for normal function of the external genitalia. In phenotypic females with 45,X/46,XY mosaicism assigned a female gender role, the dysgenetic gonads should be removed because of the risk of malignancy. Estrogen therapy should be initiated at the age of puberty, as in patients with a 45,X karyotype (see earlier). In affected infants who are assigned a male gender role, all gonadal tissue except that which appears functionally and histologically normal and is in the scrotum should be removed. An excellent phallic response to T can be anticipated. Repair of hypospadias is also indicated. At puberty, depending on the functional integrity of the retained gonads, T replacement therapy may be indicated in doses similar to those prescribed for patients with the incomplete form of XY gonadal dysgenesis. In patients with retained scrotal testes, frequent clinical examinations and ultrasonography is indicated. A gonadal biopsy postpubertally to rule out the possibility of carcinoma in situ (CIS), a premalignant lesion, should be performed. If CIS is present, low-dose radiation therapy or gonadectomy after sperm retrieval is indicated.

In infants and children with 45,X/46,XY mosaicism who have normal genitalia and normal testicular integrity as assessed by AMH, inhibit B, gonadotropin levels, and ultrasonography, the gonads should be retained and followed closely both hormonally and by ultrasound. In those 45,X/46,XY individuals with presumably “normal” testes, a gonadal biopsy should be performed, post-pubertally. If biopsy and sonography show no evidence of CIS, a second biopsy at 20 years of age is recommended. The risk of gonadal malignancies in males with 45,X/46,XY mosaicism, who have normal male genitalia and histologically and functionally normal testes in the scrotum, remains to be ascertained, although we hypothesize it may be no higher than that seen in 46,XY males.

**Dysgenetic 46,XX and 46,XY DSD (46,XX and 46,XY Gonadal Dysgenesis)**

The terms complete XX and XY gonadal dysgenesis have been applied to 46,XX or 46,XY patients who have bilateral streak gonads, a female phenotype, and no somatic stigmas of Turner syndrome. After the age of puberty, these patients exhibit sexual infantilism, castrate levels of plasma and urinary gonadotropins, normal or tall stature, and eunuchoid proportions.

**Dysgenetic 46,XX DSD (46,XX Gonadal Dysgenesis)**

Normal ovarian determination is dependent on X chromosomal genes as well as autosomal genes. Unlike the testes, the ovary requires the presence of germ cells in order to develop and function. Therefore, mutations in genes on the autosomes and X chromosome that affect gonadal determination (eg, DMRT1 and SF-1) as well as those that affect germ cell differentiation and development, migration into the gonadal ridge, and maturation into oocytes can cause XX gonadal dysgenesis. Expansion of the CAG repeat region of the fragile X locus can cause accelerated oocyte depletion and premature ovarian failure. Haploinsufficiency of FOXL2, a gene on chromosome 3q23, is a cause of autosomal dominant blepharophimosis- ptosis-epicanthus inversus syndrome (BPES type 1) and XX gonadal dysgenesis. A woman with a FOXL2 mutation, but without the BPES phenotype, has been described. Recently, SF-1 mutations in members of four families as well as 2/25 subjects with isolated ovarian insufficiency have extended the spectrum of phenotypes associated with SF-1 mutations. A multiplicity of genes involved in meiosis, DNA repair and folliculogenesis have recently been implicated as a cause of ovarian dysgenesis.

Familial and sporadic cases of XX gonadal dysgenesis are reported with an estimated incidence as high as 1:8300 females in Finland. Pedigree analysis of familial cases is consistent with autosomal recessive inheritance. Analysis of familial cases in Finland linked a locus on chromosome 2p to XX gonadal dysgenesis in females; the gene for the FSH receptor resides on chromosome 2p. A mutation in exon 7 of the gene encoding the FSH receptor segregates with XX gonadal dysgenesis. This mutation is in the extracellular ligand-binding domain of the FSH receptor and reduces the binding capacity and, consequently, signal transduction of the receptor. At puberty, this resulted in variable ovarian function, including streak ovaries and hypergonadotropic hypogonadism in some girls. Several studies of females with 46,XX gonadal dysgenesis in Western Europe and the United States were negative for FSH receptor gene mutations, suggesting that a mutation in this gene is a rare cause of XX gonadal dysgenesis outside of Finland. Males homozygous for this mutation are phenotypically normal, with spermatogenesis varying from normal to absent.

Studies of familial cohorts have supported heterogeneity in the pathogenesis of this syndrome. Siblings, one with a 46,XX karyotype and the other with a 46,XY karyotype, both with gonadal agenesis, have been reported, supporting the involvement of an autosomal gene in this family. However, in view of the normal phenotype in XY males observed with a mutation in the FSH receptor, it seems unlikely that these patients have an FSH receptor defect. In one family, four affected women had an inherited interstitial deletion of the long arm of the X chromosome involving the q21-q27 region (see Figure 14–2). This region apparently...
contains a gene or genes critical to ovarian development and function. In several affected families, XX gonadal dysgenesis was associated with deafness of the sensorineural type as well as other neurologic dysfunction.

**Diagnosis:** 46,XX gonadal dysgenesis should be suspected in phenotypic females with sexual infantilism and normal Müllerian structures who lack the somatic stigmas of the syndrome of gonadal dysgenesis (Turner syndrome). Karyotype analysis reveals only 46,XX cells. As in Turner syndrome, gonadotropin levels are high, inhibin A and B and AMH levels as well as estrogen levels are low. Ultrasound or MRI reveals a streak or dysgenetic ovary, and treatment consists of cyclic estrogen and progesterone replacement as previously discussed for patients with Turner syndrome.

Sporadic cases of XX gonadal dysgenesis, similar to familial cases, may represent a heterogeneous group of patients from a pathogenetic point of view. XX gonadal dysgenesis should be distinguished from ovarian failure due to radiation and chemotherapy for childhood malignancies, infections such as mumps, antibodies to gonadotropin receptors, biologically inactive FSH, gonadotropin-insensitive ovaries, and galactosemia.

### 46,XY DSD (Complete or Partial Gonadal Dysgenesis)

46,XY gonadal dysgenesis occurs both sporadically and in familial aggregates. Patients with the complete form of this syndrome have female external genitalia, normal or tall stature, bilateral streak gonads, Müllerian duct development, sexual infantilism, eunuchoid habitus, and a 46,XY karyotype. Clitoromegaly is common and, in familial cases as well as sporadic cases, a continuum of involvement ranging from the complete syndrome to ambiguity of the external genitalia has been described. The phenotypic difference between the complete and incomplete forms of XY gonadal dysgenesis is related to the degree of differentiation of testicular tissue and the functional capacity of the fetal testis to produce T and AMH. Early in infancy and after the age of puberty, plasma gonadotropin levels are markedly elevated.

Analyses of familial and sporadic cases of 46,XY gonadal dysgenesis indicate that about 15% to 20% of patients have a mutation of the SRY gene that affects DNA binding or bending by the SRY protein or a mutation in the calmodulin or importin domains of the SRY gene that affects the nuclear localization signals. Most patients in whom mutations have been detected have had complete gonadal dysgenesis. Patients with deletions of the short arm of the Y chromosome may have, in addition to gonadal dysgenesis, stigmas of Turner syndrome. A mutation in the HMG box of the SRY gene has been described in normal 46,XY fathers of daughters who had 46,XY gonadal dysgenesis. These familial cohorts suggest the possibility of germ cell mosaicism in the father or that a mutation or modifier genes may affect either the level or the timing of SRY expression and in this manner result in either normal or abnormal testicular differentiation. Mutations outside the HMG box region of the SRY gene or in X-linked or autosomal genes involved in testicular determination and function may be responsible for those individuals in whom no molecular abnormality in the SRY gene has been found.

Three of six 46,XY patients with complete gonadal dysgenesis in one study had homozygous mutations of the gene encoding DHH (Desert Hedgehog).

A number of patients with 46,XY gonadal dysgenesis has been reported with a duplication of the Xp21.2 → p22.12 region of the X chromosome. This region contains the DAX1 gene. Deletion or mutation of DAX1 in males causes adrenal hypoplasia congenita and hypogonadotropic hypogonadism. The finding that 46,XY males with adrenal hypoplasia and hypogonadotropic hypogonadism have normal sex differentiation suggests that DAX1 is not required for testicular differentiation in the human; duplication of DAX1, however, impairs testis differentiation possibly by upregulating B-catenin/WNT4, which downregulates SOX9 preventing testicular development.

XY gonadal dysgenesis associated with campomelic dysplasia is due to a mutation of one allele of an SRY-related gene, SOX9 on chromosome 17. Sometimes the mutation occurs in upstream regulatory elements of the gene. In addition, XY gonadal dysgenesis has been associated with 9p–(DMRT1) and 10q–deletions, mutations in, as well as duplication of, 1p31-32 (WNT4).

Steroidogenic factor-1 (SF-1) is a transcriptional regulator of adrenal and gonadal development, hormone synthesis, and functions with other genes in the sex determination and differentiation cascade. The phenotype is variable and depends on whether the individual has a heterozygous or homozygous mutation as well as functional deficiency in SF-1 activity as a result of the specific mutation. The phenotype is also most likely affected by background genetic factors and cofactors. Mutations in the gene encoding SF-1 are associated with 46,XY DSD. Similar to the mouse knockout, the severely affected XY individual presents with gonadal streaks with female sex differentiation and neonatal onset adrenal insufficiency. Recently, 46,XY patients with ambiguous genitalia (and in one case, female external genitalia) with or without Müllerian ducts and normal adrenal function have been reported, which suggests that adrenal development and function are less sensitive to SF-1 dosage levels than gonadal development and function. The phenotypic spectrum of SF-1 deficiency includes 46,XY males with microopenis and in one case normal male external genitalia and anosmia as well as infertile males and 46,XX females with primary or secondary ovarian failure. The phenotypic spectrum was recently expanded to include a 46,XY newborn with hypospadias and microopenis who virilized normally at puberty but had evidence of progressive Sertoli cell deficiency as evidenced by elevated FSH levels and low inhibin B levels. Thus, as with other genes in the sex determination cascade, gene dosage and cofactors play a critical role in phenotypic expression. Both heterozygous and homozygous mutations in SF-1 have been described in 46,XX females with isolated primary ovarian insufficiency.

Mutations and deletions of the Wilms tumor repressor gene WT1 are a cause of XY gonadal dysgenesis and renal disease (eg, Denys-Drash syndrome, Frasier syndrome, and the WAGR syndrome). Denys-Drash syndrome is due to a mutation in a coding exon of the WT1 gene. These mutations act in a dominant-negative fashion to produce the Denys-Drash phenotype, which
is characterized by testicular dysgenesis, early renal failure due to mesangial sclerosis, and a predisposition to the development of Wilms tumor. Müllerian ducts may be present or absent depending on the degree of Sertoli cell dysfunction. The external genitalia are undervirilized. Frasier syndrome is due to a mutation in the donor splice site of exon 9, resulting in loss of three amino acids—lysine, threonine, and serine (KTS), thus changing the ratio of KTS+ to KTS− isomers of this protein. The resultant phenotype is characterized by streak gonads, the presence of Müllerian structures, female external genitalia, late-onset nephropathy due to segmental glomerulosclerosis, and an increased risk of gonadoblastoma. WAGR syndrome is due to a deletion of a segment of 11p13, which contains the WTI gene and the PAX6 gene causing haploinsufficiency of these genes. The resultant phenotype includes Wilms tumor, aniridia genitourinary abnormalities, and mental retardation.

A 46,XY patient with normal female genitalia and Müllerian structures had a homozygous mutation of CBX2—the human homologue of m33, a gene that when mutated causes sex reversal in mice. This gene is postulated to be upstream of SRY in the ever-expanding gene cascade of sex development. The patient had elevated FSH levels in infancy and the presence of "bilateral ovaries" with sparse primordial follicles on biopsy at 4½ years of age suggesting gonadal dysgenesis.

Mutations in the Map3k1 have been recently demonstrated to cause sex reversal in mice as well as 46,XY humans. Recently, mutations in this gene have been described in patients with partial and complete gonadal dysgenesis. In two families, the mutation was inherited as a sex-limited autosomal dominant. Interestingly, in these families the mutation resulted in activation of the MAPK pathway as opposed to inactivation as observed in the mouse and in a 46,XY fertile female. A resolution to this apparent discrepancy in action is still to be clarified.

**Therapy:** Therapy for phenotypic females with 46,XY gonadal dysgenesis involves prophylactic gonadectomy at diagnosis, due to the high risk of malignancy in these gonads, and estrogen substitution at puberty. In the incomplete form of XY gonadal dysgenesis, assignment of a male gender is possible and treatment with testosterone to augment phallic size in infancy is recommended. Prophylactic gonadectomy must be considered, because fertility is unlikely (gonadotropins are invariably elevated, and AMH and inhibin B levels are low or unmeasurable). In addition, there is an increased risk of malignant transformation of the dysgenetic gonads in these patients, especially those who are SRY-positive and have intra-abdominal dysgenetic gonads and those with Frasier and Denys-Drash syndrome. If a gonad is preserved in the scrotum because it is histologically normal and hormonally functional, it should be followed closely by physical examination and ultrasound and biopsied postpubertally to rule out CIS, a premalignant lesion. In affected individuals raised as males, we recommend that prosthetic testes be implanted at the time of gonadectomy and androgen substitution therapy instituted at the age of puberty. Testosterone enanthate in oil (or another long-acting T ester) is used, beginning with 50 mg intramuscularly every 4 weeks and gradually increasing after a bone age of 14½ years to a full replacement dose of 200 mg intramuscularly every 2 weeks. Alternatively T patches or gels may be used.

**OVOTESTICULAR DSD (INDIVIDUALS WITH BOTH OVARIAN AND TESTICULAR TISSUE)**

In these individuals, both ovarian and testicular tissues are present in one or both gonads. Differentiation of the internal and external genitalia is highly variable. The external genitalia may simulate those of a male or female, but most often they are atypical. Cryptorchidism and hypospadias are common. A testis or ovotestis, if present, is located in the labioscrotal folds in one-third of patients, in the inguinal canal in one-third, and in the abdomen in the remainder. A uterus is usually present, although it may be hypoplastic or unicornuate. The differentiation of the genital ducts usually follows that of the ipsilateral gonad. The ovotestis is the most common gonad found in these individuals (60%), followed by an ovary and, least commonly, by a testis. At puberty, breast development is usual in untreated patients, and menses occur in over 50% of cases. Whereas the ovary or the ovarian portion of an ovotestis may function normally, the testis or testicular portion of an ovotestis is invariably dysgenetic and should be removed in 46,XX patients raised as females.

Sixty percent have a 46,XX karyotype, 20% are 46,XY, and about 20% have sex chromosome mosaicism or 46,XX/46,XY chimerism. Those with a 46,XX karyotype are genetically heterogeneous. Only a small proportion, including some in family cohorts with 46,XX males, are SRY positive. In these individuals, Y-to-X and Y-to-autosome translocations, hidden sex chromosome mosaicism, or chimerism may explain the pathogenesis. A number of families have been reported in which both SRY-negative 46,XX males and 46,XX ovotesticular DSDs occurred. This latter observation suggests a common genetic pathogenesis in these patients. Possible genetic mechanisms to explain SRY-negative individuals include (1) mutation of a downstream autosomal gene or modifier gene involved in testicular determination; (2) mutation, deletion, or anomalous inactivation of an X- or autosome-linked locus involved in repression of testis determination. A 46,XX ovotesticular DSD with palmoplantar keratoderma, congenital bilateral corneal opacification, onychodystrophy, and hearing impairment has been reported. This patient had a homozygous splice site mutation in the RSPO1 gene. This is the first demonstration of a mutation in a single gene (in the ovarian determining pathway) causing ovotesticular DSD; or (3) circumscribed chimerism or mosaicism that occurred only in the gonads. Studies of eight ovotestes from 46,XX individuals detected low levels of the SRY gene. Immunohistochemistry has identified SRY protein localized predominantly in Sertoli and germ cells.

**Diagnosis:** Ovotesticular DSD should be considered in all patients with ambiguous genitalia. The finding of a 46,XX/46,XY karyotype or a bilobulate gonad compatible with an ovotestis in the inguinal region or labioscrotal folds suggests the diagnosis. Basal plasma T levels are elevated above 40 ng/dL in affected patients under 6 months of age, and T levels increase after hCG stimulation. The estradiol and inhibin A response to human
menopausal gonadotropins or recombinant human FSH is a reliable test for the presence of ovarian tissue. This test, when coupled with the hCG-induced rise in T, differentiates infants with both ovarian and testicular tissue from those with other disorders of sexual differentiation.

If all other forms of 46,XY and 46,XX DSD have been excluded and hormonal studies are nondiagnostic, laparotomy and histologic confirmation of both ovarian and testicular tissue establish the diagnosis. The management of these individuals is contingent on both the age at diagnosis and of a careful assessment of the functional capacity of the gonads, the genital duct differentiation, and the appearance of the external genitalia. In general, 46,XX individuals are raised as females, with the possible exception of the well-virilized patient in whom no uterus is found. Preservation of the ovarian tissue and removal of all testicular tissue are sometimes possible in patients who have an ovary on one side or an ovotestis with distinct margins of separation (bilocate). Fertility has been reported in 46,XX individuals with functional ovarian gonadal tissue.

**Gonadal Neoplasms in Dysgenetic Gonads**

Gonadal tumors are rare in patients with 47,XXY Klinefelter syndrome and 45,X gonadal dysgenesis. However, the prevalence of gonadal neoplasms is greatly increased in patients with 46,XY DSDs with dysgenetic testes (Table 14-2). The frequency is increased in 45,X/46,XY mosaics who have female or ambiguous genitalia; in those with a structurally abnormal Y chromosome; and in those with XY gonadal dysgenesis, either with a female phenotype or with ambiguous genitalia (eg, Frasier [60%], Denys-Drash syndrome [40%]) (see Table 14–2). Gonadoblastomas, germ cellomas, seminomas, and teratomas are found most frequently. Prophylactic gonadectomy is indicated in these patients as well as in those with Turner syndrome who manifest signs of virilization, regardless of karyotype. The significance of hidden mosaicism for Y chromosomal DNA determined by polymerase chain reaction analysis in patients with 45,X Turner syndrome is controversial with respect to the risk of gonadal neoplasms. Registry studies in Denmark indicate that the incidence of gonadoblastoma in patients with Turner syndrome without a cytogenetically identified Y chromosome is rare. Thus, routine use of polymerase chain reaction studies of all patients with 45,X Turner syndrome is not indicated. Gonadoblastomas have been reported in patients with mosaic chromosomes of Y origin lacking the SRY gene. Thus, screening by FISH for Y chromosomal DNA in blood seems prudent in these patients, as well as other patients with Turner syndrome, as it enables one to count a large number of cells with a minimum of effort and time. The testis should be preserved in patients who are to be raised as males, only if it is histologically and functionally normal, and it is or can be situated in the scrotum. The fact that a testis is palpable in the scrotum does not preclude malignant degeneration and tumor dissemination, because seminomas tend to metastasize at an early stage before a mass is obvious.

Malignant testicular germ cell tumors including seminomas, embryonal carcinomas, teratomas, and yolk sac tumors appear to develop from CIS. These cells are thought to arise in utero from fetal gonocytes and to metamorphose with time in the dysgenetic ovarian gonadal tissue.

*Gonadectomy is recommended in these patients at diagnosis because germ cell tumors in these patients may occur in infancy and childhood.

*Patients with CAIS should be allowed to feminize spontaneously at puberty. In CAIS patients who refuse prophylactic gonadectomy, a biopsy of the gonads to rule out CIS is recommended. In XO/XY males with scrotal testes being raised as males, careful follow-up with ultrasound prepubertally and biopsy postpubertally to rule out CIS is indicated.

environment into testicular malignancies. The incidence of CIS and seminomas is low in patients with complete androgen insensitivity but significantly higher in patients with partial androgen insensitivity with intra-abdominal gonads (see Table 14-2). Clues to the presence of CIS are the presence of an inhomogeneous testicular parenchyma and testicular microlithiasis, as well as a low inhibin B level. It has been suggested that immunohistochemistry for Oct 3/4 is mandatory when evaluating testicular biopsies for CIS, since Oct 3/4 is a gene that may be involved in germ cell tumors and is not normally expressed in postpubertal testes. An increased prevalence of low sperm counts, cryptorchidism, hypospadias, and testicular cancer has been reported in Denmark compared to Finland. This has been called the testicular dysgenesis syndrome and ascribed to both genetic and environmental factors such as exposure to endocrine disruptors.

46,XX DSD ANDROGEN INDUCED (FEMALE PSEUDOHERMAPHRODITISM)

Affected individuals have normal ovaries and Müllerian derivatives associated with ambiguous external genitalia. In the absence of testes, a female fetus is masculinized if subjected to increased circulating levels of androgens derived from a fetal or maternal source. The degree of masculinization depends on the stage of differentiation at the time of exposure (Figure 14-13). After 12 weeks of gestation, androgens produce only clitoral hypertrophy. Rarely, ambiguous genitalia that superficially resemble those produced by androgens are the result of other teratogenic factors.

Fetal Source: Congenital Adrenal Hyperplasia (Figure 14-14, Table 14-3)

Congenital adrenal hyperplasia (CAH) is responsible for most cases of 46,XX DSD and about 50% of all cases of ambiguous genitalia. There are six major types of CAH, all transmitted as autosomal recessive disorders. The common denominator of all six types is a defect in the synthesis of cortisol that results in an increase in ACTH and consequently adrenal hyperplasia and the secretion of steroids synthesized prior to the enzymatic block. Both males and females can be affected, but males are rarely diagnosed at birth unless they have ambiguous genitalia, are salt-losers and manifest adrenal crises, are identified during newborn screening, or are known to be at risk because they have an affected sibling. Defects in 21-hydroxylase and 11β-hydroxylase are confined to the adrenal gland and produce virilization.

A new form of CAH has been described due to mutations in the gene encoding P450 oxidoreductase (POR), a single flavoprotein that donates electrons to all microsomal cytochrome P450 enzymes, including 17α-hydroxylase/17,20-lyase, 21-hydroxylase, and aromatase. The mothers of affected fetuses are at risk for virilization during pregnancy if aromatase activity is significantly affected by the mutation. 46,XX patients with this defect in adrenal and ovarian steroidogenesis have ambiguous genitalia, whereas those with a 46,XY karyotype have incomplete masculinization of the external genitalia.

P450c21 Hydroxylase Deficiency

21-Hydroxylase activity is mediated by P450c21, a microsomal cytochrome P450 enzyme that is expressed as an autosomal recessive. A deficiency of this enzyme results in the most common type of adrenal hyperplasia, with an overall prevalence of 1:14,000 live births in Caucasians. More than 90% of patients with CAH in North America and Europe have 21-hydroxylase deficiency. The locus for the gene that encodes 21-hydroxylase is on the short arm of chromosome 6, close to the locus for C4 (complement) between HLA-B and HLA-D. DNA analysis has detected two genes, designated P450c21A (CYP21p) and P450c21B (CYP21), in this region in tandem with the two genes for complement, C4A and C4B, as well as two genes Xa and Xb, which overlap one another on the opposite strands of DNA from P450c21A and P450c21B. Xa and Xb code for an extracellular matrix protein called Tenascin-X. P450c21A is a nonfunctional pseudogene (ie, it is missing critical structural sequences and does not encode a functional 21-hydroxylase). Seventy-five to eighty percent of patients...
with classic P450c21 deficiency have point mutations that change a portion of the P450c21B to a sequence similar to that in the nonfunctional P450c21A gene—hence a microgene conversion. Approximately 15% of severely affected 21-OH genes have a deletion extending from a position between exon 3 and exon 8 of the P450c21A pseudogene to a similar region of the 21-OHB gene, resulting in a nonfunctional fusion 21-OHA/21-OHB gene. This is the result of misalignment and unequal crossing over. The remainder have de novo point mutations and macrogene conversions.

Classic salt-wasting 21-hydroxylase deficiency is associated with point mutations, deletions, or gene conversions that abolish or severely reduce 21-hydroxylase activity. Most patients with 21-hydroxylase deficiency are compound heterozygotes (ie, they have a different genetic mutation on each of their P450c21B allelic genes) having inherited a mutant gene from each of their parents. A spontaneous mutation in the 21-hydroxylase gene occurs in 1% to 2% of patients.

The phenotypic spectrum—salt loss with severe virilization, simple virilization, or late onset of virilization—is a consequence of the degree of enzymatic deficiency. The phenotype is determined in patients with compound heterozygosity by the functionally less severely mutated P450c21B allele. In rare cases, there is variability between genotype and phenotype. The gene for P450c21 (21-hydroxylase) deficiency is not only closely linked to the HLA supergene complex, but certain specific HLA subtypes are found to be statistically increased in patients with 21-hydroxylase deficiency.

**P450c21 hydroxylase deficiency with virilization and salt loss** The salt-losing variant of P450c21 hydroxylase deficiency accounts for about 80% of patients with classic 21-hydroxylase deficiency and involves a severe reduction (98%) in P450c21-hydroxylase activity, leading to impaired secretion of both cortisol and aldosterone. This results in electrolyte and fluid losses after the fifth day of life and, as a consequence, hyponatremia, hyperkalemia, acidosis, dehydration, and vascular collapse. Rarely, this can occur as late as 6 to 12 weeks, usually associated with a concomitant physiologic stress. In the female fetus before 12 weeks' gestation, high fetal DHT levels result from increased T and DHEA-S secreted from the 21-hydroxylase-deficient adrenal gland which cannot synthesize cortisol when aromatase activity is

<sup>†</sup>StAR, steroidogenic acute regulatory protein. StAR deficiency leads to secondary P450scc deficiency.

<sup>★</sup>A nonclassic form has been reported.

<sup>★</sup>Patients may manifest dysmorphic features (Antley-Bixler syndrome). Virilization is not progressive in females. Males with mild mutations may have normal genitalia and infertility.

<sup>★</sup>Normal female genitalia in nonclassic late-onset and cryptic form. These forms do not manifest clinical or biochemical evidence of aldosterone deficiency.

<sup>†</sup>The 20% of patients who appear to be non-salt losers may manifest classic adrenal crises with severe illness and will develop hyponatremia when challenged with a low sodium diet.

<sup>†</sup>Late-onset form with ambiguous or hypospadiac male genitalia and cortisol insufficiency in childhood.

relatively low. In addition, P450c21-21-hydroxylase deficiency results in an elevated level of 17OH progesterone which is not readily converted to androstenedione in humans but may be converted via a backdoor steroid pathway to DHT, a nonaromatizable androgen (see Figure 14–10). It has been suggested that DHT synthesis from elevated 17OH progesterone levels may contribute to the fetal masculinization of the external genitalia and the postnatal virilization of patients with P450c21-hydroxylase deficiency. Elevated DHT levels from 8 to 12 weeks of gestation results in varying degrees of labioscrotal fusion and clitoromegaly in affected 46,XX females. After 12 weeks, androgen receptor activity in the labioscrotal folds diminishes, and only clitoromegaly ensues from the elevated DHT levels.

Masculinization of the external genitalia of affected females who are salt-losers tends to be more severe than individuals with apparent non–salt-losing P450c21-hydroxylase deficiency. Affected males may have macrogenitosomia. Recently, patients with 21-hydroxylase and 11β-hydroxylase deficiency have been shown to have adrenomedullary hypofunction secondary to low intra-adrenal concentrations of cortisol and developmental defects in formation of the adrenal medulla. This defect in catecholamine synthesis may predispose these patients to hypoglycemia with stress in infancy.

**P450c21 hydroxylase deficiency with virilization alone** The simple virilizing form of P450c21 (21-hydroxylase) deficiency results in impaired cortisol synthesis, increased ACTH levels, and increased adrenal androgen precursor and androgen secretion. It accounts for about 20% of individuals with classic P450c21 hydroxylase deficiency and is primarily due to missense mutations such as 1172N, which retain enough P450c21-hydroxylase activity to produce sufficient aldosterone to prevent hyponatremia/hyperkalemia under normal circumstances. In general, affected females have a less severe degree of masculinization of their external genitalia than those with the salt-wasting form of P450c21 hydroxylase deficiency. In the male fetus, no abnormalities in the external genitalia are evident at birth, but the phallus may be enlarged. These patients produce sufficient amounts of aldosterone to prevent the signs and symptoms of mineralocorticoid deficiency except when they are salt-deprived. They may also manifest a defect in mineralocorticoid synthesis as evidenced by an elevated plasma renin level. Virilization continues after birth in untreated patients. This results in rapid growth and bone maturation as well as the physical signs of excess androgen secretion (eg, acne, seborrhea, increased muscular development, premature development of pubic or axillary hair, and phallic enlargement). True (central) precocious puberty can occur following initiation of glucocorticoid therapy in affected children with advanced bone ages.

**Nonclassic P450c21 hydroxylase deficiency** Mild defects in P450c21 (21-hydroxylase) activity not causing a DSD have been reported. Patients can be symptomatic (late-onset or nonclassic) or asymptomatic (cryptic form). These mild forms of P450c21 hydroxylase deficiency are HLA-linked, as is classic P450c21 hydroxylase deficiency; however, they occur much more frequently than the classic form of the disease in certain ethnic populations. It has been postulated that nonclassic P450c21 hydroxylase deficiency is the most common autosomal recessive disorder. The frequency of nonclassic P450c21 hydroxylase deficiency is thought to be as high as 1 in 27 for Ashkenazi Jews, 1 in 53 for Hispanics, 1 in 333 for Italians, and 1 in 1000 for other Caucasians. The prevalence of heterozygosity for a nonclassic allele has varied from 1.2 to 6%. Affected patients with nonclassical 21-hydroxylase deficiency are either homozygous for a mild mutation (eg, V281L) or are compound heterozygotes with the other allele harboring a severe mutation (27%-76% of the time). Thus, it is prudent to genotype the partners of a nonclassic patient who is carrying a severe mutation, in order to offer genetic counseling and, if necessary, prenatal diagnosis. The clinical expression of nonclassical congenital adrenal hyperplasia is very variable in individuals with the same genotypes within families with some being asymptomatic (cryptic). Females with late-onset P450c21 hydroxylase deficiency have normal female genitalia at birth. Mild virilization occurs later in childhood and adolescence manifesting primarily as hirsutism. Other signs of excess androgen secretion, such as the premature development of pubic or axillary hair (premature pubarche), slight clitoral enlargement, advanced bone age, menstrual irregularities acne, polycystic ovary syndrome, decreased fertility, may also occur. Affected males have normal male genitalia at birth. Later in childhood, some become symptomatic and exhibit premature growth of pubic or axillary hair, and advancement of their bone age. Although they are tall as children, they end up short as adults due to advanced bone maturation and premature epiphysial fusion unless they are treated.

**Diagnosis** The diagnosis of P450c21 hydroxylase deficiency should always be considered in the following: (1) patients with ambiguous genitalia who have a 46,XX karyotype with a uterus and ovaries on ultrasonography; (2) apparent cryptorchid males; (3) infants who present with shock, hypoglycemia, and serum chemistries compatible with adrenal insufficiency; and (4) males or females with signs of virilization before puberty, including premature pubarche. In the past, the diagnosis of P450c21 hydroxylase deficiency was based on the finding of elevated levels of 17-ketosteroids and pregnanetriol in the urine. Although urinary steroid determinations are still useful, they have been replaced by the simpler and more cost-effective measurement of plasma 17-hydroxyprogesterone, androstenedione, and T levels by liquid chromatography and tandem mass spectroscopy (LCMSMS).

The concentration of plasma 17-hydroxyprogesterone is elevated in umbilical cord blood but rapidly decreases into the range of 100 to 200 ng/dL (3.6 nmol/L) by 48 hours after delivery. In premature infants and in stressed full-term newborns, the levels of 17-hydroxyprogesterone are higher than those observed in nonstressed full-term infants. In patients with P450c21 hydroxylase deficiency, the 17-hydroxyprogesterone values usually are greater than 5000 ng/dL (150 nmol/L) on baseline samples drawn after 48 hours, depending on the age of the patient and the severity of P450c21 hydroxylase deficiency. Patients with mild P450c21 hydroxylase deficiency (eg, late-onset and cryptic forms) may have borderline basal 17-hydroxyprogesterone values, but they can be distinguished from heterozygotes by the magnitude of the
17-hydroxyprogesterone response to the parenteral administration of ACTH as well as by genotyping. Patients with baseline 17-OH progesterone levels over 10,000 μg/dL after 2 days of age or those with ACTH-induced responses that are over 10,000 μg/dL have classic 21-hydroxylase deficiency. Those who have levels at baseline which are above the normal range and who respond to ACTH with levels at 1500 to 10,000 ng/dL probably have non-classic 21-hydroxylase deficiency. Those who are unaffected or heterozygotes respond to ACTH with a rise to less than 1500 ng/dL. Patients with borderline 17-OH progesterone responses can be genotyped to ascertain their status. As 17-OH progesterone levels are elevated in patients with 11-hydroxylase deficiency, 3-beta-dehydrogenase, 17,20-lyase, and P450 oxidoreductase deficiencies, it is prudent to do an ACTH stimulation test measuring 17-OH progesterone, 11-deoxycortisol, 17-OH pregnenolone, DOC, progesterone, T, and cortisol at baseline and at 1 hour before reaching a definitive diagnosis. Elevated 21-deoxycortisol levels are a specific and sensitive indicator of 21-hydroxylase deficiency. 21-deoxycortisol measurements can be used to differentiate between patients with elevated 17-hydroxypregesterone levels, who have 21-hydroxylase deficiency and sick newborns and premature infants who have false positive 17-hydroxypregesterone levels on screening.

In patients with the salt-losing form of 21-hydroxylase deficiency, aldosterone levels in both plasma and urine are low in relation to the serum sodium concentration, while plasma renin activity is markedly elevated. The plasma aldosterone-renin ratio will be low. Breast milk and infant formulas have a low concentration of sodium which usually unmasks the diagnosis of salt loss by 7 to 14 days. The salt-losing episode is heralded by a rise in serum potassium with a subsequent fall in sodium and bicarbonate. The diagnosis of non-classic (late-onset 21-hydroxylase deficiency) can be made in the symptomatic patient (eg, one with early development of pubic hair, acne, and other signs of androgen excess) by measuring a plasma 17-OH progesterone level between 7 to 9 AM. Levels below 200 ng/dL rule out late-onset CAH. Higher levels should be evaluated by an ACTH test which will distinguish 21-hydroxylase deficiency from other causes of elevated 17-OH progesterone levels.

The diagnosis of 21-hydroxylase deficiency in newborn males has been facilitated by routine neonatal screening or 17-OH progesterone by filter paper (Guthrie cards) at 2 to 3 days of life. Screening reduces the morbidity and mortality associated with late or nondiagnosis especially in male infants with the salt-losing form of 21-hydroxylase deficiency. Males with simple virilization may not be diagnosed until later in infancy when virilization and advanced bone maturation associated with pubertal testes are evident. Prematurity and illness are confounding factors since both are associated with elevated levels of 17-OH progesterone. If the patient is reported positive by the laboratory and the levels are borderline or moderately elevated, it is prudent to examine the patient, review the history (especially confounders such as prematurity, concomitant stress, day of life specimen obtained, etc.), and repeat the 17-OH progesterone screen by LCMSMS (liquid chromatography, tandem mass spectrometry) from a venous sample. The parents should be counseled about possible symptomatology until the results return. If the screening value is a lot higher than the cutoffs, then examination, electrolytes, plasma 17-OH progesterone, androstenedione, and T levels by LCMSMS should be obtained. Depending on the age and clinical status of the infant, hospitalization, an ACTH test and therapy should be considered. A karyotype and pelvic ultrasound are always indicated in any infant with atypical genitalia and in apparent males with undescended testes especially those with evidence of salt loss.

**P450c11 hydroxylase deficiency** Classic P450c11 hydroxylase deficiency (virilization with hypertension) is rare. It occurs in 1:100,000 births in persons of European ancestry. However, in the Middle Eastern population, it is much more common. In the patient with classic disease, a defect in 11-hydroxylation leads to decreased cortisol levels with a consequent increase in ACTH and the hypersecretion of DOC (deoxycorticosterone) and 11-deoxycortisol in addition to adrenal androgens. Marked heterogeneity in the clinical and hormonal manifestations of this defect has been described, including mild, late-onset, and even cryptic forms. Patients with this form of adrenal hyperplasia classically exhibit virilization, secondary to increased androgen production, and hypertension, related to increased DOC secretion. Plasma renin activity is either normal or suppressed. The hypertension is variable; it occurs in approximately two-thirds of patients and may be associated with hypokalemic alkalosis. Newborns with 11-hydroxylation deficiency may manifest transient salt loss probably related to their salt-restricted diet and relative resistance to mineralocorticoids.

Two P450c11 hydroxylase genes have been localized to the long arm of chromosome 8: P450c11b1 and P450c11b2. Similar to 21-hydroxylase, these two genes are 95% homologous. P450c11b1 encodes the enzyme for 11-hydroxylation and is expressed in the zona fasciculata and zona reticularis and is ACTH dependent. It primarily mediates 11-hydroxylation of 11-deoxycorticisol to cortisol and DOC to corticosterone. It has about one-twelfth the capacity of P450c11b2 for 18-hydroxylation and does not oxidize 18-hydroxycorticosterone to aldosterone. P450c11b2 encodes the angiotensin-dependent isozyme aldosterone synthase and is only expressed in the zona glomerulosa, where it mediates 11-hydroxylation, 18-hydroxylation, and 18-oxidation. Mutations, deletions, and gene duplications of these genes can produce a wide variety of clinical manifestations from virilization and hypertension (P450c11b1 deficiency) to isolated salt-wasting (P450c11b2 [aldosterone synthase] deficiency) to glucocorticoid-remedial hypertension (due to fusion of the ACTH-dependent regulatory region of the 11-hydroxylation gene with the coding region of aldosterone synthase). Both genes encoding P450c11b1 and P450c11b2 are located on chromosome 8 and thus are not linked to HLA. ACTH stimulation tests have thus far failed to demonstrate a consistent biochemical abnormality in obligate heterozygotes.

**Diagnosis:** The diagnosis of P450c11b1-hydroxylase deficiency can be confirmed by demonstration of elevated basal or ACTH-induced plasma levels of 11-deoxycortisol and DOC, at least three times higher than the 95th percentile for age, and increased excretion of their metabolites in urine (mainly tetrahydro-11-deoxycorticisol). As previously noted, these patients have
elevated 17-OH progesterone levels and need to be distinguished from those with other forms of CAH by measuring the steroid levels at baseline or after ACTH stimulation.

**StAR, P450scC, 17α-hydroxylase (17,20-lyase), 3β-HSD** Defects in steroidogenic acute regulatory protein (StAR), P450scC (side chain cleavage), 17α-hydroxylase (17,20-lyase), and 3β-HSD type II have in common blocks in cortisol and sex steroid synthesis in both the adrenals and the gonads. The latter types produce chiefly incomplete masculinization in the male and little or no virilization in the female (Table 14-3). Consequently, these are discussed primarily as forms of 46,XY DSD (disorders of androgen synthesis).

### Treatment

Treatment of patients with salt-losing adrenal hyperplasia may be divided into acute and chronic phases. In acute adrenal crises, a deficiency of both cortisol and aldosterone results in hypoglycemia, hyperkalemia, hypovolemia, acidosis, and shock. If the patient is hypoglycemic, an intravenous bolus of glucose (0.25-0.5 g/kg; maximum 25 g), should be administered. If the patient is in shock, an infusion of normal saline (20 mL/kg) may be given over the first hour; thereafter, replacement of glucose, fluid, and electrolytes is calculated on the basis of deficits and standard maintenance requirements. Hydrocortisone sodium succinate (50 mg/m²) should be given as a bolus and another 50 to 100 mg/m² over 24 hours, divided into every 6 hour doses. If hyponatremia and hyperkalemia are present, fludrocortisone (0.05-0.1 mg) by mouth may be given along with the intravenous saline and hydrocortisone. Because hydrocortisone has mineralocorticoid activity, it may suffice to correct the electrolyte abnormality along with the saline. In extreme cases of hyponatremia, hyperkalemia, and acidosis, sodium bicarbonate and a cation exchange resin (eg, sodium polystyrene sulfonate) may be needed. In patients with presumed chronic hyponatremia, it is always prudent to raise the sodium cautiously and slowly to avoid the possibility of central pontine myelinolysis. Initially, in newly diagnosed patients and newborns in the first few days of treatment, hydrocortisone in doses of 25 to 50 mg/m²/d are commonly used to facilitate suppression of the CRH-ACTH-adrenal axis. This dose should be reduced as soon as the steroid levels are suppressed to the desired range, usually after 5 to 7 days.

Once the patient is stabilized and a definitive diagnosis has been arrived at by means of appropriate steroid studies, the patient should receive suppressive doses of glucocorticoids to permit normal growth, development, and bone maturation (hydrocortisone, 10-15 mg/m²/d by mouth in three divided doses). The dose of hydrocortisone must be titrated in each patient depending on steroid hormone levels in plasma and urine, linear growth, bone maturation, and clinical signs of steroid overdose or of virilization. Therapy can be monitored by consistently timed (in relation to dose administration) steroid determinations, for example, the measurement of 17-OH progesterone, androstenedione, and T at 8 AM before the morning dose of hydrocortisone. A target concentration for 17-OH progesterone (400-1200 ng/dL) with androstenedione and T levels in the normal range has been suggested. However, these levels will vary depending on when the evening dose of hydrocortisone is administered. Salt-losers need treatment with mineralocorticoid (fludrocortisone, 0.05-0.2 mg/d by mouth) and added dietary salt (1-3 g/d) in infancy. The dose of mineralocorticoid should be adjusted so that the electrolytes and blood pressure, as well as the plasma renin activity, are in the normal range.

Recently, as a result of the difficulty of optimally treating these patients, several novel therapies have been proposed. These include adrenalectomy in patients with null mutations of P450c21, GH to augment final height, and the use of physiologic doses of hydrocortisone (8 mg/m²), fludrocortisone, flutamide (an androgen receptor blocker), and an aromatase inhibitor in combination.

The parents need to be presented the **whole picture** diagnosis, natural history, possible medical and surgical therapy, risks, complications, and unknowns. It is critical that they have the knowledge and time to make an informed decision about any surgical procedures on their child. Only patients with markedly ambiguous external genitalia (Prader III-V) should be considered for surgery. Vaginoplasty or clitoral recession or clitoroplasty for markedly enlarged clitoris—not clitoridectomy—is indicated. Surgical reconstruction done in infancy may need refinement at puberty. Surgery, if done, must emphasize function rather than cosmesis. It should be performed by a surgeon who is experienced in the operative procedure and is cognizant of the importance of preserving the functional integrity of the genital area. The variability of normalcy in relationship to size and appearance of the external genitalia of adult women has recently been quantified. These data can serve as a reference with respect to the need for surgery in older patients with CAH. The timing of any surgery remains controversial. This is a decision that needs to be made after careful discussion with the parents. It should be noted that there are no outcome data for delaying functionally cosmetic surgery on an infant with ambiguous genitalia until an age of consent as suggested by some psychologists and patient advocates.

The dose of glucocorticoid needs to be increased in response to stress, for example, temperature above 100°F orally, gastroenteritis with dehydration, trauma, and surgery. The daily maintenance hydrocortisone dose should be tripled and divided into every 6 hour doses around the clock until the fever or gastroenteritis has abated for 12 hours. Thereafter, the child may resume his/her maintenance dose. In the event that the oral dose cannot be administered, hydrocortisone (50 mg/m²) or its equivalent can be given intramuscularly and the child maintained on a dose of 50 to 100 mg/m²/d in divided doses until he/she is able to take medication by mouth. It is prudent to check electrolytes in any patient who is a salt-loser, manifests vomiting, and is a candidate for parenteral hydrocortisone. Even if electrolytes are normal, patients who are unable to take medication and fluid orally for longer than 6 to 8 hours usually require hospitalization for parenteral fluids, especially if they are salt-losers. All caregivers should be prepared to administer hydrocortisone in an emergency, and all patients should have a medi-alert notification with them.
Prenatal therapy of pregnant women who are at risk of carrying a female fetus with atypical genitalia due to 21-hydroxylase deficiency is controversial. Therapy with oral dexamethasone given to the mother beginning at 6 to 7 weeks of gestation has been advocated to reduce or eliminate virilization of the affected female genitalia. Statistically, only one in eight fetuses will be a female with CAH. Although this therapy is effective, in diminishing genital ambiguity, more long-term studies are needed to ascertain the long-term morbidities, both physical and psychological.

In postpubertal patients who have reached their final height, glucocorticoid replacement can be implemented with more potent glucocorticoids that have longer half-lives than hydrocortisone such as prednisone (5-7 mg/d divided into two doses) or methylprednisolone (4-6 mg/d in two doses). As with children, the lowest dose of medication required to optimally suppress adrenal androgen secretion and prevent glucocorticoid side-effects should be used. The dose needs to be titrated to the plasma steroid values, or better yet, the urinary 17 ketosteroids—an integrated 24-hour assessment of androgen secretion. Similar to hydrocortisone, the dose is a function of absorption, metabolism, and sensitivity and varies from patient to patient.

A host of studies indicate that the vast majority of 46,XX females with 21-hydroxylase deficiency and consequent virilization of their external genitalia have a female gender identity. Gender dysphoria, although rare, is more prevalent in these patients than in the general population. Behavior characterized as masculinization/defeminization occurs in affected females who play more with traditionally boys’ toys, are more aggressive, and show less interest in infants than their unaffected female siblings.

Treatment of adults with CAH should be directed toward preventing and remedying the morbidities of long-term glucocorticoid therapy and optimizing sexual, reproductive, and bone health (see Auchus PMID 20613954). Continued monitoring of serum 17-OH progesterone, androstenedione, and T levels (in females) and/or 24-hour urinary 17-ketosteroids is indicated in order to prevent further virilization or the morbidity of excess glucocorticoid therapy. While many salt-losers appear not to need mineralocorticoid due to increased salt intake or extra adrenal 21-hydroxylating, it is prudent to follow plasma renin activity, since elevated plasma renin levels are a marker of mineralocorticoid deficiency and are associated with the need for higher doses of glucocorticoids to suppress adrenal androgen secretion. Multiple factors play a role in the decreased fertility rate seen in women with CAH. These include decreased sexual activity due to vaginal stenosis which results in painful intercourse, poor surgical repairs resulting in lack of sensation, lack of desire for maternity, and poor self-image. In males, spermatogenesis and Leydig cell function may be compromised by poor hormonal control or testicular adren al rest tumors which can be readily identified by ultrasound.

Dual energy x-ray absorptiometry (DXA) scans have shown that osteopenia is present in 40% to 50% of patients less than 30 years and 70% of patients over 30 years old. The severity of the osteopenia/osteoporosis is related to the severity of the CAH, the age of the patient, and dose of glucocorticoid given. Thus, periodic DXA scans and vitamin D and calcium supplementation are indicated, both prophylactically and therapeutically. Quality of life issues need to be addressed. These include physical and psychological status as well as social and sexual relationships.

**Glucocorticoid Receptor Gene Mutation**

Glucocorticoid resistance due to a homozygous mutation in the gene encoding the glucocorticoid receptor reportedly induces 46,XX DSD. Glucocorticoid resistance results in an increase in ACTH levels with a consequent increase in cortisol, mineralocorticoids, and adrenal androgens. The latter steroids induce virilization, which in the female infant results in 46,XX DSD.

**Feto-Placental Source**

**P450 oxidoreductase**  P450 oxidoreductase (POR) is a flavo-protein that transfers electrons from nicotinamide adenine dinucleotide to all microsomal P450s. These include P450c21, P450 17-hydroxylase/17,20-lyase and P450 aromatase which are involved in steroidogenesis, lanosterol 14-alpha-demethylase (P45014DM), and squalene monooxygenase (SQUE), which are involved in cholesterol synthesis. POR deficiency is inherited as an autosomal recessive, and affected individuals are either homozygous or compound heterozygotes, predominantly for an A287P mutation in Caucasians and an R487H mutation in Japanese. More than 50 different mutations have been described. A broad range of phenotypes has been reported related to the degree of enzymatic function determined by the mutation and the specificity of the mutation for each one of the enzymes involved. Most, but not all patients reported with this condition, have skeletal abnormalities such as craniosynostosis, midfacial hypoplasia, and radioulnar synostosis. The phenotype of the skeletal dysmorphism has been termed the Antley-Bixler syndrome and appears to correlate with the degree of decrease in enzyme activity resulting from the mutations. The skeletal abnormalities of Antley-Bixler syndrome are digenic in origin. Individuals with normal genitalia and the Antley-Bixler phenotype have a mutation in the gene encoding fibroblast growth factor receptor-2 (FGFR-2) and no abnormality in steroidogenesis, whereas those with one or more of the above-mentioned skeletal abnormalities and ambiguous genitalia are found to have mutations in POR.

POR deficiency can cause ambiguous genitalia in both males and females, and hypospadias, hypospadias, and infertility in males with mild mutations. The spectrum of patients reported includes females with normal genitalia who present with PCOS-like symptoms and have primary amenorrhea. There is evidence to suggest that virilization of the external genitalia in females with POR deficiency results from the synthesis of DHT in utero via the “backdoor” pathway (see Figure 14–10). Androgen excess can also result from a decrease in P450 aromatase activity in the placenta, which can cause maternal and fetal virilization during pregnancy. In patients with mild mutations, maternal virilization is not present, and males may have normal genitalia and rarely micropenis. The virilization in females is not progressive. After birth, however, in a Japanese cohort, pubertal maturation was definitely affected in females.
Diagnosis: POR deficiency should be suspected in males and females with ambiguous genitalia and the Antley-Bixler phenotype, in females whose virilization does not progress postnatally, and in patients with modestly elevated 17-OH progesterone levels. The diagnosis can be suspected from ACTH-induced steroid levels. Cortisol levels are normal at baseline, but there is a blunted response to ACTH. Both serum progesterone and 17-OH progesterone values in response to ACTH are higher than normal suggesting a defect in both 17- and 21-hydroxylation, whereas DHEA and androstenedione levels may be low. Genotyping will verify the diagnosis. Depending on the baseline concentration and ACTH-induced cortisol level, cortisol replacement may be indicated in some patients. In view of the blunted cortisol responses observed, it is prudent to give stress steroid coverage for illness, surgical procedures, and severe trauma.

**P450 AROMATASE DEFICIENCY**

Another form of androgen-induced 46,XX DSD is due to aromatase deficiency. Mutations in the gene CYP19, encoding P450 aromatase, result in defective placental conversion of C19 steroids to estrogens (C18), leading to exposure of the fetus to excessive amounts of T and to masculinization of the external genitalia of the female fetus. Virilization of the mother during gestation occurs commonly. The female fetus is virilized, due to the inability of the placenta to aromatize testosterone produced by the placenta from the conversion of fetal adrenal DHEA. At puberty, defective aromatase activity in the ovary leads to pubertal failure, hypergonadotropic hypogonadism, polycystic ovaries, mild virilization, tall stature, and osteopenia. A striking delay in bone age with continuing growth occurs in both affected males and females, despite increased concentrations of plasma T, supporting the concept that estrogens, rather than androgens, are the major sex steroids affecting bone maturation, bone turnover, and epiphyseal fusion in males as well as females. A nonclassic phenotype has been described in two females with sufficient aromatase activity to result in the development of Tanner stage 2 and 4 breast development.

**Diagnosis:** The diagnosis of aromatase deficiency is suggested by the above clinical picture as well as elevated plasma androstenedione and T levels in the face of low estrogen levels, elevated gonadotropins, and ovarian cysts in females. Gonadotropin levels are elevated due to lack of estrogen feedback. There is striking osteopenia. Low plasma concentrations of maternal estriol during pregnancy associated with maternal virilization can facilitate the prenatal diagnosis. Affected males have normal genitalia, normal pubertal development, osteoporosis, and tall stature due to lack of epiphyseal fusion as a result of estrogen deficiency.

**MATERNAL SOURCE ANDROGENS AND PROGESTOGENS**

Masculinization of the external genitalia of a female infant can occur, if the mother is given T, other androgenic steroids, or certain synthetic progestational agents during pregnancy. Norethindrone, ethisterone, norethynodrel, and medroxyprogesterone acetate have all been implicated in masculinization of the female fetus. These drugs were given in the past in an effort to control threatened or habitual abortions. Nonadrenal 46,XX DSD can occur as a consequence of maternal ingestion of danazol, the 2,3-d-isoxazol derivative of 17α-ethyl T. In rare instances, masculinization of a female fetus is due to a virilizing maternal ovarian or adrenal tumor, congenital virilizing adrenal hyperplasia in the mother, or a luteoma of pregnancy. The fetus is protected from excess T exposure by the ability of the fetal-placental unit to aromatize T to estrogens, especially after the first trimester. The diagnosis of 46,XX DSD arising from transplacental passage of androgenic steroids is based on exclusion of other forms of female pseudohermaphroditism and a history of drug exposure. Surgical correction of the genitalia, if needed, is the only therapy necessary.

Nonadrenal 46,XX DSD can be associated with imperforate anus, renal anomalies, and other malformations of the lower intestine and urinary tract and in some affected individuals. There may be anomalies of the ovaries and Müllerian structures. Sporadic as well as familial cases have been reported.

**46,XY DSD (Male Pseudohermaphroditism)**

Patients with 46,XY DSD have gonads that are testes, but the genital ducts or external genitalia, or both, that are not completely masculinized. 46,XY DSD can result from deficient T secretion as a consequence of (1) defective testicular differentiation (testicular dysgenesis); (2) failure of T secretion by Leydig cell due to a mutation in the Leydig cell hCG/LH receptor which is associated with Leydig cell hypoplasia as well as an inability to respond to hCG/LH stimulation; (3) impaired secretion of T; (4) failure of conversion of T to DHT; (5) failure of target tissue response to T and DHT; (6) impaired secretion of AMH or defective AMH receptors; and (7) environmental influences.

**Testicular Unresponsiveness to hCG and LH (Leydig Cell Hypoplasia)**

Male sexual differentiation is dependent on the production of T by fetal Leydig cells. Leydig cell T secretion is initially autonomous and then later hCG dependent during the critical period of male sexual development in the latter part of the first trimester. After the first trimester, Leydig cell T secretion is dependent on stimulation by pituitary LH, as evidenced by the finding of micropenis in 46,XY patients associated with anencephaly, apituitarism, or congenital hypothalamic hypopituitarism.

Absence, hypoplasia, or unresponsiveness of Leydig cells to hCG-LH results in deficient T production and, consequently, ambiguous male genitalia. The extent of the genital ambiguity is a function of the degree of T deficiency. The phenotype ranges from complete forms with female external genitalia, undescended testes, absent Müllerian ducts, rudimentary Wolffian ducts, and hypergonadotropic hypogonadism to milder forms with microgenitalis or males with normal male genitalia and hypergonadotropic hypogonadism at puberty. Testes are small postpubertally and have
decreased or absent Leydig cells, normal-appearing Sertoli cells, and seminiferous tubules with spermatogenic arrest. A number of patients with absent, hypoplastic, or unresponsive Leydig cells due to a mutation in the gene encoding the LH-hCG receptor have been reported. Studies in patients with the clinical and chemical features of Leydig cell hypoplasia indicate that 50% of the patients with this phenotype have had no identifiable mutation in the LH-hCG receptor. Recently a mutation in a previously unrecognized exon has been described in some of these patients. 46,XX females with mutations in the LH beta subunit of LH receptor have female external genitalia, feminization at puberty, oligospermia, and infertility.

**Diagnosis:** Plasma 17α-hydroxyprogesterone, androstenedione, and T levels are low, and hCG elicits little or no response in T or its precursors in the complete form and a blunted T response in the partial form, in which partial virilization can occur at puberty. Adrenal steroidogenesis is normal in these patients. Treatment depends on the age at diagnosis and the extent of masculinization. A female sex assignment has usually been chosen in patients with female external genitalia. In patients with predominantly male external genitalia, T augments penile development in infancy and childhood and virilizes the patient at puberty.

**Inborn Errors of Testosterone Biosynthesis**

Figure 14-15 demonstrates the major pathway in T biosynthesis in the testes; each step is associated with an inherited defect that results in T deficiency and, consequently, 46,XY DSD. Steps 1, 2, and 3 are enzymatic deficiencies that occur in both the adrenals and gonads and result in defective synthesis of both corticosteroids and T. Thus, they represent forms of CAH, whereas steps 4 and 5 in T synthesis are confined to the testes.

**Star deficiency (congenital lipoid adrenal hyperplasia), P450scc** 46,XY DSD with female or ambiguous genitalia, sexual infantilism, and adrenal insufficiency are consequences of very early defects in the synthesis of all steroids affecting the conversion of cholesterol to Δ5-pregnenolone and result in severe adrenal and gonadal deficiency. Recessive mutations in the gene encoding StAR, a protein that effects transport of cholesterol from the outer to the inner mitochondrial membrane (where it is converted to pregnenolone), have been identified in almost all patients with the clinical syndrome of congenital lipoid adrenal hyperplasia. Mutations in this gene located on chromosome 8 are prevalent in Japan and Korea where patients with lipoid adrenal hyperplasia represent the second most common form of CAH.

**FIGURE 14-15** Enzymatic defects in the biosynthetic pathway for testosterone. All five of the enzymatic defects cause 46,XY DSD (male pseudohermaphroditism) in affected males. Although all of the blocks affect gonadal steroidogenesis, those at steps 1, 2, and 3 are associated with major abnormalities in the biosynthesis of glucocorticoids and mineralocorticoids in the adrenal. Chemical names for enzymes are shown with traditional names in parentheses. (Modified and reproduced, with permission, from Conte FA, Grumbach MM. Pathogenesis, classification, diagnosis, and treatment of anomalies of sex. In: DeGroot L, ed. *Endocrinology*. Grune & Stratton; 1989.)
after 21-hydroxylase deficiency. StAR is expressed in the adrenals and gonads but not in the placenta. Hence, placental synthesis of progesterone, which is required to maintain pregnancy after midgestation, is not affected by mutations in StAR. Affected males usually have female or, less commonly, ambiguous external genitalia with a blind vaginal pouch and hypoplastic male genital ducts, no Müllerian derivatives, adrenal insufficiency, and hypergonadotropic hypogonadism. Many infants with StAR deficiency do not manifest evidence of salt wasting until after several weeks of life. The accumulation of cholesterol in steroidogenic organs that are functioning in utero (adrenals and testes) destroys the function of these organs resulting in the phenotype, for example, adrenal insufficiency and impaired differentiation of the genitalia in males. Death in early infancy from adrenal insufficiency is not uncommon. Affected females have normal genitalia and go into puberty as the ovaries are relatively quiescent until puberty and roughly 14% of steroidogenesis is not StAR-dependent, apparently allowing for estrogen production until cholesterol engagement destroys the function of the ovary and results in hypergonadotropic hypogonadism and large polycystic ovaries filled with cholesterol. The absence of Müllerian anlage distinguishes StAR/P450scc deficiency from patients with a similar deficiency with or without mineralocorticoid deficiency. Those affected are not at risk of surreptitious or therapeutic exposure to progesterone, which is required to maintain pregnancy after midgestation by the maternal corpus luteum.

**Diagnosis:** The diagnosis is confirmed by the lack of or low levels of all C21, C19, and C18 steroids in plasma and urine and an absent response to ACTH and hCG stimulation. Large lipid-laden adrenals, that displace the kidneys downward, may be demonstrated by intravenous urography, abdominal ultrasonography, or CT scan. Treatment involves replacement with appropriate doses of glucocorticoids and mineralocorticoids, prophylactic orchietomy in affected 46,XY patients raised as females, and estrogen replacement at puberty. Since the adrenals are not functionally hyperplastic, the glucocorticoid dose needed in these patients is less than is the case of P450c21-hydroxylase deficiency. A nonclassic late-onset form of this condition has been described. Affected males have normal external genitalia; they develop, usually in the first decade of life, cortisol deficiency with or without mineralocorticoid deficiency. Those individuals with only cortisol deficiency need to be distinguished from those with isolated familial glucocorticoid deficiency due to mutations in the ACTH receptor (MC2R) and the melanocortin-2 receptor accessory protein (MRAP).

**Diagnosis:** The diagnosis is confirmed by the lack of or low levels of all C21, C19, and C18 steroids in plasma and urine and an absent response to ACTH and hCG stimulation. Large lipid-laden adrenals, that displace the kidneys downward, may be demonstrated by intravenous urography, abdominal ultrasonography, or CT scan. Treatment involves replacement with appropriate doses of glucocorticoids and mineralocorticoids, prophylactic orchietomy in affected 46,XY patients raised as females, and estrogen replacement at puberty. Since the adrenals are not functionally hyperplastic, the glucocorticoid dose needed in these patients is less than is the case of P450c21-hydroxylase deficiency. A nonclassic late-onset form of this condition has been described.

**P450scc** The P450scc gene has been cloned and localized to chromosome 15. It codes for the enzyme scc, which is the first step in the conversion of cholesterol to pregnenolone in all steroidogenic organs. Seven patients with mutations in the P450scc gene(s) have been reported. All seven cases reported have had a 46,XY karyotype. Female genitalia were present in five of seven, clitoromegaly in one patient, and midshaft hypospadias in another. The onset of adrenal insufficiency varied from the neonatal period to as late as 9 years of age in the patient with hypospadias. The latter patient and two more recently described patients with compound heterozygosity for P450scc mutations had residual P450scc activity. These patients had later onset of adrenal insufficiency than seen in classic patients and the males had hypospadias. These patients are similar to the non-classic form of StAR deficiency, both clinically and hormonally, except none had normal or enlarged adrenals on MRI or ultrasound. It has been suggested that patients with P450scc deficiency survive gestation due to either residual P450scc activity or due to continuing progesterone secretion beyond midgestation by the maternal corpus luteum.

**Diagnosis:** P450scc deficiency is suggested by the finding of a 46,XY DSD with undervirilization of the external genitalia, absent Müllerian ducts, adrenal insufficiency, and low baseline and deficient steroid responses to ACTH and hCG. The absence of adrenal enlargement on MRI or ultrasound distinguishes P450scc deficiency from a StAR deficiency.

**3β-Hydroxysteroid dehydrogenase type 2 Δ5-isomerase deficiency** 3β-HSD type 2 Δ5-isomerase deficiency is an early defect in steroid synthesis that results in inability of the adrenals and gonads to convert 3β-hydroxy-Δ5 steroids to 3-keto-Δ5 steroids. Deficiency leads to 46,XY or 46,XX DSD and adrenal insufficiency. This enzyme is encoded for by a recessive gene on the short arm of chromosome number 1. There are two highly homologous genes encoding 3β-HSds on chromosome 1. The type 1 3β-HSD gene is expressed in the placenta, liver, skin, and other peripheral tissues, whereas type 2 is expressed in the adrenals and gonads. 3β-HSD is not a cytochrome P450 enzyme, and it requires NAD+ as a cofactor.

Mutations causing frame-shifts, stops, and missense have been reported in the type 2 gene in affected patients. Mutations which decrease enzymatic activity of the type 2 enzyme significantly result in a severe deficiency of aldosterone, cortisol, T, and estradiol secretion (see Figure 14-15). Males with this defect are incompletely masculinized due to the defect in 3β-hydroxysteroid dehydrogenase in the testes. They have a small penis, hypospadias, a blind vaginal pouch, and absent Müllerian structures. Females have normal female genitalia or mild clitoromegaly.

The undervirilization in males is readily explainable by the block in T synthesis in the testes during the critical period of male genital differentiation. However, the mild virilization observed in some females is still not readily explained. It has been suggested that the conversion of Δ5,17-OH pregnenolone to 17-hydroxyprogesterone in vitro by peripheral 3β-HSD-1 facilitates the production of low levels of DHT via the backdoor pathway (see Figure 14–10). Alternatively, the conversion of excess DHEA-S to T by 3β-HSD-1 in the placenta during the critical window of sex differentiation, when aromatase activity is relatively low, may be implicated. Further studies of steroidogenesis in affected patients with null mutations may shed light on this question.

Adrenal crises with salt loss usually occurs in early infancy in affected patients. Affected males may experience normal male puberty but often have prominent gynaecomastia. Rare cases with normal puberty and fertility have been reported. Individuals with a mild non-salt-losing form of 3β-HSD type 2 deficiency are reported as well as a late-onset form in individuals presenting with premature pubarche alone. These patients had elevated Δ5 steroids as well as mutations in the 3β-HSD type 2 gene.
Diagnosis: The diagnosis of 3β-HSD deficiency type 2 is based on finding elevated concentrations of Δ⁵-pregnenolone, Δ⁵-17α-hydroxypregnenolone, DHEA and its sulfate, and other 3β-hydroxy-Δ⁴ steroids in the plasma and urine. 3-Keto-Δ⁴ steroids (ie, 17α-hydroxyprogesterone and androstenedione) may be elevated due to peripheral conversion of 3β-hydroxy-Δ⁵ to 3-keto-Δ⁴ steroids by the enzyme encoded by the type 1 gene. The diagnosis of 3β-HSD-2 deficiency may be facilitated by detecting abnormal levels of serum Δ⁵-17α-hydroxypregnenolone and DHEA and its sulfates as well as abnormal ratios of Δ⁵ to Δ⁴ steroids after intravenous administration of ACTH. For example, after ACTH stimulation, 17-hydroxypregnenolone levels are more than 5.3 SD above the mean for normal individuals in affected infants, more than 35 SD above the mean in prepubertal children, and more than 21 SD above the mean in adults. The 17-hydroxy-pregnenolone/cortisol ratio is more than 6.4 SD above the mean in infants, more than 23 SD above the mean in prepubertal children, and more than 221 SD above the mean in adults. The diagnosis is confirmed by detecting mutations in the type 2 3β-HSD-Δ⁵ isomerase gene. Suppression of the increased plasma and urinary 3β-hydroxy-Δ⁴ steroids by the administration of dexamethasone distinguishes 3β-HSD deficiency from a virilizing adrenal tumor.

Treatment of this condition is similar to that of other forms of adrenal hyperplasia.

P450c17 deficiency, 17α-hydroxylase deficiency A single gene on chromosome 10 encodes both adrenal and testicular P450c17 hydroxylase as well as 17,20-lyase activity. This enzyme catalyzes the 17-hydroxylation of pregnenolone and progesterone to 17-hydroxypregnenolone and 17-hydroxyprogesterone as well as the scission (lyase) of 17-hydroxypregnenolone to the C₁₉ steroid (DHEA) in the adrenal cortex and gonads. Mutations affecting 17-hydroxylase activity have included stop codons, frame-shifts, deletions, and missense substitutions. P450c17 deficiency is transmitted in a manner similar to other enzymatic defects in steroidogenesis as an autosomal recessive trait.

A defect in 17α-hydroxylation in the zona fasciculata of the adrenal and in the gonads results in impaired synthesis of 17-hydroxyprogesterone and 17-hydroxypregnenolone and, consequently, cortisol and sex steroids. The secretion of large amounts of corticosterone and DOC leads to hypertension, hypokalemia, and alkalosis. Although these patients are cortisol-deficient, the excess mineralocorticoid secretion, as well as elevated levels of corticosterone, prevents symptomatic adrenal insufficiency except during stress. Increased DOC secretion from the zona fasciculata results in hypertension and hypokalemia, and suppression of renin (low renin hypertension) and, decreased aldosterone secretion. Affected 46,XY individuals with less than 25% enzymatic activity present with female genitalia with a blind vaginal pouch or hypoplastic male genitalia, hypertension, and hypokalemic alkalosis with hypergonadotropic hypogonadism at puberty. Mullerian structures are absent; Wolfian structures are hypoplastic. Partial forms of 17-hydroxylase deficiency have been described with hypospadias, with or without hypertension.

Affected 46,XX females have normal development of the internal ducts and external genitalia but manifest sexual infantilism with elevated gonadotropin concentrations at puberty and low renin hypertension. Affected females with 5% or greater activity of the enzyme can make estrogen at puberty and feminize, although menses are usually irregular.

Diagnosis: 17α-Hydroxylase deficiency should be suspected in a 46,XY DSD with hypokalemic alkalosis and hypertension, as well as a 46,XX female with the above findings and sexual infantilism at puberty. ACTH stimulation testing will reveal elevated levels of DOC, corticosterone, and 18-hydroxycorticosterone as well as progesterone and Δ⁴ pregnenolone, but low levels of 17-hydroxyprogesterone, 17-hydroxypregnenolone, sex steroids, and cortisol. Glucocorticoid therapy, as given for 21-hydroxylase deficiency, suppresses ACTH and hence deoxycorticosterone production. This decreases the blood pressure and returns the potassium and aldosterone levels to normal. These patients usually require sex steroid replacement at puberty.

Smith-Lemli-Opitz syndrome The phenotypic spectrum of this syndrome typically includes microcephaly, mental retardation, ptosis, micrognathia, severe hypospadia, micropenis, growth failure, and, rarely, adrenal insufficiency. The genitalia in affected 46,XY males may range from normal male to female. The syndrome is caused by a mutation in the gene encoding sterol Δ⁷-reductase, DHCR7, causing defective cholesterol synthesis. The diagnosis is made by the clinical features and confirmed by demonstration of low levels of cholesterol and increased levels of 7-dehydrocholesterol.

Enzyme Defects Primarily Affecting Testosterone Biosynthesis by the Testes

7,20-lyase deficiency The enzyme encoded by the P450c17 gene mediates both the 17-hydroxylation of pregnenolone and progesterone to 17-hydroxypregnenolone and 17-hydroxyprogesterone and the scission of the C₁₉ bond of 17-hydroxypregnenolone to yield DHEA in the adrenals and gonads (see Figure 14–15). In humans, the scission of 17-hydroxyprogesterone to androstenedione occurs at a low level. In this rare autosomal recessive disorder, the defect involves only the scission of the C₁₉ steroids to C₁₇ steroids. This results in a defect in T synthesis and, as a consequence, 46,XY DSD in the male and affected females with estradiol deficiency, hypergonadotropic hypogonadism, and giant ovarian cysts. The initially reported 46,XY DSD individuals both had micropenis, perineal hypospadia, a bifid scrotum, a blind vaginal pouch, and cryptorchidism. The administration of hCG resulted in a marked rise in plasma 17-hydroxyprogesterone with a poor response in plasma DHEA, androstenedione, and T consistent with a diagnosis of isolated 17,20-lyase deficiency. Analyses of the P450c17 gene in affected individuals has revealed mutations that result in a specific decrease in 17,20-lyase activity encoded by the P450c17 gene, but not 17-hydroxylase activity.

Affected 46,XY males with 17,20-lyase deficiency may present with female external genitalia. Patients with 17,20-lyase deficiency have low circulating levels of T, androstenedione, DHEA, and estradiol in the face of markedly elevated levels of progesterone.
and 17-hydroxyprogesterone. At puberty, poor virilization occurs with elevated gonadotropins in affected 46,XY patients.

Cytochrome b5 reductase is a cofactor for 17,20-lyase. Mutations in this gene cause methemoglobinemia as well as a defect on 17,20-lyase. Two patients have been reported with mutations in b5 reductase causing 46,XY DSD.

Diagnosis: The diagnosis of 17,20-lyase deficiency can be confirmed by demonstration of an increased ratio of 17-hydroxy C19 steroids to C19 steroids (T, DHEA, Δ5-androstenediol, and androstenedione) after stimulation with ACTH or hCG and by DNA analysis of the P450c17 gene. Patients require sex steroid replacement at puberty.

**17β-Hydroxysteroid dehydrogenase-3 (17β-HSD-3) deficiency** At least six isoenzymes of 17β-HSD mediate steroidogenesis in humans. The last step in T biosynthesis by the testes involves the reduction of androstenedione to T, and estrone to estradiol by 17-hydroxysteroid dehydrogenase-3, an NADPH-dependent microsomal enzyme. This gene is located on chromosome 9q22 and is expressed primarily in the testes. As with other genes which code for enzymes, it is autosomal recessive. 17β-HSD-3 is not expressed in the ovary. The conversion of estrone to estradiol is mediated by 17β-HSD-1 expressed in the granulosa cells of the ovary.

Mutations in 17β-HSD-3 are a cause of 46,XY DSD. At birth, males with a deficiency of the enzyme 17β-HSD-3 have predominantly female or mildly ambiguous external genitalia resulting from T deficiency during the critical period of male differentiation. They have male duct development, absent Müllerian structures with a blind vaginal pouch, and inguinal or intra-abdominal testes. Affected infants with female genitalia are invariably raised as females, and the phenotypic appearance of the genitalia, along with the absence of Müllerian duct derivatives, can be confused with complete androgen insensitivity. The finding of Wolffian ducts, associated with female external genitalia in these patients, is not yet well explained. At puberty, progressive virilization with clitoral hypertrophy occurs as a result of peripheral conversion of androstenedione to T by 17β-HSD-5. This is often associated with the concurrent development of gynecomastia related to increased estrone levels. Plasma gonadotropins, androstenedione, and estrone levels are elevated, whereas T and estradiol concentration are relatively low.

Analysis of a cohort of 17 patients with classic 17β-HSD-3 deficiency revealed 14 mutations in the 17β-HSD-3 gene. Twelve patients had homozygous mutations, four were compound heterozygotes, and one was a presumed heterozygote. In a large cohort from the Gaza Strip, an Arg→Gln mutation was found with partial (15%-20%) enzymatic activity. In this isolate, virilization at puberty generally resulted in a change of gender identity from female to male.

Diagnosis: 17-HSD-3 deficiency should be included in the differential diagnosis of (1) 46,XY DSDs with absent Müllerian derivatives who have no abnormality in glucocorticoid or mineralocorticoid synthesis; and (2) 46,XY DSDs who virilize at puberty, especially if they also exhibit gynecomastia. The diagnosis of 17β-HSD-3 deficiency is confirmed by the demonstration of inappropriately high plasma levels of estrone and androstenedione and increased ratios of plasma androstenedione to T and estrone to estradiol after prolonged stimulation with hCG in infants and children.

Management of affected individuals depends on the age at diagnosis, the degree of ambiguity of the external genitalia, surgical options, and family and cultural views, as it does with those with other forms of 46,XY DSD. In the patient assigned a male sex identity, plastic repair of the genitalia and T augmentation of phallic growth prepubertally, as well as T replacement therapy at puberty, is necessary to suppress the pituitary gonadotropin levels and, consequently, the elevated estrone levels that result in gynecomastia in untreated pubertal patients. Retained testes must be observed closely by palpation and ultrasound because an increased incidence of malignancy has been reported in a small cohort of patients. In patients reared as females, the appropriate treatment is castration or prevention of virilization with GnRH agonist at puberty until the individual's gender identity can be confirmed. Affected 46,XX females have no abnormalities in phenotype or gonadal function because 17β-HSD-3 is not expressed in the ovary.

The prevalence of a female-to-male gender role change in patients with 17β-HSD-3 deficiency appears to approximate that found in patients with 5α-reductase-2 deficiency. Both these conditions are associated with spontaneous virilization at puberty in patients whose testes were not removed. However, a number of the large cohorts of patients with 17β-HSD-3 deficiency summarized in the literature are from areas where a primacy is placed on a male role by the cultural advantages of the society. In individuals diagnosed in infancy, the information on the change in sex makes discussion of this issue with the parents mandatory before they make an informed decision about sex assignment.

**Enzyme Defects Affecting DHT Synthesis; 5α-Reductase-2 Deficiency (Pseudovaginal Perineoscrotal Hypospadias, Peripheral)**

The products of two genes catalyze the conversion of T to DHT. They are termed type 1 and type 2 5α-reductase. The type 1 enzyme is expressed in skin postnatally until 2 to 3 years of age and thereafter remains low until puberty. No instances of mutation in the type 1 gene as yet have been reported. The type 2 isoenzyme is found in fetal genital skin, male accessory glands, and the prostate. 5α-Reductase-2 deficiency is transmitted as an autosomal recessive trait, and the enzymatic defect exhibits genetic heterogeneity. In patients with 5α-reductase deficiency, the isozyme with a pH 5.5 optimum is deficient (type 2). The gene encoding this enzyme contains five exons and is located on chromosome 2, band p23. A variety of mutations are reported, including deletions, nonsense, splicing defects, and the more common missense mutations. Two-thirds of patients are homozygous for a single mutation, and the remainder are compound heterozygotes.

The defective conversion of T to DHT produces a unique form of 46,XY DSD. Phenotypically, these individuals may vary from those with a microphallus to individuals with pseudovaginal
perineoscrotal hypospadias. At birth, in the most severely affected individuals, ambiguous external genitalia are characterized by a small hypospadiac phallus bound down in chordee, a bifid scrotum, and a urogenital sinus that opens onto the perineum. A blind vaginal pouch is present, opening either into a urogenital sinus or directly into the urethra. The testes are either inguinal or labial. Müllerian structures are absent, and the Wolffian structures are well differentiated. At puberty, affected males virilize; the voice deepens, muscle mass increases, and the phallus enlarges. The bifid scrotum becomes rugose and pigmented. The testes enlarge and descend into the labioscrotal folds, and spermatogenesis may ensue. Gynecomastia is notably absent in these patients. Of note is the absence of acne, temporal hair recession, and hirsutism. The striking virilization noted at puberty, as opposed to its absence in utero, is attributed to the expression and function of the type 1 gene at puberty and, as a consequence, the generation of sufficient amounts of DHT by peripheral conversion to induce phallic growth and other signs of masculinization. A remarkable feature of this form of 46,XY DSD is the change in gender identity by many from female to male at puberty.

In the first 1 to 3 months of life after the onset of puberty, patients with 5α-reductase-2 deficiency have normal to elevated T concentrations and slightly elevated plasma concentrations of LH. As expected, plasma DHT is low, and the T/DHT ratio is abnormally high. Apparently, lack of 5α reduction of T to DHT in utero, during the critical phases of male sex differentiation, results in incomplete masculinization of the urogenital sinus and external genitalia. However, T-dependent Wolffian structures are normally developed. Partial and mild forms of 5α-reductase deficiency have been described, in which affected individuals can present with hypospadias and/or microphallus. Compound heterozygotes for 5α-reductase-2 deficiency who had a hypospadias repair in infancy and, as adults, were fertile.

**Diagnosis:** 5α-Reductase-2 deficiency should be suspected in 46,XY DSDs with a blind vaginal pouch and in males with hypospadias and microphallus. The diagnosis can be confirmed by demonstration of an abnormally high plasma T/DHT ratio, either under basal conditions (>10.5) or after hCG stimulation (>8.5). The T-DHT levels need to be measured accurately, preferably by LCMSMS. Other confirmatory findings, especially in newborns, include an increased 5β/5α ratio of urinary C_{19} and C_{21} steroid metabolites. 5α-reductase deficiency should be ruled out in all 46,XY DSDs who have a normal or elevated T response to hCG. In the event that the T/DHT ratio in blood or the 5β/5α ratio of urinary steroids is not diagnostic, genotyping should be performed.

The early diagnosis of this condition is particularly critical. In view of the natural history of this disorder, a male gender assignment is indicated, and DHT or high-dose T therapy should be initiated in order to augment phallic size. Repair of hypospadias should be performed in infancy or early childhood. In patients who are diagnosed after infancy in whom gender identity is unequivocally female after the age of informed consent, genitoplasty, prophylactic orchietomy, and estrogen substitution therapy are still the treatments of choice.

**Disorders of Androgen Action (Androgen Receptor and Postreceptor Defects)**

**Syndrome of complete androgen resistance (insensitivity) and its variants** The androgen receptor gene is located on the X chromosome between Xq11 and Xq13. Androgen resistance is transmitted as an X-linked recessive trait. Of note about 30% of mutations occur spontaneously. The gene is composed of eight exons. Exon 1 encodes the amino terminal end of the androgen receptor protein and is involved in the regulation of transcription. Exons 2 and 3 encode the DNA-binding zinc finger. The 5' portion of exon 4 is called the hinge region and plays a role in nuclear targeting. Exons 5 to 8 specify the carboxyl terminal portion of the androgen receptor—the androgen-binding domain. The gene has eight serine residues that can be phosphorylated, three lysine residues that can be acetylated, and two lysine residues that can be sumoylated. More than 600 mutations in the androgen receptor are described.

The syndrome of complete androgen resistance (insensitivity) is characterized by a 46,XY karyotype, bilateral testes, absent or hypoplastic Wolffian ducts, female-appearing external genitalia with a hypoplastic clitoris and labia minora, a blind vaginal pouch, and absent or rudimentary Müllerian derivatives. Testes are present in the labial folds, inguinal canal or intra-abdominally. At puberty, female secondary sexual characteristics develop, but menarche does not ensue. Pubic and axillary hair is usually sparse and in one-third of patients is totally absent. Affected patients are taller than average females (mean height 162.3 cm). Some patients have a variant form of this syndrome and exhibit slight clitoral enlargement. These patients may exhibit mild virilization in addition to the development of breasts and a female habitus at puberty.

Androgen resistance during embryogenesis prevents masculinization of the external genitalia and complete differentiation of the Wolffian ducts. The finding of Wolffian duct derivatives in some patients with apparent complete androgen resistance has been attributed to mutant receptors that have some residual activity and can respond to high local levels of T in vivo or to cofactors which modulate androgen sensitivity. Secretion of AMH by the fetal Sertoli cells leads to regression of the Müllerian derivatives—the ducts, uterus, and upper one-third of the vagina. At puberty, androgen resistance results in augmented LH secretion with increases in T secretion and estradiol production due to lack of T feedback on the hypothalamus. FSH levels are normal because of inhibin B and estradiol feedback. Estradiol arises mainly from peripheral conversion of T and androstenedione as well as from direct secretion by the testes. Androgen resistance, coupled with increased testicular estradiol secretion and conversion of T to estradiol, results in the development of female secondary sexual characteristics at puberty. The timing of the onset of the pubertal growth spurt is similar to that in normal females.

Patients with complete androgen resistance exhibit heterogeneity in DHT binding to the androgen receptor. Receptor-negative and receptor-positive individuals with qualitative defects such as thermolability, instability, and impaired binding affinity as well as individuals with presumed normal binding are reported. Analysis
of the androgen receptor gene in individuals with androgen resistance has shed light on the heterogeneity of DHT binding. Patients with the receptor-negative form of complete androgen resistance usually have point mutations or substitutions in exons 5 to 8, which encode the androgen-binding domain of the receptor; a striking number of missense mutations occur in the ligand-binding region of the androgen receptor.

Other genetic defects such as deletions, mutations in a splice donor site, and nonsense mutations causing premature termination codons are less common in this group of patients. Mutations in exon 1 commonly cause complete androgen resistance; almost all code for a premature stop codon that results in a truncated nonfunctional androgen receptor. Mutations in exon 3 (which encodes the DNA-binding segment of the androgen receptor) are associated with normal binding of DHT to the receptor but the inability of the ligand-receptor complex to bind to DNA and initiate mRNA transcription. These mutations result in receptor-positive complete androgen resistance. The phenotype of the affected patient correlates better with the transcriptional activity of the ligand-androgen receptor complex than with in vitro studies of the androgen receptor–binding activity.

Other factors that play a role in genotype-phenotype variations include somatic mosaicism, transcriptional coregulatory proteins, and other modifier genes. Somatic mutations—mutations that occur after zygote formation—result in the presence of both wild-type and mutant androgen receptor. Individuals with a somatic mutation may exhibit virilization at puberty owing to the presence of the wild-type receptor, even though some of these patients may present in infancy with the clinical picture of apparent complete androgen resistance.

**Diagnosis:** In the absence of a family history, the presence of a testis-like mass in the inguinal canal or labia majora may be the only clue to the diagnosis. Approximately 1% to 2% of females with inguinal hernia have androgen resistance. Postpubertally, the patients present with primary amenorrhea, normal breast development, and absent or sparse pubic or axillary hair. Pelvic examination or ultrasound confirms the absence of a cervix and uterus.

The complete and incomplete forms of androgen resistance must be distinguished from other forms of 46,XY DSD due to androgen deficiency, such as biosynthetic defects in T synthesis and 5α-reductase deficiency. There is no readily available, rapid, in vivo or in vitro assay to determine androgen sensitivity. The diagnosis is suggested by the clinical picture, the family history, and the presence of elevated basal and hCG-induced T levels with normal levels of DHT. Neonates with complete androgen resistance do not have elevated basal LH and T levels and do not experience a postnatal rise in these values, as is observed in normal infants and in those with incomplete androgen resistance. It has been suggested that an elevated AMH concentration is a marker of androgen resistance and androgen deficiency. It is not specific, as it may be elevated in other causes of 46,XY DSD. Defective or absent androgen receptor expression in Sertoli cells is responsible for the absence of AMH suppression. Determination of abnormalities in androgen binding as well as transactivation studies are diagnostic, but they are labor intensive and not universally available, whereas mutational analysis of the androgen receptor gene is commercially available.

**Management:** The patients with complete androgen resistance, as with most other patients with DSD, is complex. It requires a team of experienced physicians—an endocrinologist, psychologist and/or psychiatrist, a surgeon, and a social worker, as well as a primary care physician. When the diagnosis is definitive, the parents need to be fully informed about the karyotype, genetics, pathophysiology, medical and surgical options, and the natural history of complete androgen resistance. They should be informed that so far, except for very rare patients, gender identity, role, and behavior are female. Inguinal hernia, if present, need to be repaired. A gonadal malignancy rate of 1% to 2% is present after 14 years of age. Thus, it is prudent to allow these girls to feminize spontaneously at puberty and after full disclosure, discuss the question of prophylactic gonadectomy with them and their parents (who have been previously informed of this possibility). Spontaneous feminization at puberty may help to reinforce their sense of being a normal although infertile female. Allowing them to make an informed decision about gonadectomy reinforces their sense of autonomy. Hormonal replacement will be necessary postgonadectomy.

Postpubertally, the functional adequacy of the vagina should be assessed. Vaginoplasty is rarely necessary. Vaginal dilation with plastic molds is invariably successful in augmenting vaginal size and should be initiated if necessary postpubertally with the patient's informed consent.

The continuing involvement of the psychologist or psychiatrist will facilitate the question of when, how, and by whom the patients should be fully informed of their karyotype, infertility, and therapeutic options. There is no mandated guideline for this, and the approach needs to be individualized for each patient and family. In general, information is given in an age-appropriate way, taking into consideration the patient's age, cognitive abilities, and psychologic development. It is a gradual process, done in an understandable, caring way, which culminates in full disclosure. Continuing psychologic/psychiatric counseling should be available concerning sexual relationships and psychosocial issues. The Androgen Insensitivity Society (http://www.aissg.org) is a valuable support group for patients as well as parents and provides information, experiences from older, affected patients and parents, and the ability to meet and talk with females who have similar DSDs.

**Syndrome of partial androgen resistance (insensitivity) and its variants (Reifenstein syndrome)** Patients with partial androgen resistance manifest a wide spectrum of phenotypes as far as the degree of masculinization is concerned. The external genitalia at birth are classically characterized by perineoscrotal hypospadias, microgenitus, and a bifid scrotum. The testes may be undescended. Isolated hypospadias may occur in the mildest form of partial androgen resistance. There is variability of masculinization of affected males even within kindships. Mullerian duct derivatives are absent and Wolffian duct derivatives are present, but they are usually hypoplastic. At puberty, virilization usually recapitulates that seen in utero and is generally poor; pubic and axillary hair as well as gynecomastia are usually present. The
most common phenotype postpubertally is the male posthypospadias repair with a small phallus and gynecomastia. Axillary and pubic hairs are normal. The testes remain small and exhibit azoospermia as a consequence of germinal cell arrest. Unlike patients with complete androgen resistance, in infancy the levels of plasma LH and T are elevated. Postpubertally, as in individuals with complete androgen resistance, LH, T, and estradiol are elevated. However, the degree of feminization in these individuals, despite increased estradiol levels, is less than that found in those with the syndrome of complete androgen resistance.

Androgen receptor studies in these patients have usually shown quantitative or qualitative abnormalities in androgen binding. Mutations leading to partial reduction of androgen action result in incomplete virilization. As previously noted, the best correlation with the phenotype is the degree of impairment of transcriptional activity of the ligand-androgen receptor complex. A wide variety of androgen receptor gene mutations may result in the same phenotype, and a specific mutation is not always associated with the same phenotype. In general, point mutations that result in more conservative amino acid substitutions are more likely to result in partial rather than complete androgen resistance. In 111 individuals with partial androgen resistance in which DNA was sequenced, only 27 (24%) had an identifiable mutation. The majority of the patients with mutations had abnormal DHT binding to the androgen receptor.

**Diagnosis:** The differential diagnosis of patients with ambiguous genitalia and absent Müllerian structures includes partial androgen resistance, all the forms of dysgenetic 46,XY DSD, Leydig cells unresponsive to hCG/LH, biosynthetic errors in T synthesis, 5α-reductase deficiency, and SF-1 mutations. These entities may be parsed by steroid analysis in response to ACTH and hCG stimulation. A protocol frequently used for hCG stimulation is as follows: (1) a baseline LH, FSH by ICMA, AMH, inhibin B, androstenedione, T/DHT; (2) 2000 U/m² hCG × 3 days; (3) serum androstenedione, T/DHT, and urine for steroid analysis 24 hours after the third dose of hCG. hCG will elicit an augmented T response in patients with partial androgen resistance and 5α-reductase deficiency. 5α-Reductase deficiency can be generally ruled out by a T/DHT ratio <8.5 after hCG or by the ratio of 5β/5α steroid metabolites in urine. However, in some reported cases with mild mutations, only genotyping was diagnostic. All the above entities, except for partial androgen resistance, will result in a "normal" penile response to a trial of administration of T enanthate in oil, 25 mg intramuscularly × 3 months in infants. We have utilized this test to diagnose partial androgen insensitivity syndrome (PAIS) before assigning a definitive sex of rearing.

Follow-up data have indicated dissatisfaction in many patients with PAIS, whether they are raised as males or females. The prevalence of gender dysphoria in partial androgen resistance is estimated at 10%. In individuals reared as males, a major decrease in all aspects of sexual function has been documented. If a decision is made to raise the infant in a female sex role, then gonadectomy prior to puberty or GnRH therapy pending definitive ascertainment of gender identity is indicated to avoid the possible risk of signs of virilization at puberty. In view of the incidence of gender dysphoria and the apparent unhappiness about their assigned sex in individuals with partial androgen resistance, a male sex of rearing is a judicious choice in individuals with Prader III or greater ambiguous genitalia or hypoplastic male genitalia because it preserves a choice. In some patients, high doses of T has engendered penile enlargement. Psychologic/psychiatric consultation is important in these individuals whether raised as males or females, since available follow-up studies indicate dissatisfaction with the outcome when they are assigned a male or female sex of rearing.

**Androgen resistance in men with normal male genitalia** Partial androgen resistance has been described in a group of infertile men who have a normal male phenotype but may exhibit gynecomastia. Unlike other patients with androgen resistance, some of these patients have normal plasma LH and T levels. Infertility in otherwise normal men may be the only clinical manifestation of androgen resistance. Infertility, however, is always associated with androgen resistance. Five phenotypic males in one affected family had gynecomastia and a small penis. Plasma LH and T levels were elevated, and a subtle qualitative abnormality in ligand binding was found. Fertility was documented in four of the five males. This is the mildest form of androgen resistance.

**Dysgenetic 46,XY DSD (Ambiguous Genitalia due to Dysgenetic Gonads)**

See previous discussions of sex determination, XY gonadal dysgenesis, XO/XY mosaicism, Denys Drash/Frasier/WAGR syndromes, etc.

**Testicular Regression Syndrome (Vanishing Testes Syndrome; XY Agonadism; Rudimentary Testes Syndrome; Congenital Anorchia)**

Cessation of testicular function during the critical phases of male sex differentiation can lead to various clinical syndromes depending on when testicular function ceases. At one end of the clinical spectrum of these heterogeneous conditions are the XY patients in whom testicular deficiency occurred before 8 weeks of gestation, which results in female differentiation of the internal and external genitalia—so-called XY gonadal dysgenesis. At the other end of the spectrum are the patients with anorchia or vanishing testes in which the testes are lost later in gestation after the critical period of male genital differentiation from 8 to 12 weeks. These patients have normal male differentiation of their internal and external structures, but gonadal tissue is absent. The phallus varies in size dependent upon when Leydig cell failure occurs. Testicular regression may occur unilaterally especially on the left side or bilaterally, and the condition is seen in family cohorts. The latter suggests a genetic etiology, but only one individual with a mutation in the gene (SF-1) has been reported.

**Diagnosis:** Bilateral anorchia should be suspected in all 46,XY phenotypic males with undescended testes especially those with micropenis. MRI usually reveals absence of the gonads in the inguinal canal and no Müllerian duct derivatives. Plasma gonadotropins, especially FSH are elevated under 4 years of age and after
An increase in disorders of development and function of the urogenital tract in males has been noted over the past 50 years. It has been hypothesized that this increased incidence of reproductive abnormalities observed in human males is related to increased exposure to uterine to endocrine disrupters especially estrogens and androgen receptor blockers found in the diet both naturally and as a result of chemical contamination. It has been demonstrated that p,p’-DDE (dichlorodiphenyldichloroethylene)—the major and persistent DDT metabolite—binds to the androgen receptor and inhibits androgen action in developing rodents. Other chemicals such as phthalates, herbicides, and fungicides inhibit androgen actions. The term testicular dysgenesis syndrome describes a phenotype that has been attributed to endocrine disrupters. Further studies on the levels as well as the risks to humans of environmental chemicals and other endocrine disrupters are necessary before abnormalities of the reproductive tract can be confidently ascribed to these agents.

### Persistent Müllerian Duct Syndrome (Defects in the Synthesis, Secretion, or Response to Anti Müllerian Hormone)

This male-limited autosomal recessive syndrome is associated with normal male development of the external genitalia but with Müllerian duct derivatives. The retention of Müllerian structures is either due to failure of the Sertoli cells to synthesize and secrete AMH or to an end-organ defect in the response of the Müllerian duct to AMH. The gene for AMH maps to chromosome 19; a variety of mutations in the AMH gene cause the syndrome as well as mutations in the gene encoding the AMH receptor. Individuals with mutations in the AMH receptor have Müllerian ducts, despite the normal to high concentrations of plasma AMH. Therapy involves removal of the Müllerian structures.

### Environmental Chemicals

An increase in disorders of development and function of the urogenital tract in males has been noted over the past 50 years. It has been hypothesized that this increased incidence of reproductive abnormalities observed in human males is related to increased exposure to uterine to endocrine disrupters especially estrogens and androgen receptor blockers found in the diet both naturally and as a result of chemical contamination. It has been demonstrated that p,p’-DDE (dichlorodiphenyldichloroethylene)—the major and persistent DDT metabolite—binds to the androgen receptor and inhibits androgen action in developing rodents. Other chemicals such as phthalates, herbicides, and fungicides inhibit androgen actions. The term testicular dysgenesis syndrome describes a phenotype that has been attributed to endocrine disrupters. Further studies on the levels as well as the risks to humans of environmental chemicals and other endocrine disrupters are necessary before abnormalities of the reproductive tract can be confidently ascribed to these agents.

### UNCLASSIFIED FORMS OF ABNORMAL SEXUAL DEVELOPMENT IN MALES

#### Hypospadias

Hypospadias is one of the most common genital abnormalities. It has an incidence of 1 in 125 live male births in the United States. It is often associated with ventral curvature of the penis, a condition called chordee. The aberrant urethral meatus can open anywhere along the shaft of the penis, penoscrotally (at the base of the shaft), or even on the perineum.

The etiology of hypospadias is multifactorial, and both genetic and environmental factors appear to play a role in its pathogenesis. Deficient virilization of the male genitalia implies subnormal fetal testosterone production or action at the end organ. Hence, mutations in genes such as WT1, SF-1, SRY, SOX9, and DHH can result in dysgenetic 46,XY DSD with varying degrees of hypospadias and other genital abnormalities. Mutations in genes that encode steroidogenic enzymes (eg, 3β-HSD, 17α-hydroxylase, 17,20-lyase, POR, and SF-1) or those that affect androgen action and lead to partial androgen resistance as well as 5α-reductase-2 deficiency are all uncommon causes of hypospadias. In the majority of cases of isolated hypospadias with no other genital abnormality, the etiology is uncertain. Hypospadias is also a component of a number of dysmorphic syndromes, including Smith-Lemli-Opitz syndrome (a defect in cholesterol synthesis), as well as hand, foot, and genital syndrome due to a mutation in HOX13.

Several paternal and maternal risk factors have been associated with the occurrence of hypospadias in a fetus. These include subfertility and/or genital anomalies in the father, maternal age, IUGR, and fetal exposure to oral progestins or combined progestins and estrogens. These all are associated with an increased risk of hypospadias. Ten percent of hypospadias cases occur in familial cohorts. An increase in hypospadias has also been noted in infants conceived by in vitro fertilization. However, advanced maternal age and subfertility, as well as the administration of progesterational agents to the mother, may play a role in these patients.

There is a 15% risk of hypospadias in the sibling of a child with hypospadias and a 7% risk if the father has hypospadias, suggesting a genetic etiology. A mutation in a gene called MAML2 (mastermind-like domain containing 1, previously known as CXorf6 (chromosome X open reading frame 6), which appears to impair T secretion during the critical period (8–12 weeks) of male external genital differentiation, results in hypospadias.

Analysis of international demographic trends for hypospadias indicates that it is highly variable in different countries worldwide. The prevalence of hypospadias in Denmark is 1.1%, which is significantly higher than the prevalence in other Scandinavian countries, especially Finland. Hypospadias was associated with fetal growth retardation (small for gestational age), lower placental weight, and elevated plasma FSH levels at 3 months. Androgen receptor mutations were not found, and the CAG repeats in the androgen receptors were normal for the Danish population. It was suggested that environmental exposure is a likely explanation, but data of environmental exposure including demographic differences in endocrine disruptors (eg, organochloride, phalathes, xenoestrogens) are lacking.

Patients with severe hypospadias (perineoscrotal) especially those with micropenis and/or cryptorchidism should be evaluated. The evaluation should include gonadotropin, AMH, inhibin B, and an assessment of testosterone secretion either during the “window of opportunity” at 1-3 months of age or in response to hCG stimulation.
**Micropenis**

Micropenis without hypospadias results from a heterogeneous group of disorders; the most common cause is fetal T deficiency. Micropenis is rarely associated with 5α-reductase deficiency or mild defects in the androgen receptor (Table 14-4). In the human male fetus, T synthesis by the fetal Leydig cell during the critical period of male differentiation (8-12 weeks) appears to be autonomous at first, then influenced by hCG. After midgestation, fetal pituitary LH modulates fetal T synthesis by the Leydig cell and, consequently, affects the growth of the differentiated penis. Thus, males with congenital hypopituitarism or isolated gonadotropin deficiency and late fetal testicular failure (after 8-12 weeks) present with normal male differentiation and micropenis at term birth (by definition a penis length <2.5 cm) (Table 14-5).

Evaluation of the infant with micropenis should include anterior pituitary functions (ie, determination of the plasma concentration of GH, prolactin, ACTH, cortisol, thyroid-stimulating hormone, thyroxine, and gonadotropins), to rule out multiple pituitary hormone deficiencies. In infancy, there is a “window of opportunity” at 1 to 3 months of age when the perinatal rise in gonadotropin and T/DHT occurs. A lack of rise in T/DHT and LH and FSH suggests hypogonadotropic hypogonadism, while an abnormally high (>10.5 on unstimulated sample) T/DHT ratio suggests 5α-reductase-type 2 deficiency. All patients with micropenis should receive a trial of T therapy to ascertain the phallic response and to augment its length into the normal range for age. Infants with fetal T deficiency as a cause of micropenis—whether due to gonadotropin deficiency or to a primary testicular disorder—respond to 25 mg of T enanthate in oil intramuscularly monthly for 3 months with a mean increase of 2 cm in penile length. Older children require higher doses—50 mg intramuscularly × 3 doses. A long-term study of eight males with micropenis, due to congenital hypogonadotropic hypogonadism who were followed in our clinic, revealed that fetal deficiency of gonadotropins and T did not prevent the penis from responding to T in infancy and at the age of puberty. Final penile length for all patients who were treated with one or more short courses of repository T in infancy or childhood and with replacement doses of T in adolescence was in the normal adult range. Furthermore, these patients had a male gender identity, erections, ejaculation, and orgasm. No clinical, psychologic, or physiologic indication supports conversion of males with micropenis, due to diminished fetal T secretion, to females.

**Aphallia**

Complete absence of the phallus is a rare anomaly. The urethra may open on the perineum or into the rectum. Assignment of a female sex of rearing, castration, and plastic repair of the genitalia and urethra has been the approach followed in the past; however, this policy is currently questioned by some investigators because

of concern about the action of normal male fetal levels of circulating T on the fetal brain and its potential effect on postnatal psychosexual development and gender identity. There are no long-term follow-up studies of gender identity in patients with aphallia. A study investigated 46,XY patients with cloacal extrophy who were castrated in the neonatal period and assigned a female gender role. Fifty percent of this cohort announced their gender identity as male in childhood or adolescence. These data suggest that prenatal exposure to normal amounts of T during gestation is probabilistic but not deterministic in the establishment of gender identity.

**UNCLASSIFIED FORMS OF ABNORMAL SEXUAL DEVELOPMENT IN FEMALES**

Müllerian duct agenesis is characterized by congenital absence of the uterus and the upper one-third of the vagina and is termed the Mayer-Rokitansky-Küster-Hauser (MRKH) syndrome. Ovarian function is usually normal. If Müllerian agenesis is associated with renal abnormalities and cervicothoracic dysplasia, it is referred to as the MURCS syndrome. Patients with the MRKH syndrome or the MURCS syndrome have not as yet had genetic mutations identified, although familial cases have been reported. Recently, an atypical form of the MRKH syndrome has been described in three patients who had primary amenorrhea with normal breasts and pubic hair development, lack of Müllerian duct development, and clinical and biochemical evidence of androgen excess. All three patients had a heterozygous mutation of the WNT4 gene. These patients illustrate the role of WNT4 in Müllerian duct development in humans as well as in inhibiting Leydig cell development and androgen synthesis by the ovary.

**Features Which Suggest a DSD**

A DSD should be suspected in apparent females with clitoromegaly (>0.9 cm) at birth in those with a mass in the labia, inguinal canal or with an inguinal hernia, and in those with edema of the distal extremities and/or loose skin folds over the nape of the neck. A DSD should be suspected in infants with truly ambiguous genitalia, in putative males with cryptorchidism, micropenis (<2.5 cm), and hypospadias, especially perineal, siblings or relatives of patients with DSDs, and in infants whose prenatal genital appearance by sonography is not congruent with their karyotype on amniocentesis.

**MANAGEMENT OF PATIENTS WITH DSD**

The evaluation and management of the patient with atypical genitalia is complex and best undertaken by a team consisting of a pediatric endocrinologist, psychiatrist or psychologist, pediatric surgeon or urologist, social worker, religious counselor if appropriate, and an informed primary care physician at a center of excellence. The goal of management of patients with atypical genitalia is to establish an etiologic diagnosis promptly and with the informed consent of the parents, assign a sex of rearing which is most compatible with the prospect for a stable gender identity, well-adjusted life, sexual adequacy, and fertility if possible. Steps in the diagnosis of the infant with a DSD are set forth in Figures 14-16 and 14-17.

Before any decision about sex assignment is made, a thorough, comprehensive evaluation must be undertaken. The diagnostic evaluation should include a karyotype, pelvic sonography and determination of gonadotropins, and adrenal and gonadal steroids, AMH, and inhibin B levels. Depending on the karyotype and ultrasound, further analysis of steroids after hCG and ACTH stimulation may be indicated (see Figure 14-17). In all 46,XY DSDs with a micropenis (Tables 14-4 and 14-5), it is prudent to assess the phallic response to T to exclude partial androgen resistance before the decision about definitive sex assignment is made by the parents. Clitoral enlargement (Table 14-6) in 46,XX females suggests either an endogenous or exogenous source of androgens.

Gender identity—the identification of oneself as either male or female—is a complex and incompletely understood dimorphic phenomenon. During the last 20 years, it has been increasingly evident that both nature (eg, prenatal exposure to T) as well as genes on the X and Y chromosome, and nurture (sex assignment, psychosocial and experiential factors) play a role in determining one’s gender identity. In any given infant, one can never be sure whether nature or nurture will be deterministic or prevail. Thus, physicians are faced with the daunting task of helping parents to make a critical decision about the sex of rearing of their child in the face of incomplete understanding of the complexity of gender identity. The task is further complicated by the limited ability to make a definitive etiologic diagnosis in many 46,XY DSDs, as well as by the lack of outcome data that incorporate modern guidelines, recent surgical advances, and advances in psychologic/psychiatric support for both the child and the parents.

It is the physician’s and consultant’s tasks to evaluate the patient thoroughly and to fully inform the parents. The ultimate decision of sex of rearing is made by the completely well-informed parents. It must be clearly stated which anatomic abnormalities can be surgically repaired, that hormone therapy can be given at an appropriate time and that continuing psychosocial support will be available both from the physicians involved and from community-based support groups. Repeated, lucid, simple, comprehensive discussions about the cause of their child’s atypical genitalia and what is known about the long-term follow-up of similar patients with DSD, as well as the results of reconstructive surgery in terms of sexual gratification and fertility, must be discussed. The discussion needs to take into account parental concerns, religious views, cultural factors, social mores, and the parents’ level of understanding. The parents need to be assured that an expeditious, definitive diagnosis can be made, that naming the baby, sending out birth announcements, and filing the birth certificate may need to be delayed. They will need support, reassurance, and counseling as to how to deal with relatives and others.

In the individual with atypical genitalia, the option of assigning a sex of rearing but deferring surgery unless it is medically

necessary until the patient has the opportunity to give his or her informed consent, has been proposed by advocacy groups and espoused by some DSD clinics. However, it should be noted that there are no data on patients with DSD and atypical genitalia to support the efficacy of this approach. On the other hand, a long-term study of 41 patients with DSD suggested that early surgical intervention accompanied by endocrinologic and psychologic/psychiatric support for the patient and parents resulted in positive outcomes in terms of cosmesis, minimal impairment in quality of life and appropriate gender identity. We concur with this position and feel that it is desirable to initiate plastic repair of the external genitalia as soon as is feasible with the informed consent of the parents. Surgeons experienced in genital repair recommend a one-stage repair by 4 to 6 months of age. In children raised as females, clitoroplasty should be performed only by experienced surgeons with the emphasis being on function rather than cosmesis. We do not recommend routine clitoroplasty for mild to moderate clitoromegaly (Prader II or III). Vaginoplasty can be deferred until adolescence when the patient may participate in the decision for surgery. Each patient is unique and must be treated as such. There is no rubric that can be applied to the management of all patients. However, the following are a few guidelines.

Male sex assignment is recommended in 46,XY DSDs, with the exception of those with complete androgen resistance syndrome; those who have completely female external genitalia; those with partial androgen resistance, who have less than Prader III ambiguity; or those who have a compelling reason for female sex assignment, including the parents’ informed decision. In the latter case, extensive discussion with the family is especially warranted, particularly in the 46,XY infant whose ambiguous genitalia is evidence of significant fetal T exposure. The parents need to be aware of the effect of T during gestation on gender identity and counseled about the possibility of gender dysphoria if the child is assigned a female sex of rearing. In this case, it may be prudent to do no surgery unless medically indicated, until the child’s gender identity can be verified, and informed consent for surgery obtained from the patient. In patients with XO/XY mosaicism, 17β-HSD-3 deficiency, and 5α-reductase deficiency diagnosed in infancy, the significant occurrence of female to male gender role change should be discussed with the parents. In some societies, the

FIGURE 14-17 Steps in the differential diagnosis of 46,XY DSD.

The phenotype and comorbidities of any mutation causing a 46,XY DSD are variable and depend on the degree of enzymatic activity resulting from the particular mutation. Thus, in these patients, the degree of ambiguity of the external genitalia varies, and the Mullerian structures may or may not be present.

CYP17 (P450c17) catalyzes the 17-hydroxylation of progesterone and pregnenolone to 17-hydroxyprogesterone and 17-hydroxypregnenolone, as well as the scission (lyase) of 17-hydroxypregnenolone to DHEA. Patients with 17,20-lyase have elevated basal and hCG-induced levels of
The StAR (steroidogenic acute regulatory) protein is involved in the transport of cholesterol from the outer to the inner mitochondrial membrane, where the enzyme CYP11A1 (P450scc) resides. StAR mutations result in a markedly diminished ability to convert cholesterol to Δ5 pregnenolone, although side chain cleavage (CYP11A1) activity is intact. WAGR, Wilms tumor, aniridia, genital anomalies, and mental retardation; SF-1, steroidogenic factor-1; CYP 17, 17α-hydroxylase/17,20-lyase; 3β-HSD 2, 3β-hydroxysteroid dehydrogenase/Δ5-isomerase; 17β-HSD 3, 17β-hydroxysteroid dehydrogenase (oxidoreductase) type 3; T, testosterone; DHT, dihydrotestosterone; AMH, anti-Mullerian hormone; DHEA, dehydroepiandrosterone; POR, P450 oxidoreductase; b5, cytochrome b5.

Social, cultural, and economic benefits of a male sex assignment are more compelling than phallic adequacy and are a prevailing—if not the most important—factor in the parents’ sex of rearing decision. Male sex assignment in 46,XY DSD individuals, especially those who can respond to T allows for a choice later in adolescence, by not removing functional genital structures which cannot be replaced.

All 46,XX DSDs with Prader I to IV (see Figure 14-13) external genitalia should be raised as females. 46,XX DSDs with Prader V genitalia (penile urethra) represent a management dilemma. As with other forms of DSD, there are at present insufficient long-term outcome data on these patients. Raising the child as male would require gonadectomy of a potentially fertile female. These infants are raised as females if diagnosed in infancy. If diagnosed after infancy and a male gender assignment has been made, a full discussion with the parents and psychological evaluation of the child should ensue before any definitive decisions are made regarding gender assignment. Reassignment of sex in childhood is always a difficult psychosocial problem for the patient, the parents, and the physicians involved. Although easier in the infant under 1 year of age, it should only be undertaken after much deliberation and with provision for long-term medical and psychiatric supervision and counseling.

*Data from Lloyd I, Crouch NS, Minto CL, et al. Female genital appearance: “normality” unfolds. BJOG. 2005;112:643-646. [PMID:15842291]

Psychologic studies in 46,XX DSD secondary to CAH suggest that the vast majority of 46,XX DSDs with CAH have a female gender identity. In some individuals, sex-specific behavior may be more masculine. The incidence of bisexuality and homosexuality is increased. In one study, the prevalence of bisexuality and homosexuality correlated modestly with the degree of masculinization of nonsexual behavior and the genitalia.

Removal of rudimentary gonads in children with Y-containing cell lines and gonadal dysgenesis should be performed at the time of initial repair of the external genitalia; gonadoblastomas, seminomas, and germinomas can occur during the first decade (see Table 14-2). Histologically and functionally normal scrotal testes can be retained in 45,XY/46,XX males and others with regular monitoring as previously discussed.

In a patient with complete androgen resistance, the tests may be left in situ (provided they are not situated in the labia majora) to provide endogenous estradiol at puberty. There is one possible exception that of the rare somatic mosaics for the androgen receptor who are at risk of virilization at puberty, due to the presence of a population of cells with normal androgen receptors. Having had the female identity reinforced by normal feminization at puberty, prophylactic castration can then be performed, if informed consent by the patient and parents is obtained.

In patients with partial androgen resistance reared as females or in patients with errors of T biosynthesis reared as females in whom some degree of masculinization occurs at puberty, orchidectomy should be performed before the age of puberty or later if doubt exists about the gender identity. GnRH agonists can be given to prevent androgen secretion and virilization until the gender identity is confirmed. Cyclic estrogen and progestin replacement therapy are used in individuals reared as females in whom a uterus is present. In males, masculinization is achieved by the administration of repository or topical preparations of T.

Continuing endocrinologic and psychologic support are critical aspects of follow-up and should be available throughout infancy, childhood, adolescence, and adulthood for the patient.

17-hydroxyprogesterone and 17-hydroxypregnenolone and low levels of androstenedione and DHEA. Cytochrome b5 is a cofactor for 17,20-lyase activity of 17α-hydroxylase. Mutations result in ambiguous genitalia and methemoglobinemia.
as well as for the parents. Patients should have progressive, step-by-step, age-appropriate discussions about their diagnosis, its pathophysiology, their quality of life, and the potential for fertility. Disclosure is critical! However, in those mature adult DSD patients who are well-adjusted and happy with their lives and their assigned sex and who in the past have not had the opportunity of having full disclosure, disclosure may be on a need to know basis. Patients have access to their medical records. It is infinitely better to proceed with full disclosure if the patient has expressed a desire to know more about their diagnosis and management. Full disclosure should be approached in a similar manner as that carried out with parents and with the cooperation and help of a psychologist or psychiatrist familiar with the patient and issues of gender identity. The patient (when possible) and the parents should always be involved in decisions about surgery and sex hormone replacement.

In sum, the physician and the medical team concerned with the diagnosis, selection of sex of rearing, and management of the infant with DSD must be prepared to address the complex ethical, cultural, social, religious, clinical, legal, and surgical issues presented by the DSD patient in order to maximize the patient’s potential for a well-adjusted, normal life. This task remains complicated by deficiencies in the availability of long-term outcome data as well as the inability to diagnose specifically many patients with a DSD especially those with a 46,XY karyotype.

Puberty is best considered as one stage in the continuing process of growth and development that begins during gestation and continues until the end of reproductive life. After an interval of childhood quiescence—the juvenile pause—the hypothalamic pulse generator increases activity in the peripubertal period, just before the physical changes of puberty commence. This leads to increased secretion of pituitary gonadotropins and, subsequently, gonadal sex steroids that bring about secondary sexual development, the pubertal growth spurt, and fertility. Historical records show that the age at onset of particular stages of puberty in boys and girls in Western countries has steadily declined over the last several hundred years; this is probably due to improvements in socioeconomic conditions, nutrition, and, therefore, the general state of health during that period. This trend appears to be continuing but now due more to the effects of the obesity epidemic than the improvement in general health.

Many endogenous and exogenous factors can alter age at onset of puberty. While obesity may decrease the age of onset of puberty, chronic illness and malnutrition often delay puberty. There is a significant concordance of age at menarche between mother-daughter pairs and within ethnic populations, indicating the influence of genetic factors. Recent study of genetic loci associated with the age of onset of puberty suggests the existence of several genes that are likely involved in the regulation of menarche and puberty.

### PHYSIOLOGY OF PUBERTY

#### Physical Changes Associated with Puberty

Descriptive standards proposed by Tanner for assessing pubertal development in males and females are in wide use (denoted as Sexual Maturation stages or, often, Tanner stages). They focus attention on specific details of the examination and make it possible to objectively record subtle progression of secondary sexual development that may otherwise be overlooked. Self-assessment of pubertal development by subjects using reference pictures is used in clinical studies but reliability is less than that achieved by physical examination.
A. Female changes  The first sign of puberty in the female, as noted in longitudinal studies, is an increase in height velocity that heralds the beginning of the pubertal growth spurt; girls are not usually examined frequently enough to demonstrate this change in clinical practice, so breast development is the first sign of puberty noted by most examiners. Breast development (Figure 15–1) is stimulated chiefly by ovarian estrogen secretion, although other hormones also play a part. The size and shape of the breasts may be determined by genetic and nutritional factors, but the characteristics of the stages in Figure 15–1 are similar in all females. Standards are available for the change in areolar (nipple) plateau diameter during puberty: nipple diameter changes little from stages B1 to B3 (mean of 3.4 mm) but enlarges substantially in subsequent stages (mean of 7.4 mm at stage B4 to 10 mm at stage B5), presumably as a result of increased estrogen secretion at the time of menarche. Areolae become more pigmented and erectile as development progresses. Other features reflecting estrogen action include enlargement of the labia minora and majora, dulling of the vaginal mucosa from its prepubertal reddish hue to more of a pink color (due to cornification of the vaginal epithelium), and production of a clear or slightly whitish vaginal secretion prior to menarche. Pubic hair development (Figure 15–2) is determined chiefly by adrenal and ovarian androgen secretion. Breast development and growth of pubic hair usually proceed at similar rates, but because discrepancies in rates of advancement are possible, it is best to stage breast development separately from pubic hair progression.

Uterine size and shape change with pubertal development as reflected by ultrasonographic studies. With prolonged estrogen stimulation, the fundus-cervix ratio increases, leading to a bulbous form, and the uterus elongates. An endometrial stripe appears with the onset of puberty that is not found in premature thelarche. Ovaries enlarge with pubertal progression. Small cysts are normally present in prepubertal girls and a multicystic appearance develops during puberty, but the polycystic appearance seen in abnormalities of puberty or during the reproductive years in normal girls is not present. Experienced ultrasonographers can determine the developmental stage of the uterus and ovaries by comparing the results with established standards.

It is important to note that girls achieve reproductive maturity prior to physical maturity and certainly prior to psychologic maturity.

B. Male changes  The first sign of normal puberty in boys is usually an increase in the size of the testes to more than 2.5 cm in the longest diameter, excluding the epididymis: this is equivalent to a testicular volume of 4 mL or more. Most of the increase in testicular size is due to seminiferous tubular development secondary to stimulation by follicle-stimulating hormone (FSH), with a smaller component due to Leydig cell stimulation by luteinizing hormone (LH). Thus, if only Leydig cells are stimulated, as with a human chorionic gonadotropin (hCG)-secreting tumor, the testis does not grow as large as in normal puberty. Pubic hair development is brought about by adrenal and testicular androgen secretion and is classified separately from genital development, as noted in Figure 15–3. A longitudinal study of more than 500 boys suggests adding a stage 2a (absence of pubic hair in the presence of a testicular volume of 3 mL or more) to the classic five stages of pubertal development. Further pubertal development occurred in 82% of the subjects in stage 2a after the passage of 6 months: thus, reaching stage 2a would allow the examiner to reassure a patient that further spontaneous development is likely soon. The appearance of spermatozoa in early morning urinary specimens (spermarche) occurs at a mean chronologic age of 13.4 years or a similar mean bone age; this usually occurs at gonadal stage 3 to 4 and pubic hair stage 2 to 4. Remarkably, spermaturia is more common earlier in puberty than later, suggesting that sperm are directly released into the urine early in puberty while ejaculation may be required for the presence of sperm in the urines of older children. However, boys are reported with spermaturia and no secondary sexual development.

It is important to note that boys achieve reproductive maturity prior to physical maturity and certainly prior to psychologic maturity.

**Stage P1:** Preadolescent; the veil over the area is no further developed than that over the anterior abdominal wall (ie, no pubic hair). 

**Stage P2:** Sparse growth of long, slightly pigmented, downy hair, straight or only slightly curled, appearing chiefly along the labia. This stage is difficult to see on photographs and is subtle. 

**Stage P3:** Hair is considerably darker, coarser, and curlier. The hair spreads sparsely over the superior junction of the labia majora. 

**Stage P4:** Hair is now adult in type, but the area covered by it is still considerably smaller than in most adults. There is no spread to the medial surface of the thighs. 

**Stage P5:** Hair is adult in quantity and type, distributed as an inverse triangle of the classic feminine pattern. Spread is to the medial surface of the thighs but not up the linea alba or elsewhere above the base of the inverse triangle.

**C. Age at onset**  
Ideally, the upper and lower boundaries encompassing the age at onset of puberty should be set at 2.5 standard deviations (SDs) above and below the mean (encompassing 98.8% of the normal population). Previously, there was no comprehensive study of the start of secondary sexual development adequate to determine the lower limits of normal in US children, as national studies began reporting children who were already 12 years of age or older. Thus, European standards, primarily those of Tanner, were modified for use in the United States. However, a study conducted in medical offices by specially trained pediatricians studying 17,070 girls brought in for routine visits provided information on girls in the United States as young as 3 years. The study revealed that 3% of white girls reach stage 2 breast development by 6 years of age and 5% by 7 years, whereas 6.4% of black girls had stage 2 breast development by 6 years and 15.4% by 7 years. Although this was not a randomly chosen population sampled by longitudinal study (and this led to controversy), it is the largest study available. These data led to the Lawson Wilkins Pediatric Endocrine Society statement that the diagnosis of precocious puberty could be defined as secondary sexual development starting prior to 6 years in black girls and prior to 7 years in white girls who are otherwise healthy. Recent analysis of data from NHANES III demonstrated that children of normal BMI values rarely have breast or pubic hair development before 8 years, although increased BMI in a subset of girls or Hispanic and African American ethnicity led to earlier development. It is essential to use any such guidelines only in healthy girls with absolutely no signs of neurologic or other disease that might pathologically advance puberty or a grave diagnosis may be missed.

Recent data indicate that boys with elevated body mass indices have earlier onset of puberty. However, there has been no change in the age at onset of puberty in boys in the general population, so 9 years is taken as the lower limit of normal pubertal development in males, whereas 13½ years is the upper limit of normal development (although 14 years is often used as a simplified limit). The mean age at menarche in the United States is 12.8 years since the last government study was published in 1974. White girls have menarche later (12.9 years) than black girls (12.3 years), but this 6-month difference is less than the 1-year difference in the age at onset of puberty between the two groups. A compensation occurs in pubertal development so that those girls who enter puberty at the earliest ages of the normal range take more time to reach menarche, and those who enter at older ages of the normal range progress faster to menarche.

There is frequent discussion about an earlier age of puberty in children in the United States, which is demonstrated in some longitudinal studies in the US and abroad. The Bogalusa Heart Study shows that the gap between the age of menarche in Blacks and Whites has widened in the past decades, and this may be due to differing patterns of weight (and fat) gain. However longitudinal
FIGURE 15-3 Stages of male genital development and pubic hair development, according to Marshall and Tanner. Genital: Stage G1: Preadolescent. Testes, scrotum, and penis are about the same size and proportion as in early childhood. Stage G2: The scrotum and testes have enlarged, and there is a change in the texture and some reddening of the scrotal skin. There is no enlargement of the penis. Stage G3: Growth of the penis has occurred, at first mainly in length but with some increase in breadth; further growth of testes and scrotum. Stage G4: Penis further enlarged in length and girth with development of glans. Testes and scrotum further enlarged. The scrotal skin has further darkened. Stage G5: Genitalia adult in size and shape. No further enlargement takes place after stage G5 is reached. Pubic hair: Stage P1: Preadolescent. The vellus is no further developed than that over the abdominal wall (ie, no pubic hair). Stage P2: Sparse growth of long, slightly pigmented, downy hair, straight or only slightly curled, appearing chiefly at the base of the penis. This is subtle. Stage P3: Hair is considerably darker, coarser, and curler and spreads sparsely. Stage P4: Hair is now adult in type, but the area it covers is still considerably smaller than in most adults. There is no spread to the medial surface of the thighs. Stage P5: Hair is adult in quantity and type, distributed as an inverse triangle. Spread is to the medial surface of the thighs but not up the linea alba or elsewhere above the base of the inverse triangle. Most men have further spread of pubic hair. (Photographs from Van Wieringen JC, et al. Growth Diagrams 1965 Netherlands: Second National Survey on 0-24 Year Olds. Institute for Preventive Medicine NO Leiden, Wolters-Noordhoff Publishing; 1971; with permission.)

study from the Fells Institute shows that those girls who develop early have a tendency to increase their body mass index values after more than those who start puberty later. The presence or absence of menarche however, does not affect the interpretation of a BMI value. Late onset of pubertal development above the upper age limit of normal may indicate hypothalamic, pituitary, or gonadal failure or, alternatively, normal variation (constitutional delay). The time from onset of puberty until adult development is complete is also of importance; significant delays in reaching subsequent stages may indicate any type of hypogonadism.

D. Growth spurt The striking increase in growth velocity in puberty (pubertal growth spurt) is under complex endocrine control involving thyroid hormone, growth hormone (GH), and estrogen. Hypothyroidism decreases or eliminates the pubertal growth spurt. The amplitude of GH secretion increases in puberty, as does production of insulin-like growth factor (IGF-I); peak serum IGF-I concentrations are reached about 1 year after peak growth velocity, and serum IGF-I levels remain above normal adult levels for up to 4 years thereafter. GH and estrogen are important in the pubertal growth spurt; when either or both are deficient, the growth spurt is decreased or absent. Estrogen indirectly stimulates IGF-I production by increasing the secretion of GH. It also directly stimulates IGF-I production in cartilage. Estrogen is the most important factor in stimulating maturation of the chondrocytes and osteoblasts, ultimately leading to epiphyseal fusion. A patient reported with estrogen receptor deficiency was tall, with continued growth past the age of 20 years with a remarkable retardation of skeletal maturation (and decreased bone density). Patients with aromatase deficiency, and therefore, impaired conversion of testosterone to estrogen, also demonstrate diminished advancement of bone age and decreased bone density, as well as continued growth extending into the third decade. With exogenous estrogen administration, the bone age advanced, and the bone density increased. Such patients demonstrate the key role played by estrogen in advancing bone age and bringing about the
cessation of growth by epiphyseal fusion as well as the importance of estrogen in increasing bone density.

In girls, the pubertal growth spurt begins in early puberty and is mostly completed by menarche. In boys, the pubertal growth spurt occurs toward the end of puberty, at an average age 2 years older than in girls. Total height attained during the growth spurt in girls is about 25 cm; in boys, it is about 28 cm. The mean adult height differential of 12 cm between men and women is due in part to heights already attained before onset of the pubertal growth spurt and in part to the height gained during the spurt.

Twin studies from Finland demonstrate that the heritability estimate (proportion of variance of age of onset of puberty attributable to genetic variance) for age at onset of pubertal growth spurt was 0.91, 0.93 for age at peak height velocity, and 0.97 for adult height. In addition, the age at onset of the pubertal growth spurt was negatively associated with BMI in childhood.

Precocious puberty may coexist with GH deficiency: this situation may occur, for example, in a child with a brain tumor causing central precocious puberty, who is treated with central nervous system radiation that subsequently causes GH deficiency. The precocious puberty may raise the growth rate to the normal range, cloaking the GH deficiency but the child does not grow at the excessive rate characteristic of precocious puberty with GH sufficiency.

### E. Changes in body composition

Changes in body composition are also prominent during pubertal development. Prepubertal boys and girls start with equal lean body mass, skeletal mass, and body fat, but at maturity men have approximately 1½ times the lean body mass, skeletal mass, and muscle mass of women, whereas women have twice as much body fat as men. Attainment of peak values of percent-age of body fat, lean body mass, and bone mineral density is earlier by several years in girls than in boys, as is the earlier peak of height velocity and weight gain in girls.

The most important phases of bone accretion occur during infancy and during puberty. Girls reach peak mineralization between 14 and 16 years of age, whereas boys reach a later peak at 17.5 years; both milestones occur after peak height velocity (Figure 15-4). The density of bone is determined by genetic factors; decreased bone mass is found in familial patterns even if subjects are studied before puberty. Patients with delay in puberty for any reason have a significant decrease in bone accretion and a delay in reaching peak bone mineral density, although bone density may later reach normal values in those with constitutional delay in puberty. Moderate exercise increases bone mass, but excessive exercise itself delays puberty; the ultimate outcome of excessive exercise in girls is the combination of exercise-induced amenorrhea, premature osteoporosis, and disordered eating, which is known as the female athletic triad.

Unfortunately, in the United States, only a minority of adolescents receive the recommended daily allowance of calcium (>1000 mg/d depending on age) and vitamin D, and a future epidemic of osteopenia or even osteoporosis in normal subjects who have this deficiency is a possibility although genetic influences are prominent in later adult bone density. It is especially important to ensure adequate calcium intake and vitamin D in patients with delayed or absent puberty and in patients treated with gonadotropin-releasing hormone (GnRH) agonists.

### F. Other changes of puberty

Other changes that are characteristic of puberty are mediated either directly or indirectly by the change in sex steroids. For example, seborrheic dermatitis may appear, the mouth flora changes, and periodontal disease, rare in childhood, may occur. Insulin resistance intensifies in normal adolescents as well as those with type I diabetes mellitus.

### Endocrine Changes from Fetal Life to Puberty

Pituitary gonadotropin secretion is controlled by the hypothalamus, which releases pulses of GnRH into the pituitary-portal system to reach the anterior pituitary gland by 20 weeks of gestation. Control of GnRH secretion is exerted by a hypothalamic pulse generator in the arcuate nucleus. It is sensitive to feedback control from sex steroids and inhibin, a gonadal protein product that controls the frequency and amplitude of gonadotropin secretion during development in both sexes and during the progression of the menstrual cycle in females (see Chapter 13).

In males, LH stimulates the Leydig cells to secrete testosterone, and FSH stimulates the Sertoli cells to produce inhibin. Inhibin
feeds back on the hypothalamic-pituitary axis to inhibit FSH. Inhibin is also released in a pulsatile pattern, but concentrations do not change with pubertal progression.

In females, FSH stimulates the granulosa cells to produce estrogen and the follicles to secrete inhibin, and LH appears to play a minor role in the endocrine milieu until menarche. Then LH triggers ovulation and later stimulates the theca cells to secrete androgens (see Chapter 13).

A. Fetal life The concept of the continuum of development between the fetus and the adult is well illustrated by the changes that occur in the hypothalamic-pituitary-gonadal axis. Gonadotropins are demonstrable in fetal pituitary glands and serum during the first trimester. The pituitary content of gonadotropins rises to a plateau at midgestation. Fetal serum concentrations of LH and FSH rise to a peak at midgestation and then gradually decrease until term. During the first half of gestation, hypothalamic GnRH content also increases, and the hypothalamic portal circulation achieves anatomic maturity. These data are compatible with a theory of early unrestrained GnRH secretion stimulating pituitary gonadotropin secretion, followed by the appearance of central nervous system factors that inhibit GnRH release and decrease gonadotropin secretion after midgestation. Because the male fetus has measurable serum testosterone concentrations but lower serum gonadotropin concentrations than the female fetus, negative feedback inhibition of gonadotropin secretion by testosterone appears to operate after midgestation.

B. Changes at birth At term, serum gonadotropin concentrations are suppressed in the neonate, but with postnatal clearance of high circulating estrogen concentrations, negative inhibition is reduced and postnatal peaks of serum LH and FSH are measurable for several months to up to a few years after birth. Serum testosterone concentrations may be increased to midpubertal levels during the several months after birth in normal males, and serum estradiol rises in pulses for the first 2 years in infant girls. These peaks of gonadotropins and sex steroids in normal infants complicate the diagnosis of central precocious puberty at these youngest ages, because it is difficult to decide whether to attribute the gonadotropin and sex steroid peaks to central precocious puberty or to normal physiology (the mini-puberty of infancy). While episodic peaks of serum gonadotropins may occur until 2 years of age, serum gonadotropin concentrations are low during later years in normal childhood.

C. The juvenile pause or the midchildhood nadir of gonadotropin secretion While serum gonadotropin concentrations are low in midchildhood, sensitive assays indicate that pulsatile secretion occurs and that the onset of puberty is heralded more by an increase in amplitude of secretory events than a change in frequency. Twenty-four-hour mean concentrations of LH, FSH, and testosterone rise measurably within 1 year before the development of physical pubertal changes. Patients with gonadal failure—such as those with the syndrome of gonadal dysgenesis (Turner syndrome)—demonstrate an exaggeration of the normal pattern of gonadotropin secretion, with exceedingly high concentrations of serum LH and FSH during the first several years of life. Such patients show that negative feedback inhibition is active during childhood; without sex steroid or inhibin secretion to exert inhibition, serum gonadotropin values are greatly elevated. During midchildhood, normal individuals and patients with primary hypogonadism have lower serum gonadotropin levels than they do in the neonatal period, but the range of serum gonadotropin concentrations in hypogonadal patients during midchildhood is still higher than that found in healthy children of the same age. The decrease in serum gonadotropin concentrations in primary agonal children during midchildhood is incompletely understood, but has been attributed to an increase in the central nervous system inhibition of gonadotropin secretion during these years. Thus, the juvenile pause in normal children and those with primary gonadal failure appears to be due to central nervous system restraint of GnRH secretion.

D. Peripubertal gonadotropin increase Prepubertal children demonstrate a circadian rhythm of LH and FSH secretion of low amplitude with a pattern of low levels of sex steroid secretion lagging behind the gonadotropin rhythm. The delay is presumably due to the time necessary for biosynthesis and secretion of sex steroids. Thus, the changes that are described later and that occur at puberty do not arise de novo but are based on preexisting patterns of endocrine secretion. In the peripubertal period, endogenous GnRH secretion increases in amplitude and frequency during the early hours of sleep and serum testosterone and estrogen concentrations rise several hours later, suggesting that biosynthesis or aromatization occurs during the period of delay—a pattern that differs from the prepubertal period mainly in the increased amplitude of the secretion encountered in puberty. As puberty progresses in both sexes, the peaks of serum LH and FSH occur more often during waking hours; and, finally, in late puberty, the peaks occur at all times, eliminating the diurnal variation.

During the peripubertal period of endocrine change prior to secondary sexual development, gonadotropin secretion becomes less sensitive to negative feedback inhibition. Before this time, a small dose of exogenous sex steroids virtually eliminates gonadotropin secretion, whereas afterward a far larger dose is required to suppress serum FSH and LH. Thus, an equilibrium of pubertal concentrations of gonadotropins and sex steroids is reached.

The switch that triggers the onset of puberty is unknown, but several neurotransmitters are involved in the process, including gamma-aminobutyric acid and N-methyl-D-aspartate. Most recently, KISS1, a human metastasis suppressor gene at locus 19p13.3, which codes for metatin (or kispeptin), a 145 amino acid peptide, has been implicated. Metatin is the endogenous agonist for GPR54, a Gq/11-coupled receptor of the rhodopsin family (metatin receptor), which is found in the brain, mainly in the hypothalamus and basal ganglia, as well as in the placenta. KISS1 mRNA levels increase with puberty in intact male and female monkeys from the juvenile to midpubertal stages. Furthermore, administration of KISS1 via intracerebral catheters to GPR5H-primed
juvenile female rhesus monkeys stimulates GnRH release, release that is abolished by infusion of GnRH antagonist. Thus, it is postulated that KISS1 signaling through the GPR54 receptor of primate hypothalamus may be activated at the end of the juvenile pause and contribute to the pubertal resurgence of pulsatile GnRH release of puberty, serving as a trigger for the onset of puberty.

Highly sensitive sandwich assays (immunoradiometric [IRMA]) and immunochromiluminometric assays (ICMA) are available for gonadotropin determination. They can be used to indicate the onset of pubertal development solely with basal samples usually without the necessity for GnRH testing (see GnRH and GnRH agonist testing in the Central Precocious Puberty section). Elevated basal LH values (>0.3 IU/L) determined by third-generation assays in random blood samples are highly predictive of elevated peak GnRH-stimulated LH and therefore indicate the onset of central precocious puberty or normal puberty. These third-generation assays further reflect the remarkable logarithmic increase in spontaneous LH secretion in the latest stages of prepuberty and earliest stages of puberty as the testicular volume increases from 1 mL to 10 mL; these increases in serum LH are far greater proportionately than those found in the last stages of pubertal development. The magnitude of increase in serum testosterone is also greater in the early stages of puberty and correlates with the increase in serum LH during this same period of early pubertal development. Note that standard LH and FSH assays are not sensitive enough to detect the changes seen with the ultrasensitive assays. Furthermore, the laboratory must have pubertal standard values available to permit accurate interpretation of the measurements. Since both types of assays are available commercially, care in ordering is needed.

E. Sex steroid secretion Sex steroid secretion is correlated with the development of gonadotropin secretion. During the postnatal period of increased episodic gonadotropin secretion, plasma concentrations of gonadal steroids are episodically elevated. This indicates the potential for secretory activity in the neonatal gonad. Later, when gonadotropin secretion decreases in midchildhood, gonadal activity decreases, but the testes can still be stimulated by LH or hCG and the ovaries by FSH, with resulting secretion of gonadal steroids. An ultrasensitive estradiol assay demonstrates higher values of serum estradiol in prepubertal girls than in prepubertal boys, indicating definite basal ovarian activity during the juvenile pause. With the onset of puberty, serum gonadal steroid concentrations progressively increase. While sex steroids are secreted in a diurnal rhythm in early puberty, as are gonadotropins, sex steroids are bound to sex hormone-binding globulin (SHBG), so that the half-life of sex steroids is longer than that of gonadotropins. Thus, random daytime measurements of serum sex steroids are more helpful in determining pubertal status than random measurements of serum gonadotropins but still are not infallible.

Most (97%-99%) of the circulating estradiol and testosterone is associated with SHBG. The free hormone is the active fraction, but SHBG modulates the activity of the total testosterone and estradiol. Prepubertal boys and girls have equal concentrations of SHBG, but because testosterone decreases SHBG and estrogen increases SHBG, adult males have only half the concentration of SHBG compared with adult females. Thus, lower SHBG levels amplify androgen effects in men. While adult men have 20 times the amount of plasma testosterone that adult women have, adult men have 40 times the amount of free testosterone that adult women have.

F. GnRH stimulation The use of intravenous, exogenous GnRH has further clarified the pattern of pubertal development. When GnRH is administered to children less than 2 years of age, pituitary secretion of LH and FSH increases markedly. During the juvenile pause, the period of low basal gonadotropin secretion (after age 2 until the peripubertal period), exogenous GnRH has less effect on LH release. By the peripubertal period, intravenous GnRH or GnRH agonist induces a greater rise in LH concentrations in boys and girls, and this response continues until adulthood. There is no significant change in the magnitude of FSH secretion after GnRH with the onset of puberty, though females at all ages release more FSH than males.

Gonadotropins are released in secretory spurts in response to endogenous GnRH, which itself is secreted episodically about every 90 to 120 minutes in response to a central nervous system pulse generator. GnRH can be administered to patients in episodic boluses by a programmable pump that mimics the natural secretory episodes. A prepubertal subject without significant gonadotropin peaks demonstrates the normal pubertal pattern of episodic secretion of gonadotropins after only a few days of exogenously administered GnRH boluses. Hypogonadotropic patients, who in the basal state do not have normal secretory episodes of gonadotropin release, may be converted to a pattern of normal adult episodic gonadotropin secretion by this method of pulsatile GnRH administration.

This phenomenon is used in clinical practice to bring about ovulation or spermatogenesis to foster fertility. Varying the timing of pulsatile GnRH administration can regulate the ratio of FSH to LH just as the frequency of endogenous hypothalamic GnRH release shifts during the menstrual cycle and puberty to alter this ratio naturally. Increasing the frequency of GnRH pulses increases the LH-FSH ratio; an increased ratio is characteristic of midcycle and peripubertal dynamics. Alternatively, if GnRH is administered continuously rather than in pulses or if long-acting superactive analogs of GnRH are given, a brief period of increased gonadotropin secretion is followed by LH and FSH suppression (see later). This phenomenon is responsible for the therapeutic effects of GnRH analogs in conditions such as central precocious puberty.

G. Leptin and puberty Leptin is a hormone produced in adipose cells that suppresses appetite through interaction with its receptor in the hypothalamus. Leptin plays a major role in pubertal development in mice and rats. Genetically leptin-deficient mice (ob/ob) do not initiate puberty. Leptin replacement promotes pubertal development in this mouse, and leptin administration causes an immature normal mouse to progress through
puberty. A leptin-deficient girl at 9 years of age was remarkably obese and had a bone age of 13 years (usually appropriate for the onset of normal puberty) but no significant gonadotropin pulses and no physical evidence of pubertal development. With leptin treatment, gonadotropin peaks appeared, and pubertal development followed. Individuals with leptin receptor deficiency also have disordered puberty. While these and other data suggested that leptin might be the elusive factor that triggers the onset of puberty, clinical data proved otherwise. Longitudinal studies demonstrate that leptin increases in girls during puberty in synchrony with the increase in fat mass, while leptin decreases in boys, with increased lean body mass and decreased fat mass in relation to testosterone production. While leptin does not appear to trigger the onset of puberty in normal adolescents, leptin may accompany pubertal changes rather than cause them. Leptin is a necessary component of pubertal development in human beings but not a major stimulant to this development.

Ovulation and Menarche

The last stage in hypothalamic-pituitary development is the onset of positive feedback, leading to ovulation and menarche. The ovary contains a paracrine system that regulates follicular atresia or development; it is only in the last stages of puberty that gonadotropins come into play in the maturation of the follicle. After midpuberty, estrogen in the appropriate amount at the appropriate time can stimulate gonadotropin release, whereas higher doses of estrogen can suppress gonadotropin secretion. The frequency of pulsatile GnRH release increases during the late follicular phase of the normal menstrual cycle and raises the ratio of LH to FSH secretion. This stimulates the ovary to produce more estrogen and leads to the midcycle LH surge that causes ovulation. Administration of pulsatile GnRH by programmable pump can be used to bring about fertility in patients with hypothalamic GnRH deficiency by mimicking this natural pattern as noted earlier.

However, even if the midcycle surge of gonadotropins is present, ovulation may not occur during the first menstrual cycles; 90% of menstrual cycles are anovulatory in the first year after menarche, and it is not until 4 to 5 years after menarche that the percentage of anovulatory cycles decreases to less than 20%. This high prevalence of anovulatory periods may be due to unrecognized PCOS in the young rather than a normal developmental phenomenon in some individuals. However, some of the first cycles after menarche may be ovulatory, and fertility is possible in the first cycle.

Just as boys are reproductively mature prior to physical maturity, girls may become fertile and even pregnant prior to physical or emotional maturity.

Adrenarche

Although the hypothalamic-pituitary axis has been well characterized in recent years, our understanding of the mechanism of control of adrenal androgen secretion is still somewhat rudimentary. The adrenal cortex normally secretes the weak androgens dehydroepiandrosterone (DHEA), its sulfate, dehydroepiandrosterone sulfate (DHEAS), and androstenedione in increasing amounts beginning at about 6 to 7 years of age in girls and 7 to 8 years of age in boys (Table 15-1). A continued rise in adrenal androgen secretion persists until late puberty. Thus, adrenarche (the secretion of adrenal androgens) occurs years before gonadarche (the secretion of gonadal sex steroids). The observation that patients with Addison disease, who do not secrete adrenal androgens, and patients with premature adrenarche, who secrete increased amounts of adrenal androgens, have precocious puberty has led to the hypothesis that adrenal androgens play a role in the induction of the hypothalamic-pituitary-gonadal axis and its maturation.

*Estradiol; ultrasensitive by HPLC MS/MS, in cycling females:
Follicular stage 39-375 pg/mL
Midcycle stage 94-762 pg/mL
Luteal stage 48-440 pg/mL

LH-pediatric is an immunometric (sandwich) electrochemiluminescent (ECL) ultrasensitive assay. FSH-pediatric is a immunometric (sandwich) chemiluminescent ultrasensitive ELISA (C-ELISA) assay.
Testosterone by HPLC MS/MS.

Estradiol, ultrasensitive is a tandem mass spectrometry by HPLC MS/MS as say.

DHEA-S is a competitive chemiluminescent immunoassay.

Values according to Quest Diagnostics, 2010; other laboratories will return other standards.
androgens at an early age, usually enter gonadarche at a normal age. This suggests that age at adrenarche does not significantly influence age at gonadarche. Furthermore, patients treated with a GnRH agonist to suppress gonadotropin secretion progress through adrenarche despite their suppressed gonadarche.

Miscellaneous Metabolic Changes

The onset of puberty is associated with many changes in laboratory values that are either directly or indirectly caused by the rise of sex steroid concentrations. Thus, in boys, hematocrit rises, and high-density lipoprotein (HDL) concentrations fall as a consequence of increasing testosterone. In both boys and girls, alkaline phosphatase rises normally during the pubertal growth spurt (often this rise is incorrectly interpreted as evidence for a tumor or liver abnormality). Serum IGF-I concentrations rise with the growth spurt, but IGF-I is more closely correlated with sex steroid concentration than with growth rate. IGF-I levels peak 1 year after peak growth velocity is reached and remain elevated for 4 years thereafter, even though growth rate is decreasing. Prostate-specific antigen (PSA) is measurable after the onset of puberty in boys and provides another biochemical indication of pubertal onset.

DELAYED PUBERTY OR ABSENT PUBERTY (SEXUAL INFANTILISM)

Any girl of 13 or boy of 14 years of age without signs of pubertal development falls more than 2.5 SD above the mean and is considered to have delayed puberty (Table 15–2). By this definition, 0.6% of the healthy population is classified as having delay in growth and adolescence. These normal patients need reassurance rather than treatment and ultimately progress through the normal stages of puberty, albeit later than their peers. The examining physician must make the sometimes difficult decision about which patients older than these guidelines are constitutionally delayed and which have organic disease.

Constitutional Delay in Growth and Adolescence

A patient with delayed onset of secondary sexual development, whose stature is shorter than that of age-matched peers but who consistently maintains a normal growth velocity for bone age and whose skeletal development is delayed more than 2 SD from the mean, is likely to have constitutional delay in puberty (Figure 15–5). These patients are at the older end of the normal distribution curve describing the age at onset of puberty. A family history of a similar pattern of development in a parent or sibling supports the diagnosis. The subject is usually thin as well. In many cases, even if they show no physical signs of puberty at the time of examination, the initial elevation of gonadal sex steroids has already begun, and their basal LH concentrations measured by ultrasensitive third-generation assays or their plasma LH response to intravenous GnRH or GnRH agonist is pubertal. In boys, an 8 AM serum testosterone value above 20 ng/dL (0.7 mmol/L) also indicates that secondary sexual development will commence within a period of months.

In some cases, observation for endocrine or physical signs of puberty must continue for a period of months or years before the diagnosis is made. Generally, signs of puberty appear after the patient reaches a skeletal age of 11 years (girls) or 12 years (boys), but there is great variation. Patients with constitutional delay in adolescence almost always manifest secondary sexual development by 18 years of chronologic age, although there is one reported case of spontaneous puberty occurring at 25 years of age. Reports of patients with Kallmann syndrome and others with constitutional delay in puberty within one family suggest a possible relationship between the two conditions (see later and Chapter 4). Adrenarche is characterizedly delayed—along with gonadarche—in constitutional delay in puberty.

Hypogonadotropic Hypogonadism

The absent or decreased ability of the hypothalamus to secrete GnRH or of the pituitary gland to secrete LH and FSH leads to hypogonadotropic hypogonadism. This classification suggests an irreversible condition requiring replacement therapy. If the pituitary deficiency is limited to gonadotropins, patients are usually

close to normal height for age until the age of the pubertal growth spurt, in contrast to the shorter patients with constitutional delay. Bone age is usually not delayed in childhood but does not progress normally after the patient reaches the age at which sex steroid secretion ordinarily stimulates maturation of the skeleton. Patients may reach taller stature than expected. However, if GH deficiency accompanies gonadotropin deficiency, severe short stature will result.

A. Central nervous system disorders

1. Tumors—A tumor involving the hypothalamus or pituitary gland can interfere with hypothalamic-pituitary-gonadal function as well as control of GH, adrenocorticotropic hormone (ACTH), thyrotropin (TSH), prolactin (PRL), and vasopressin secretion. Thus, delayed puberty may be a manifestation of a central nervous system tumor accompanied by any or all of the following: GH deficiency, secondary hypothryroidism, secondary adrenal insufficiency, hyperprolactinemia, and diabetes insipidus. The combination of anterior and posterior pituitary deficiencies acquired after birth makes it imperative that a hypothalamic-pituitary tumor be considered as the cause.

Craniopharyngioma is the most common type of hypothalamic-pituitary tumor leading to delay of absence of pubertal development. This neoplasm originates in Rathke pouch but may develop into a suprasellar tumor. The peak age incidence of craniopharyngioma is between 6 and 14 years. Presenting symptoms may include headache, visual deficiency, growth failure, polyuria, and polydipsia; presenting signs may include visual defects (bitemporal hemianopsia is classic), optic atrophy, or papilledema. Clinical manifestations and laboratory evaluation may reflect endocrinopathies (found in 70%-75% including GH, axis abnormalities in 75%, hyperprolactinemia 48%, hypothryroidism in 25%, adrenal insufficiency in 25%, diabetes insipidus (DI) in 4%, as well as gonadotropin deficiency in 40% in one series. Bone age is often retarded at the time of presentation.

Calcification in the suprasellar region is the hallmark of craniopharyngiomas; 80% of cases have calcifications on lateral skull x-ray, and a higher percentage show this on computed tomography (CT); however, calcifications cannot be seen on magnetic resonance imaging (MRI). The tumor often presents a cystic appearance on CT or MRI scan and at the time of surgery may contain dark, cholesterol-laden fluid. The rate of growth of craniopharyngiomas is quite variable—some are indolent and some are quite aggressive. Small intrasellar tumors may be resected by transphenoidal surgery; larger ones require partial resection and radiation therapy (see Chapter 4). Recurrence of this tumor after apparent complete removal is noted and lends support to the use of radiation therapy in addition to surgery.
Extrasellar tumors that involve the hypothalamus and produce sexual infantilism include germinomas, gliomas (sometimes with neurofibromatosis), and astrocytomas (see Chapter 4). However, depending on endocrine secretory activity or location, these tumors may alternatively produce central precocious puberty. Intrasellar tumors such as chromophobe adenomas are quite rare in children compared with adults. Hyperprolactinemia—with or without a diagnosed microadenoma or galactorrhea—may delay the onset or progression of puberty; with therapy to decrease PRL concentrations, puberty progresses.

2. Other acquired central nervous system disorders—These disorders may lead to hypothalamic-pituitary dysfunction. Granulomatous diseases such as Hand-Schüller-Christian disease or histiocytosis X, when involving the hypothalamus, most frequently lead to diabetes insipidus, but any other hypothalamic defect may also occur, including gonadotropin deficiency. Tuberculous or sarcoid granulomas, other postinfectious inflammatory lesions, vascular lesions, and trauma more rarely cause hypogonadotropic hypogonadism.

3. Developmental defects—Developmental defects of the central nervous system may cause hypogonadotropic hypogonadism or other types of hypothalamic dysfunction. Cleft palate or other midline anomalies may also be associated with hypothalamic dysfunction. Optic dysplasia is associated with small, hypoplastocopic optic disks and, in some patients, absence of the septum pellucidum on CT or MRI (septo-optic dysplasia); associated hypothalamic deficiencies are often present (see Chapters 4 and 6) (Hesx-1 homedomain, HESX-1 *601802. Homeobox gene expressed in ES cells; HESX-1 #182230, septoop tic dysplasia).

Optic hypoplasia or dysplasia must be differentiated from optic atrophy; optic atrophy implies an acquired condition and may indicate a hypothalamic-pituitary tumor. Both anterior and/or posterior pituitary deficiencies may occur with either congenital midline defects or acquired hypothalamic-pituitary defects. Early-onset GH deficiency or early onset of a combination of anterior and posterior pituitary deficiencies suggests a congenital defect. Patients who have isolated deficiency of gonadotropins tend to be of normal height until the teenage years but lack a pubertal spurt. They have eunuchoid proportions of increased span for height and decreased upper to lower segment ratios. Their skeletal development is delayed for chronologic age during the teenage years, they continue to grow after an age when normal adolescents stop growing. Adult height is often increased in hypogonadotropic hypogonadal individuals.

4. Radiation therapy—Central nervous system radiation therapy involving the hypothalamic-pituitary area can lead to hypogonadotropic hypogonadism with onset at 6 to 18 months (or longer) after treatment. GH is more frequently affected than gonadotropin secretion, and GH deficiency occurs with exposure to as little as an 18-Gy dose. Other hypothalamic deficiencies such as gonadotropin deficiency, hypothyroidism, and hyperprolactinemia occur more often with higher doses of radiation.

B. Isolated gonadotropin deficiency Kallmann syndrome 1 is the most common genetic form of isolated gonadotropin deficiency (Figure 15–6). Gonadotropin deficiency in these patients is associated with hypoplasia or aplasia of the olfactory lobes and olfactory bulb causing hyposmia or anosmia. Remarkably, patients may not notice that they have no sense of smell, although olfactory testing reveals the finding. GnRH-containing neurons fail to migrate from the olfactory placode (where they originate) to the medial basal hypothalamus in Kallmann syndrome. This is a familial syndrome of variable manifestations in which anosmia may occur with or without hypogonadism in a given member of a kindred. X-linked Kallmann syndrome is due to gene deletions in the region of Xp22.3 (+308700.KAL1), causing the absence of the KALI gene which codes for anosmin, which appears to code for an adhesion molecule that plays a key role in the migration of GnRH neurons and olfactory nerves to the hypothalamus. There is an association of Kallmann syndrome 1 with X-linked ichthyosis due to steroid sulfatase deficiency, developmental delay, and chondrodysplasia punctata, probably due to a microdeletion. Associated abnormalities in Kallmann syndrome 1 may affect the kidneys and bones, and patients may have undescended testes, gynecomastia, and obesity. Mirror hand movements (bimano synkinesis) are reported, with MRI evidence of abnormal development of the corticospinal tract. Adult height is normal, although patients are delayed in reaching adult height. Kallmann syndrome 2 is inherited in an autosomal dominant pattern and is due to a mutation in the FGFR1 (fibroblast growth factor receptor 1 [*136350]) gene. Kallmann syndrome 3 (*607002) exhibits an autosomal recessive pattern and appears to be related to mutations in PROKR2 (*607123) and PROK2 (PROK2 *607002), encoding pokinin receptor-2 and prokentin-2. FGF8 may also be involved.

While kisspeptin and GRP54 (G protein–coupled receptor 54) play roles of importance in the onset of puberty, only rare patients have been reported with defects in the kisspeptin–GRP54 axis due to a mutation in the gene for the GRP54 receptor. The first human beings with defects in these molecules were reported in several kindreds, some consanguineous, presenting with hypogonadotropic hypogonadism. Other cases of hypogonadotropic hypogonadism may occur sporadically or in an autosomal recessive pattern without anosmia. The GnRH gene would seem a likely candidate for the cause of the condition, but while mutations of the GnRH receptor gene, GnRHR, were noted years ago, not until 2009 were mutations in the GnRHi gene demonstrated. Other mutations causing hypogonadotropic hypogonadism without anosmia include the GPR56, SF-1 (steroidogenic factor 1), HESX-1 (Hesx-1 homedomain), 3 LHX3 (*600577) (LIM homeobox gene 3) PROP-1 (prophet of PIT1) (*601538) genes. X-linked congenital adrenal hypoplasia is associated with hypogonadotropic hypogonadism (DAX1 #300200). Adrenal hypoplasia, congenital AHC, glycerol kinase deficiency, and muscular dystrophy have also been linked to this syndrome. The gene locus is at Xp21.3–p21.2 and involves a mutation in the DAX1 gene in many but not all patients. An autosomal recessive form of congenital adrenal hypoplasia is reported. Some hypogonadal patients lack only LH secretion and have spermatogenesis without testosterone production (fertile eunuch syndrome); others lack only FSH (see Chapters 12 and 13). While a specific genetic diagnosis for hypogonadotropic hypogonadism suggests a permanent defect,
long-term studies do not bear this out. Men with a variety of mutations followed for years are reported to revert to normal or near-normal gonadotropin function in some cases. Thus, long-term follow-up is indicated.

C. Idiopathic hypopituitarism (growth hormone deficiency in the absence of defined anatomic or organic defects) Patients with congenital GH deficiency have early onset of growth failure (Figure 15-7); this feature distinguishes them from patients with GH deficiency due to hypothalamic tumors, who usually have late onset of growth failure. Even without associated gonadotropin deficiency, untreated GH-deficient patients often have delayed onset of puberty associated with their delayed bone ages. With appropriate human growth hormone (hGH) therapy, however, onset of puberty occurs at a normal age. Patients who have combined GH and gonadotropin deficiency do not undergo puberty even when bone age reaches the pubertal stage. Idiopathic hypopituitarism is usually sporadic, but may follow an autosomal recessive or X-linked inheritance pattern due to one of the gene defects listed earlier.

The syndrome of microphallus (penile length <2 cm at birth due to congenital gonadotropin or GH deficiency) and neonatal hypoglycemic seizures (due to congenital ACTH deficiency or GH deficiency) must be diagnosed and treated early to avoid central nervous system damage due to hypoglycemia (these findings may occur in septo-optic dysplasia). Patients with this syndrome do not undergo spontaneous pubertal development. Testosterone in low doses (testosterone enanthate, 25 mg intramuscularly every month for three doses) can increase the size of the penis in infants diagnosed with congenital hypopituitarism without significantly advancing the bone age. Males with isolated GH deficiency can also have microphallus; the penis enlarges with hGH therapy in these patients. It is important to note that microphallus due to hypopituitarism may be successfully treated with testosterone leading to adult male sexual function, and sex reversal should not be considered (see Chapter 14).

Birth injury, asphyxia, or breech delivery is more common in the neonatal history of patients with idiopathic hypopituitarism, especially affected males. While some subjects with breech delivery have central nervous system MRI abnormalities including interrupted pituitary stalk and ectopic posterior pituitary gland, cause and effect is not established as some individuals with breech delivery and hypopituitarism have no such MRI findings.

D. Miscellaneous disorders

1. Prader-Willi syndrome—Prader-Willi syndrome (#176270) occurs sporadically and is associated with fetal and infantile hypotonia, short stature, poor feeding in infancy but insatiable
hunger later, leading to remarkable obesity, characteristic facies with almond-shaped eyes, small hands and feet after infancy, mental retardation, and emotional instability in patients of either sex. Delayed menarche in females and micropenis and cryptorchism in males is common; while there is hypothalamic hypogonadism, there is also testicular dysfunction in males. Osteoporosis is common in these patients during the teenage years, but sex steroid replacement, when indicated, may increase bone density, although the effects are not proven to be long lasting if sex steroids administration cease. Behavioral modification may improve the usual pattern of rampant weight gain, but the constant vigilance of caregivers is necessary. Patients have deletion or translocation of chromosome 15q11-13 derived from their fathers. If an abnormality in this area derives from the mother, Angelman syndrome results. Fluorescent in situ hybridization for this area of the chromosome is available commercially for diagnosis.

2. Laurence-Moon and Bardet-Biedl syndromes—These autosomal recessive conditions are characterized by obesity, short stature, mental retardation, and retinitis pigmentosa. Hypogonadotropic hypogonadism and primary hypogonadism have variously been reported in affected patients. A distinction between Bardet-Biedl syndrome (#209900) a disorder thought to be linked to a defect in the basal body of ciliated cells) and Laurence-Moon syndrome has been made, with the latter demonstrating polydactyly and obesity and the former being characterized by paraplegia. Recently it has been suggested that these two syndromes really represent a single entity, as was the case in the past.

3. Chronic disease and malnutrition—A delay in sexual maturation may be due to chronic disease or malnutrition. For example, children with intractable asthma have delayed pubertal development leading to short stature during the teenage years, although they ultimately reach an appropriate adult height for family. Children with other chronic diseases may not fare so well in long-term follow-up; for example, HIV infection in adolescence causes poor growth and pubertal progression. Weight loss to less than 80% of ideal body weight, caused by disease or voluntary dieting, may result in gonadotropin deficiency; weight gain toward the ideal usually restores gonadotropin function. Chronic disease may have effects on sexual maturation separate from nutritional state. For example, there is a high incidence of hypothalamic hypogonadism in thalassemia major, even with regular transfusion and chelation therapy.

4. Anorexia nervosa—Anorexia nervosa involves weight loss associated with a significant psychologic disorder. This condition usually affects girls who develop a disturbed body image and exhibit typical behavior such as avoidance of food and induction of regurgitation after ingestion. Weight loss may be so severe as to cause fatal complications such as immune dysfunction, fluid and electrolyte imbalance, or circulatory collapse. Primary or secondary amenorrhea is a classic finding in these patients and has been correlated with the degree of weight loss, although there is evidence that patients with anorexia nervosa may cease to menstruate before their substantial weight loss is exhibited. Other endocrine abnormalities in anorexia nervosa include elevated serum GH and decreased IGF-I (these are characteristic of other types of starvation), decreased serum triiodothyronine, decreased serum 1,25-dihydroxyvitamin D and elevated 24,25-hydroxyvitamin D levels. Weight gain to the normal range for height, however, does not ensure immediate resumption of menses. There is an increased incidence of anorexia nervosa in ballet dancers or ballet students; the incidence of scoliosis and mitral valve insufficiency is also increased in these patients. Functional amenorrhea may also occur in women of normal weight, some of whom demonstrate evidence of psychologic stress. Decreased LH response to GnRH administration, impaired monthly cycles of gonadotropin secretion, and retention of a diurnal rhythm of gonadotropin secretion are found in anorexia nervosa patients, patterns that indicate a reversion to an earlier stage of the endocrine changes of puberty.

5. Increased physical activity—Girls who regularly participate in activities such as strenuous athletics and ballet dancing may have delayed thelarche, delayed menarche, and irregular or absent menstrual periods. Increased physical activity and not decreased weight appears to be the cause of the amenorrhea in some girls; such amenorrheic patients may resume menses while temporarily bedridden even though weight does not yet change. Statistical analysis of mothers’ ages at menarche and the type of sport pursued by their daughters indicates that late maturation of some gymnasts may be referable to a familial tendency to late menarche, suggesting that gymnastic activity may not be the primary cause of late menarche. On the other hand, there are studies indicating that intensive gymnastics training at an early age leads to a decrease in ultimate stature.

FIGURE 15-7 Twenty-year-old male with congenital deficiency of GRF, GnRH, TRF, and CRF. Height was 8 SD below the mean, and the phallus was 2 cm × 1 cm. Bone age was 10 years, and the sella turcica was small on lateral skull x-ray. LH rose minimally from a low basal value after administration of 100 μg of GnRH. Testosterone was virtually undetectable and did not rise after administration of GnRH. (Reproduced, with permission, from Styne DM, Grumbach MM. In: Yen SSC, Jaffe RB, eds. Reproductive Endocrinology. WB Saunders, 1978.)
6. Hypothyroidism—Hypothyroidism can delay all aspects of growth and maturation, including puberty and menarche. Galactorrhea may occur in severe primary hypothyroidism due to concomitant elevation of serum PRL due to TSH stimulation. With thyroid therapy, catch-up growth and resumed pubertal development and menses occur. Conversely, severe primary hypothyroidism may be associated with precocious puberty and galactorrhea (due to elevated serum PRL) in some patients (Van Wyk-Grumbach syndrome). There is evidence that excessive TSH can stimulate FSH receptors, leading to estrogen secretion and breast development.

**Hypergonadotropic Hypogonadism**

Primary gonadal failure is heralded by elevated gonadotropin concentrations due to the absence of negative feedback effects of gonadal sex steroids and inhibit. The most common causes of hypergonadotropic hypogonadism are associated with chromosomal and somatic abnormalities (see Chapter 14), but isolated gonadal failure can also present with delayed puberty without other physical findings. When hypergonadotropic hypogonadism is present in patients with a Y chromosome or a fragment of a Y chromosome (genetic males or conditions noted later), testicular dysgenesis must be considered in the differential diagnosis. The risk of testicular cancer rises in testicular dysgenesis (testicular cancer in normal boys is rare; eg, the incidence in Scandinavia is 0.5 per 100,000 in childhood).

### A. Syndrome of seminiferous tubule dysgenesis (Klinefelter syndrome)

A common form of primary testicular failure is Klinefelter syndrome (47,XXY karyotype), with an incidence of 1:1000 males. Before puberty, patients with Klinefelter syndrome have decreased upper segment-lower segment ratios, small testes, and an increased incidence of developmental delay and personality disorders. Onset of puberty is not usually delayed, because Leydig cell function is characteristically less affected than seminiferous tubule function in this condition and testosterone is adequate to stimulate pubertal development. Serum gonadotropin levels rise to castrate concentrations after the onset of puberty; the testes become firm and are rarely larger than 3.5 cm in diameter. After the onset of puberty, there are histologic changes of seminiferous tubule hyalinization and fibrosis, adenomatous changes of the Leydig cells, and impaired spermatogenesis. Gynecomastia is common, and variable degrees of male secondary sexual development are found. Surviving sperm have been found by microdissection of some seminiferous tubules in a few patients leading to successful fertilization of a partner’s ovum. Other forms of male hypergonadotropic hypogonadism are found with 46,XX/47,XXY, 48,XXYY, 48,XXXY, and 49,XXXXY karyotypes. Phenotypic males are described with 46,XX karyotypes and some physical features of Klinefelter syndrome; they may have the SRY gene translocated to an X chromosome (see Chapter 14).

### B. Other forms of primary testicular failure

Patients surviving treatment for malignant diseases form a growing category of testicular failure. Chemotherapy—primarily with alkylating agents—or radiation therapy directed to the gonads may lead to gonadal failure. Injury is more likely if treatment is given during puberty than if it occurs in the prepubertal period, but even prepubertal therapy leads to risk. Normal pubertal development may occur in boys treated with chemotherapy before puberty, although they demonstrate elevated peak serum LH and elevated basal and peak serum FSH after GnRH, as well as a high incidence of decreased or absent sperm counts. This indicates that prepubertal status does not protect a child against testicular damage from chemotherapy and that normal physical development may hide significant endocrine and reproductive damage.

The **Sertoli cell only syndrome** (germinal cell aplasia) is a congenital form of testicular failure manifested by azoospermia and elevated FSH concentrations but generally normal secondary sexual characteristics, normal testosterone concentrations, and no other anomalies. A mutation in a gene at Yq11.23, the azoospermia factor (AZF) (415000 spermatogenic failure, nonobstructive, Y-linked) appears to play a role in the lack of production of spermatocytes.

Patients with Down syndrome may have elevated LH and FSH levels even in the presence of normal testosterone levels, suggesting some element of primary gonadal failure.

### C. Cryptorchism or anorchia

Phenotypic males with a 46,XY karyotype but no palpable testes have either cryptorchism or anorchia. Cryptorchid males should produce a rise in testosterone levels greater than 2 ng/mL 72 hours after intramuscular administration of hCG (3000 U/m²) in the newborn period, although repeated doses are required after the first postnatal months. Testes may also descend during 2 weeks of treatment with hCG given three times a week.

Patients with increased plasma testosterone levels in response to hCG administration, but without testicular descent, have cryptorchism. Their tests should be brought into the scrotum by surgery to decrease the likelihood of further testicular damage due to the elevated intra-abdominal temperature and to guard against the possibility of undetected tumor formation. Cryptorchid testes may demonstrate congenital abnormalities and may not function normally even if brought into the scrotum early in life. Furthermore, the descended testis in a unilaterally cryptorchid boy may itself show abnormal histologic features; such patients have a 69% incidence of decreased sperm counts. Thus, unilateral cryptorchid patients can be infertile even if they received early treatment of their unilateral cryptorchism. Since both the descended and the undescended testes may be affected, there may be preexisting disease that is manifested by the lack of descent of one testis. Lack of normal descent of the testes is hypothesized to cause the testicular dysgenesis syndrome (TDS), which explains the late occurrence of testicular disease. In addition, patients undergoing orchiopexy may sustain subtle damage to the vas deferens, leading to the later production of antibodies to sperm that may result in infertility. This finding may depend on the surgical technique used.

It is important to determine if any testicular tissue is present in a boy with no palpable testes, because unnoticed malignant degeneration of the tissue is a possibility. The diagnosis of anorchia due to the testicular regression syndrome may be pursued by ultrasound,
MRJ, laparotomy, or laparoscopic examination. There are other endocrine evaluations besides the hCG test that may help in diagnosis. The presence of anti-Müllerian factor in a young child indicates the presence of testicular tissue, although during puberty anti-Müllerian factor becomes undetectable, and this test cannot be employed at that stage. Inhibin may be measured as an indication of functioning testicular tissue. Except for the absence of testes, 46 XY patients who are otherwise normal and have the vanishing testes syndrome of late fetal loss of the testes have normal infantile male genital development, including Wolffian duct formation and Müllerian duct regression. The testes were presumably present in these patients early in fetal life during sexual differentiation, but degenerated after the 13th week of gestation for unknown reasons (see Chapter 14). When these boys reach adulthood, they are reported to establish a normal male gender identity. The presence of normal basal gonadotropin levels in a prepubertal boy without palpable testes at least suggests the presence of testicular tissue even if the testosterone response to hCG is low, whereas the presence of elevated gonadotropin levels without any testosterone response to hCG suggests anorchia.

**D. Syndrome of gonadal dysgenesis (Turner syndrome)** 45,XO gonadal dysgenesis is associated with short stature, female phenotype with sexual infantilism, and a chromatin-negative buccal smear. We do not recommend routinely ordering a buccal smear; it is now difficult for laboratories to perform the test reliably, and it has been replaced with modern karyotyping procedures. Patients have streak gonads consisting of fibrous tissue without germ cells. Other classic but variable phenotypic features include micrognathia, fish mouth (downturned corners of the mouth), ptosis, low-set or deformed ears, a broad shield-like chest with the appearance of widely spaced nipples, hypoplastic areolae, a short neck with low hairline and webbing of the neck (pterygium colli), short fourth metacarpals, cubitus valgus, structural anomalies of the kidney, extensive nevi, hypoplastic nails, and vascular anomalies of the left side of the heart (most commonly coarctation of the aorta associated with hypertension proximal to the coarctation). However, some affected girls can have almost normal female phenotypes. The medical history of patients with the syndrome of gonadal dysgenesis often reveals small size at birth, lymphedema of the extremities most prominent in the newborn period, and loose posterior cervical skin folds. (The terms Bonnevie-Ullrich syndrome and infant Turner syndrome are applied to this neonatal appearance.) Affected patients often have a history of frequent otitis media with conductive hearing loss. There may be frequent urinary tract infections associated with a horseshoe-shaped kidney, duplication of ureters, or other anatomic defects. Intelligence is normal, but there is often impaired spatial orientation, which may lead to difficulty in mathematics, especially geometry. Patients have no pubertal growth spurt, and reach a mean final height of 143 cm. Short stature is a classic feature of Turner syndrome, but not of other forms of hypergonadotropic hypogonadism that occur without karyotype abnormalities. The short stature is linked to the absence of the (short stature homeobox) SHOX homeobox gene of the pseudoautosomal region of the X chromosome (Xpter-p22.32) (OMIM*312865). GH function is usually normal in Turner syndrome. However, exogenous hGH treatment improves growth rate and increases adult stature toward the normal range in affected girls. It improves lipid profiles and decreases diastolic blood pressure (see Chapter 6). Pubic hair may appear late and is usually sparse in distribution owing to the absence of any ovarian secretions; thus, adrenarche progresses in Turner syndrome even in the absence of gonadarche. Autoimmune thyroid disease (usually hypothyroidism) is common in Turner syndrome, and determination of thyroid function and thyroid antibody levels is important in evaluation of these patients.

Serum gonadotropin concentrations in Turner syndrome are extremely high between birth and about age 4 years. They decrease toward the normal range in prepubertal patients in the juvenile pause and then rise again to castrate levels after age 10 years (see Chapter 14).

Sex chromatin-positive variants of gonadal dysgenesis include 45,X/46,XX, 45,X/47,XXX, and 45,X/46,XX/47,XXX mosaicism with chromatin-positive buccal smears. Patients with these karyotypes may resemble patients with the classic syndrome of gonadal dysgenesis, or they may have fewer manifestations and normal or nearly normal female phenotypes. Streak gonad formation is not invariable; some patients have had secondary sexual development, and menarche and rare pregnancies have been reported.

Sex chromatin-negative variants of the syndrome of gonadal dysgenesis have karyotypes with 45,X/46,XY mosaicism. Physical features vary; some patients have the features of classic Turner syndrome, whereas others may have ambiguous genitalia or even the features of phenotypic males. Gonads are usually dysgenetic but vary from streak gonads to functioning testes. These patients are at risk for gonadoblastoma formation; this is a benign tumor that has the potential for malignant transformation and then may metastasize. Because gonadoblastomas may secrete androgens or estrogens, patients with gonadoblastoma may virilize or feminize as though they had functioning gonads, confusing the clinical picture. Gonadoblastomas may demonstrate calcification on abdominal x-ray. Malignant germ cell tumors may arise in dysgenetic testes, and orchietomy is generally indicated. In some mosaic patients with one intact X chromosome and one chromosomal fragment, it is difficult to determine whether the fragment is derived from an X chromosome or a Y chromosome. Polymerase chain reaction techniques to search for specific Y chromosome sequences may be helpful if a karyotype reveals no Y chromosomal material.

Patients with Turner syndrome who desire fertility can be treated with in vitro fertilization techniques. After exogenous hormonal preparation, a fertilized ovum (possibly a sister's ovum fertilized by the patient's male partner, or an extra fertilized ovum from another couple undergoing in vitro fertilization) can be introduced into the patient's uterus, and the pregnancy is then brought to term by support with exogenous hormone administration. A serious possible complication is uterine rupture.

**E. Other forms of primary ovarian failure** Ovaries appear to be more resistant to damage from the chemotherapy used in the
treatment of malignant disease than are testes. Nonetheless, ovarian failure can occur with medical therapy. Damage is common if the ovaries are not surgically shielded by lead in abdominal radiation therapy. Normal gonadal function after chemotherapy does not guarantee normal function later. Late-onset gonadal failure has been described after chemotherapy. Bone marrow transplantation with whole-body irradiation for acute lymphoblastic leukemia or non-Hodgkin lymphoma appear to cause the most damage to endocrine function.

Premature menopause has also been described in otherwise healthy girls owing to the presence of anti-ovarian antibodies. Patients with Addison disease may have autoimmune oophoritis as well as adrenal failure. A sex steroid biosynthetic defect due to 17α-hydroxylase deficiency (P450c17) manifests as sexual infantilism and primary amenorrhea in a phenotypic female (regardless of genotype) with hypokalemia and hypertension (see Chapter 14). A patient with 17α-hydroxylase deficiency may have ovaries or testes and still present as a phenotypic female.

F. Noonan syndrome (pseudo–Turner syndrome, Ullrich syndrome, male Turner syndrome (OMIM#163950 Noonan syndrome 1; NS1) Noonan syndrome is associated with phenotypic manifestations of Turner syndrome such as webbed neck, ptosis, short stature, cubitus valgus, and lymphedema, but other additional clinical findings such as a normal karyotype, triangular facies, pectus excavatum, right-sided heart disease, and an increased incidence of developmental delay differentiate these patients from those with Turner syndrome. Males may have undescended testes and variable degrees of germinal cell and Leydig cell dysfunction. Noonan syndrome follows an autosomal dominant pattern of inheritance with incomplete penetrance (gene locus 12q24). hGH is approved by the FDA to increase stature in these patients.

G. Familial and sporadic forms of 46,xx or 46,xy gonadal dysgenesis These forms of gonadal dysgenesis are characterized by structurally normal chromosomes and streak gonads or partially functioning gonads. They do not have the physical features of Turner syndrome. If there is some gonadal function, 46,XY gonadal dysgenesis may present with ambiguous genitalia or virilization at puberty. If no gonadal function is present, patients appear as phenotypic sexually infantile females. Patients with 46,XY gonadal dysgenesis and dysgenetic testes should undergo gonadectomy to eliminate the possibility of malignant germ cell tumor formation.

H. Primary amenorrhea associated with normal secondary sexual development If a structural anomaly of the uterus or vagina interferes with the onset of menses but the endocrine milieu remains normal, the patient presents with primary amenorrhea in the presence of normal breast and pubic hair development. A transverse vaginal septum may seal the uterine cavity from the vaginal orifice, leading to the retention of menstrual flow—as may an imperforate hymen. The Rokitansky-Küster-Hauser syndrome (OMIM #277000) combines congenital absence of the vagina with abnormal development of the uterus, ranging from a rudimentary bicornuate uterus that may not open into the vaginal canal to a virtually normal uterus; surgical repair may be possible in patients with minimal anatomic abnormalities, and fertility has been reported. Associated abnormalities include major upper tract anomalies and spinal or other skeletal disorders. The rarest anatomic abnormality in this group is absence of the uterine cervix in the presence of a functional uterus.

46,XY disorder of sexual development (DSD), previously called male pseudohermaphroditism, is an alternative cause of primary amenorrhea if a patient has achieved thelarche. The syndrome of complete androgen resistance leads to female external genitalia and phenotype without axillary or pubic hair development in the presence of pubertal breast development (syndrome of testicular feminization; see Chapter 14).

### Differential Diagnosis of Delayed Puberty (Table 15–3)

Patients who do not begin secondary sexual development by age 13 (girls) or age 14 (boys) and patients who do not progress through development on a timely basis (girls should menstruate within 5 years

after breast budding; boys should reach stage 5 pubertal development (4½ years after onset) should be evaluated for hypogonadism. The yield of diagnosable conditions is quite low in children younger than these ages, but many patients and families request evaluation well before these limits. Without significant signs or symptoms of disorders discussed above, it is best to resist evaluation and offer support until these ages in most cases.

A patient with constitutional delay may have a characteristic history of short stature for age with normal growth velocity for bone age and a family history of delayed but spontaneous puberty. The patient’s mother may have had late onset of menses, or the father may have begun to shave late or continued growing after high school. Not all patients with constitutional delay are so classic, and gonadotropin-deficient patients may have some features similar to those of constitutional delay in adolescence. Indeed, patients with Kallmann syndrome and others with constitutional delay are occasionally found in the same kindred.

If the diagnosis is not obvious on the basis of physical or historical features, the differential diagnostic process begins with determination of whether plasma gonadotropins are (1) elevated due to primary gonadal failure or (2) decreased due to secondary or tertiary hypogonadism or constitutional delayed puberty. Gonadotropins must be measured in a third-generation assay with pediatric standards as the customary gonadotropin determinations are too insensitive to reveal the small changes of puberty. A single ultrasensitive, third-generation determination of serum LH concentration in the pubertal range suggests that puberty is progressing. Determination of the rise in LH after administration of GnRH or GnRH agonist is helpful in differential diagnosis; secondary sexual development usually follows within months after conversion to a pubertal LH response to GnRH. Because it is difficult, if not impossible, to obtain GnRH presently, GnRH agonists are more frequently used for diagnosis with serum LH values measured 2 hours after administration. Frequent nighttime sampling (every 20 minutes through an indwelling catheter) to determine the amplitude of peaks of LH secretion during sleep is an alternative to GnRH or GnRH agonist testing but is too cumbersome for most clinical settings. Unfortunately, the results of GnRH infusions or nighttime sampling are not always straightforward. Patients may have pubertal responses to exogenous GnRH but may not spontaneously secrete adequate gonadotropins to allow secondary sexual development. In females with amenorrhea, the frequency and amplitude of gonadotropin secretion may not change to allow monthly menstrual cycles. The retention of a diurnal rhythm of gonadotropin secretion (normal in early puberty) into late puberty is a pattern linked to inadequate pubertal progression. In males, a morning serum testosterone concentration over 20 ng/dL (0.7 nmol/L) indicates the likelihood of pubertal development within 6 months. Measurement of testosterone or estradiol must be done in an ultrasensitive assay with pediatric standards or, as with gonadotropin assays, the small changes of pubertal development will be missed. Presently highly sensitive high-performance liquid chromatography tandem mass spectroscopy (HPLC MS/MS) assays are available at national laboratories for this purpose.

Other methods of differential diagnosis between constitutional delay and hypogonadotropic hypogonadism have been proposed but are complex or are not definitive. Clinical observation for signs of pubertal development and laboratory evaluation for the onset of rising levels of sex steroids may have to continue until the patient is 18 years of age before the diagnosis is definite. In most cases, if spontaneous pubertal development is not noted by 18 years of age, the diagnosis is gonadotropin deficiency. Of course, the presence of neurologic impairment or other endocrine deficiencies should immediately lead to investigation for central nervous system tumor or congenital defect in a patient with delayed puberty. CT or MRI scanning is helpful in this situation.

**Treatment of Delayed Puberty**

**A. Constitutional delay in growth and adolescence**

**Psychologic support.** Teenagers who are so embarrassed about short stature and lack of secondary sexual development that they have significant psychologic problems may require psychological evaluation and therapy if they have passed the ages of 13 years for girls or 14 years for boys. Patients with constitutional delay in growth and adolescence should be counseled that normal pubertal development will occur spontaneously. Peer pressure and teasing can be oppressive. The majority of these patients do quite well, severe depression must be treated appropriately, because short patients with pubertal delay have become suicidal. In some cases, it helps to excuse the patient from physical education class, because the lack of development is most apparent in the locker room. In general, boys feel more stress than girls when puberty is delayed.

**Sex steroids.** New preparations of topical sex steroids, that have different systemic effects and length of action than parenteral or oral sex steroids, have enlarged the therapeutic armamentarium for delayed puberty. The classic recommendation for girls has been a 3-month course of conjugated estrogen (0.3 mg) or ethinyl estradiol (5-10 μg) given orally each day. Topical estrogen is said to carry less risk of hypertension, gallstones, increased fat mass, decreased insulin sensitivity, and increased triglycerides (topical estrogen does not, however, increase HDL cholesterol and decrease low-density lipoprotein [LDL] cholesterol, as does oral estrogen). Estrogen-impregnated patches are available and might be used to initiate puberty, but the lowest dose available leads to serum estrogen values higher than physiologic levels found in early puberty. They might be used for only a few days each week to reduce the delivered dose. Alternatively, 17-beta estradiol patches (0.025 mg/patch; Vivelle Dot matrix patch) may be cut into fragments the size of one-eighth to one-fourth of a patch fragments to initiate pubertal development with more physiologic estrogen values. However, the use of such topical estrogen preparations is not approved by the Food and Drug Administration (FDA).

The classic recommendation for boys is a 3-month course of testosterone enanthate or cypionate (50 mg) given intramuscularly once every 28 days for three doses. The possibility that a higher dose will cause priapism limits the initial dose to 50 mg. New patch or testosterone gel preparations could be used to initiate puberty, but the dose in manufactured packets is too high to mimic the physiologic levels found in early puberty. These preparations are made for full replacement in adult males. The entire gel packet or lowest-dose patch could be used every other day over the 3-month period of treatment, although this leads to variable daily
dosage. The gel is available in a pump but even one pump dose is too high for the initial therapy. The testosterone patches are not impregnated like the estrogen patches and cannot be cut down in size. Thus, to date, the low-dosage injection of testosterone or the use of an estimated one-half or less of the 5 mg testosterone gel packet are the only methods of reaching appropriate dosage. The topical use of testosterone is not approved by the FDA for such purposes. Therapy with oxandrolone has been suggested as a method of increasing secondary sexual development and increasing growth without advancing skeletal development. This method is not widely preferred. Furthermore, testosterone, which can be aromatized, increases the generally low endogenous GH secretion in constitutional delayed puberty to normal, whereas oxandrolone, which cannot be aromatized, does not increase GH secretion.

Hormonal treatment of boys or girls elicits noticeable secondary sexual development and a slight temporary increase in stature. The low doses recommended do not advance bone age substantially and do not significantly change adult height if used for 3 months. Low-dose sex steroid treatment has been reported to promote spontaneous pubertal development after sex steroid therapy is discontinued, although responding individuals may include those boys who are on the brink of further pubertal development and are, therefore, most likely to achieve a growth response to androgen therapy. However, a short course of therapy may improve patients’ psychologic outlook and allow them to await spontaneous pubertal development with greater confidence. Continuous gonadal steroid replacement in these patients is not indicated, because it advances bone age and leads to epiphyseal fusion and a decrease in ultimate stature. After a 3- to 6-month break to observe spontaneous development, a second course of therapy may be offered if no spontaneous pubertal progression occurs during observation.

B. Permanent hypogonadism Once a patient has been diagnosed as having delayed puberty due to permanent primary or secondary hypogonadism, replacement therapy must be considered at the average age of onset of puberty, in most cases when the diagnosis is made in childhood.

Males with hypogonadism may be treated with testosterone gel, testosterone patches, or testosterone enanthate or cypionate given intramuscularly every month, as described earlier for temporary conditions. Treatment as for constitutional delay should be started and gradually increased to the adult range over months to years to mimic the normal progression of puberty and to avoid abrupt exposure to high-dose androgen and the possibility of frequent erections or priapism. Oral halogenated testosterone and methylated testosterone are never recommended because of the risk of hepatocellular carcinoma or cholestatic jaundice. Testosterone therapy may not cause adequate pubic hair development, but patients with secondary or tertiary hypogonadism may benefit from hCG administration with increased pubic hair growth resulting from endogenous testicular androgen secretion in addition to the exogenous testosterone.

Testosterone gel or patches, as described earlier, are used for permanent replacement but are not FDA-approved for individuals less than 16 years. Girls may be treated with oral ethinyl estradiol (increasing from 5 μg/d to 10 to 20 μg/d depending on clinical results), or conjugated estrogens (0.3 or 0.625 mg/d). One may start with daily doses with eventual conversion to treatment on days 1 to 21 of the month after several months of daily ingestion. Five to ten milligrams of medroxyprogesterone acetate are then added on days 12 to 21 after physical signs of estrogen effect are noted and breakthrough bleeding occurs (and always within 6 months after initiating estrogen). Neither hormone is administered from day 22 to the end of the month to allow regular withdrawal bleeding (see Chapter 13). Later, the patient may be switched to sequential oral contraceptives to simplify treatment. As described earlier, estrogen patch therapy may have benefits (but these are not proven) over oral estrogen and may be preferable (but these are not FDA-approved for individuals under 16 years of age). Gynecologic examinations should be performed yearly for those on replacement therapy.

Hypothalamic hypogonadism may be treated with GnRH pulses by programmable pumps to achieve fertility or to promote pubertal development. Likewise, in the absence of a functional pituitary gland, hCG and menotropins (human postmenopausal gonadotropin) may be administered in pulses. These techniques are cumbersome and best reserved for the time when fertility is desired.

C. Coexisting GH deficiency The treatment of patients with coexisting GH deficiency requires consideration of their bone age and amount of growth left before epiphyseal fusion. If such a patient has not yet received adequate treatment with GH, sex steroid therapy may be kept at the lower dosage or even delayed to optimize adult height. The goal is to allow appropriate pubertal changes to support psychologic development and to allow the synergistic effects of combined sex steroids and GH without fusing the epiphyses prematurely.

Constitutional delayed puberty may be associated with decreased GH secretion in 24-hour profiles of spontaneous secretion or in stimulated testing. GH secretion increases when pubertal gonadal steroid secretion rises due to the effects of estrogen, so decreased GH secretion in this condition should be considered temporary. Nonetheless, true GH-deficient patients may have delayed puberty due to the GH deficiency or to coexisting gonadotropin deficiency. Therefore, deciding whether a pubertal patient has temporary or a permanent GH deficiency can be difficult; previous observation may indicate a long history characteristic of constitutional delay in adolescence, whereas a recent decrease in growth rate may suggest the onset of a brain tumor or other cause of hypopituitarism.

D. The syndrome of gonadal dysgenesis In the past, patients with the syndrome of gonadal dysgenesis were frequently not given estrogen replacement until after age 13 years, for fear of compromising adult height. However, low-dose estrogen therapy (5–10 μg of ethinyl estradiol orally) can be administered to allow feminization and improve psychologic status at 12 to 13 years of age without decreasing final height, as shown in several studies. Low-dose estrogen increases growth velocity, whereas high-dose estrogen suppresses it. Even if growth velocity is increased, however, adult height is not increased with such estrogen treatment.
Treatment of Turner syndrome with GH successfully increases adult stature (see Chapters 6 and 14). During childhood these girls must be regularly screened for strabismus, hearing loss, and autoimmune thyroid disease as well as learning difficulties. There are several recommendations for the preparation of these girls to transition to adult care and necessary follow-up for issues that will affect their later life, including monitoring for the development of aortic dilation at 5- to 10-year intervals since this defect may progress to aortic aneurysms. The induction of fertility was described earlier in this chapter.

**E. Bone mass** After infancy, most bone mass accrual takes place during the second decade of life, and disorders of puberty may affect this process. Delayed puberty in boys causes decreased cross-sectional bone density, when the subjects are tested as young adults, because they have not yet reached peak bone acquisition. Although there is some controversy, it appears likely that normalization of volumetric bone density occurs with maturity and exposure to a normal androgen milieu. A range of defects in girls such as anorexia nervosa, athletics-induced delayed puberty, and Turner syndrome also cause decreased bone density. The use of testosterone in boys and estrogen and progesterone in girls with hypogonadotropic hypogonadism is helpful in increasing bone mass but has not been demonstrated to result in normal adult bone mass. Appropriate ingestion of dairy products containing calcium or calcium supplementation and vitamin D should be encouraged in hypogonadal or constitutionally delayed patients and Turner syndrome also cause decreased bone density. The use of testosterone in boys and estrogen and progesterone in girls with hypogonadotropic hypogonadism is helpful in increasing bone mass but has not been demonstrated to result in normal adult bone mass. Appropriate ingestion of dairy products containing calcium or calcium supplementation and vitamin D should be encouraged in hypogonadal or constitutionally delayed patients. No long-term follow-up is yet available, however, to prove the efficacy of this therapy in susceptible subjects.

**PRECOCIOUS PUBERTY (SEXUAL PRECOCITY)**

All sources agree that the appearance of secondary sexual development before the age of 9 years in boys is precocious puberty. However, there remains controversy over the lower limits of normal in girls. There is acceptance by the Pediatric Endocrine Society that the appearance of secondary sexual development before the age of 7 years in Caucasian girls and 6 years in African-American girls constitutes precocious sexual development but others remain concerned that pubertal development between 7 and 8 years for Caucasian and 6 and 8 for African American girls indicate a pathological state (Table 15-4). However, if a girl has the onset of puberty before 8 years, one must have a high index of suspicion for pathology. The child must have absolutely no sign of central nervous system disorder or other possible cause that might trigger pathologic precocious puberty. A careful search for historical or physical features of organic disease must occur before a girl with precocious puberty between 6 or 7 and 8 is considered normal. When the cause of precocious puberty is premature activation of the hypothalamic-pituitary axis and the condition is gonadotropin dependent, the diagnosis is central (complete or true) precocious puberty; if ectopic gonadotropin secretion occurs in boys or autonomous sex steroid secretion occurs in either sex, the condition is not gonadotropin-dependent, and the diagnosis is incomplete precocious puberty. If feminization occurs in girls and virilization occurs in boys, the condition is isosexual precocity, but if the feminization occurs in boys and virilization in girls, the condition is contrasexual precocity. In all forms of sexual precocity, there is an increase in growth velocity, somatic development, and skeletal maturation. When unchecked, this rapid skeletal development may lead to tall stature during the early phases of the disorder but to short final stature because of early epiphysial fusion. This is the paradox of the tall child growing up to become a short adult. Plasma IGF-I values may be elevated for age but are appropriate for pubertal stage in untreated precocious puberty.

**A. Constitutional or familial central (complete or true) precocious puberty** Otherwise normal children who demonstrate isosexual precocity at an age slightly more than 2.5 SD below the mean may simply represent the lower reaches of the distribution...
and response to GnRH or GnRH agonists are similar to those found in normal pubertal subjects. In idiopathic central precocious puberty, as in all forms of true isosexual precocity, testicular enlargement in boys should be the first sign; in girls, breast development or, rarely, pubic hair appearance may be first. Girls present with idiopathic central precocious puberty more commonly than boys. Children with precocious puberty have a tendency toward obesity based on elevated body mass index in the untreated state. While families with inactivating mutations of the GRP54 gene experience absent or delayed puberty, a patient presented with isosexual precocious puberty and demonstrated a mutation of GRP54 that led to prolonged activation of intracellular signaling pathways in response to kisspeptin. This further emphasizes the importance of the GRP54 Kisspepetin axis in the control of puberty.

C. Central nervous system disorders

1. Tumors—Central nervous system tumors are more common causes of central precocious puberty in boys than in girls but may occur in either, so a high index of suspicion is essential. Optic gliomas or hypothalamic gliomas, astrocytomas, ependymomas, germinomas, and other central nervous system tumors may cause precocious puberty by interfering with neural pathways that inhibit GnRH secretion, thus releasing the central nervous system restraint of gonadotropin secretion. Patients with optic gliomas and neurofibromatosis type 1 may have precocious puberty, but no patients with isolated neurofibromatosis (that did not have optic gliomas) are reported with precocious puberty. Remarkably, craniopharyngiomas, which are known to cause delayed puberty, can also trigger precocious pubertal development. Radiation therapy is often indicated in radiosensitive tumors such as germinomas and craniopharyngiomas, where complete surgical extirpation is impossible. Reportedly, complete removal of craniopharyngiomas is associated with unexpected recurrence; radiation therapy appears to be a key therapy for this tumor in addition to surgery.

Hamartomas of the tuber cinereum contain GnRH and neurosecretory cells similar to those found in the median eminence; they may cause precocious puberty by secreting GnRH. Some hypothalamic hamartomas associated with central precocious puberty do not elaborate GnRH but instead contain transforming growth factor (TGF)-α, which stimulates GnRH secretion itself. With improved methods of imaging the central nervous system, hamartomas, with their characteristic radiographic appearance, are now more frequently diagnosed in patients who were previously thought to have idiopathic precocious puberty. These tumors do not enlarge and so pose no additional threat to the patients in the absence of intractable seizures. These seizures are rare in patients with the pedunculated hamartomas causing central precocious puberty. Because of the location of the hamartoma, surgery is a dangerous alternative to GnRH analog therapy.

Tumors or other abnormalities of the central nervous system may cause GH deficiency in association with central precocious puberty. GH deficiency may also occur after irradiation therapy for such tumors, even if precocious puberty was the sole endocrine finding before irradiation. Such patients grow much faster than isolated GH-deficient patients but slower than children with classic precocious puberty and adequate GH secretion. Often, the GH deficiency is unmasked after successful treatment of precocious puberty. This combination

FIGURE 15-8 Boy 2-5/12 years of age with idiopathic true precocious puberty. By 10 months of age, he had pubic hair and phallic and testicular enlargement. At 1 year of age, his height was 4 SD above the mean; the phallus was 10 cm × 3.5 cm; each testis was 2.5 cm × 1.5 cm. Plasma LH was pubertal and rose in an adult pattern after administration of 100 μg of GnRH. Plasma testosterone was 416 ng/dl. At the time of the photograph, he had been treated with medroxyprogesterone acetate (to suppress LH and FSH secretion) for 1 ½ years, with reduction of his rapid growth rate and decreased gonadotropin and testosterone secretion. At that point his height was 95.2 cm (>2 SD above mean height for his age); plasma testosterone was 7 ng/dl, and after 100 μg of GnRH, plasma LH rose only slightly, demonstrating suppression. (Reproduced, with permission, from Styne DM, Grumbach MM. In: Yen SSC, Jaffe RB, eds. Reproductive Endocrinology. WB Saunders; 1978.)

curve describing the age of onset of puberty; often there is a familial tendency toward early puberty. True precocious puberty is reported, rarely, to be due to an autosomal dominant or (in males) X-linked dominant trait.

B. Idiopathic central (complete or true) isosexual precocious puberty Affected children, with no familial tendency toward early development and no organic disease, may be considered to have idiopathic central isosexual precocious puberty. Epilepsy and developmental delay are associated with central precocious puberty in the absence of a central nervous system anatomic abnormality, indicating a central nervous system process is responsible for the condition.

Pubertal development may follow the normal course or may wax and wane. Serum gonadotropin and sex steroid concentrations
must be considered during the diagnostic process (see also Chapter 6).

2. Other causes of true precocious puberty—Infectious or granulomatous conditions such as encephalitis, brain abscess, postinfectious (or postsurgical or congenital) suprasellar cysts, sarcoidosis, and tuberculous granulomas of the hypothalamus cause central precocious puberty. Suprasellar cysts and hydrocephalus cause central precocious puberty that is particularly amenable to surgical correction. Brain trauma may be followed by either precocious or delayed puberty. Radiation therapy for acute lymphoblastic leukemia of the central nervous system, or prior to bone marrow transplantation, is characteristically associated with hormonal deficiency, but there are increasing reports of precocious puberty occurring after such therapy. Higher doses of radiation may be more likely to cause GnRH deficiency, and lower doses down to 18 Gy may lead to central precocious puberty.

D. Virilizing syndromes Patients with long-untreated virilizing adrenal hyperplasia who have advanced bone ages may manifest precocious puberty after treatment with glucocorticoid suppression. Children with virilizing tumors or those given long-term androgen therapy may follow the same pattern when the androgen source is removed. Advanced maturation of the hypothalamic-pituitary-gonadal axis appears to occur with any condition causing excessive androgen secretion and advanced skeletal age.

Incomplete Isosexual Precocious Puberty in Boys

Males may manifest premature sexual development in the absence of hypothalamic-pituitary maturation from either of two causes: (1) ectopic or autonomous endogenous secretion of hCG or LH or iatrogenic administration of hCG, which can stimulate Leydig cell production of testosterone; or (2) autonomous endogenous secretion of androgens from the testes or adrenal glands or from iatrogenic exogenous administration of androgens. (In females, secretion of hCG does not by itself cause secondary sexual development.)

A. Gonadotropin-secreting tumors These include hepatomas or hepatoblastomas of the liver as well as teratomas or choriocarcinoma of the mediastinum, gonads, retroperitoneum, or pineal gland and germinomas of the central nervous system. The testes are definitely enlarged but not to the degree found in central precocious puberty since only Leydig cells are stimulated by hCG.

B. Autonomic androgen secretion Secretion of androgens can occur because of inborn errors of adrenal enzyme function, as in 21-hydroxylase deficiency (P450c21 OMIM#201910 adrenal hyperplasia, congenital, caused by 21-hydroxylase) or 11β-hydroxylase deficiency (P450c11β OMIM#202010). Adrenal hyperplasia, congenital, caused by steroid 11-beta-hydroxylase deficiency, virilizing adrenal carcinomas, interstitial cell tumors of the testes, or premature Leydig and germinal cell maturation. Late-onset congenital adrenal hyperplasia, generally of the 21-hydroxylase deficiency form, may occur years after birth with no congenital or neonatal manifestations of virilization. Adrenal rest tissue may be found in the testes as a vestige of the common embryonic origin of the adrenal glands and the testes; in states of ACTH excess—primarily congenital adrenal hyperplasia—adrenal rests can enlarge (sometimes to remarkable size) and secrete adrenal androgens (see Chapter 14).

In boys with familial gonadotropin-independent premature Leydig and germinal cell maturation (#176410. precocious puberty, male-limited), plasma testosterone levels are in the pubertal range, but plasma gonadotropin levels and the LH response to exogenous GnRH are in the prepubertal range or lower because autonomous testosterone secretion suppresses endogenous GnRH release. The cause of this sex-limited dominant condition lies in a constitutive activation of the LH receptor (leaving the LH receptor on), causing increased cyclic adenosine monophosphate (cAMP) production in the absence of LH. Several mutations have been reported in the LH receptor gene in different families (e.g., Asp⁵⁷⁸ to Gly or Met⁷⁷¹ to Ile). The differential diagnosis rests between testosterone-secreting tumor of the adrenal, testosterone-secreting Leydig cell neoplasm, and premature Leydig and germinal cell maturation.

If hCG secretion causes incomplete male isosexual precocity, FSH is not elevated. As only the Leydig cells are stimulated and because the seminiferous tubules are not stimulated, the testes do not enlarge as much as in complete sexual precocity. If incomplete sexual precocity is due to a testicular tumor, the testes may be large, asymmetric, and irregular in contour. Symmetric bilateral moderate enlargement of the testes suggests familial gonadotropin-independent premature maturation of Leydig and germinal cells, which is a sex-limited dominant condition. The testes are somewhat smaller in this condition than in true precocious puberty but are still over 2.5 cm in diameter.

Incomplete Contraversal Precocity in Boys

Estrogen may be secreted by rare adrenal tumors leading to feminization in boys. Sertoli cell tumors associated with Peutz-Jeghers syndrome is another possible etiology.

Incomplete Isosexual Precocious Puberty in Girls

Females with incomplete isosexual precocity have a source of excessive estrogens. In all cases of autonomous endogenous estrogen secretion or exogenous estrogen administration, serum LH and FSH levels are low.

A. Follicular cysts If follicular cysts are large enough, they can secrete sufficient estrogen to cause breast development and even vaginal withdrawal bleeding; some girls have recurrent cysts that lead to several episodes of vaginal bleeding. Patients with cysts may have levels of serum estrogen high enough to mimic a tumor. Larger follicular cysts can twist on their pedicles and become infarcted, causing symptoms of acute abdomen in addition to the precocious estrogen effects.
B. Other ovarian tumors  Granulosa or theca cell tumors of the ovaries secrete estrogen and are palpable in 80% of cases. Gonadoblastomas are found in streak gonads, lipoid tumors, and cystadenomas. Ovarian carcinomas are rare ovarian sources of estrogens or androgens.

C. Adrenal rest tissue  Adrenal rest tissue has long been known to cause testicular enlargement and androgen secretion in boys, particularly with the increased ACTH secretion of untreated or incompletely congenital adrenal hyperplasia. While the hyperplastic tissue is not a neoplasm by itself, neoplastic transformation may follow.

D. Exogenous estrogen administration  Ingestion of estrogen-containing substances or even cutaneous absorption of estrogen can cause feminization in children. Epidemics of gynecomastia and precocious thelarche in Puerto Rico and Italy have variously been attributed to ingestion of estrogen-contaminated food, estrogens in the environment, soy formula, or undetermined causes. One outbreak of gynecomastia in boys and precocious thelarche in girls in Bahrain was traced to ingestion of milk from a cow which was given continuous estrogen treatment by its owner to ensure uninterupted milk production. Tea tree and lavender oils have estrogenic effects in children and exposure can cause thelarche.

E. Hypothyroidism  Severe untreated hypothyroidism can be associated with sexual precocity and galactorrhea (Van Wyk-Grumbach syndrome); treatment with thyroxine corrects hypothyroidism, halts precocious puberty and galactorrhea, and lowers PRL levels. The cause of this syndrome was initially postulated to be increased gonadotropin secretion associated with the massive increase in TSH secretion. However, it appears that TSH, at high concentrations, can activate FSH receptors.

F. McCune-Albright syndrome  McCune-Albright syndrome (#174800. McCune-Albright syndrome; MAS) is classically manifested as a triad of irregular cafe au lair spots, fibrous dysplasia of long bones with cysts, and precocious puberty. However, hyperthyroidism, adrenal nodules with Cushing syndrome, acromegaly, hyperprolactinemia, hyperparathyroidism, hypophosphatemic hyperphosphaturic rickets, or autonomous endogenous-functioning ovarian cysts (in girls) also occur. Precocious puberty may be central or incomplete; longitudinal studies demonstrate that some patients start with incomplete precocious puberty and progress to central precocious puberty. Long-term follow-up of patients with McCune-Albright syndrome reveals a high incidence of pathologic fractures and orthopedic deformities due to the bone cysts, as well as hearing impairment due to the thickening of the temporal area of the skull. Thickening of the skull base can impinge on local brain structures with fatal consequences. Bone growth may be partly mediated by elevated GH secretion and may cease with somatostatin analogue therapy. Patients may have a mutation of Arqon in exon 8 of the gene encoding the Gs alpha subunit that stimulates cAMP formation; this mutation impairs GTPase activity of the alpha subunit and increases adenylate cyclase activity leading to the endocrine abnormalities described earlier. This defect originates in somatic rather than germ cells, leading to genetic mosaicism wherever the defective gene product is expressed; thus, a wide variety of tissues can be affected.

Incomplete Contrasexual Precocity in Girls  Excess androgen effect can be caused by premature adrenarche or more significant pathologic conditions such as congenital or nonclassic adrenal hyperplasia or adrenal or ovarian tumors. P450c21 adrenal hyperplasia can be diagnosed on the basis of elevated serum 17-hydroxyprogesterone concentrations in the basal or ACTH-stimulated state (other adrenal metabolites may be elevated depending on the defect under investigation) (see Chapter 14). Both adrenal and ovarian tumors are associated with elevation of serum testosterone; adrenal tumors secrete DHEA. Thus, the source of the tumor may be difficult to differentiate if it produces only testosterone. MRI or CT scanning may be inadequate to diagnose the tumor’s organ of origin, and selective venous sampling may be needed. The rare families reported with aromatase deficiency had contrasexual development although not precocious puberty per se. One affected 46,XX individual had virilized genitalia at birth and further virilization at a pubertal age with the additional feature of polycystic ovaries. The patient, in spite of high serum testosterone concentrations, had elevated FSH and LH in the absence of estrogen production.

Variations in Pubertal Development

A. Premature thelarche  The term premature thelarche denotes unilateral or bilateral breast enlargement without other signs of androgen or estrogen secretion. Patients are usually younger than 3 years of age; the breast enlargement may regress within months or remain until actual pubertal development occurs at a normal age. Areolar development and vaginal mucosal signs of estrogen effect are usually absent or minimal. Premature thelarche may be caused by brief episodes of estrogen secretion from ovarian cysts. Plasma estrogen levels are usually low in this disorder, perhaps because blood samples are characteristically drawn after the initiating secretory event. However, ultrasensitive estradiol assays show a difference in estrogen production between control girls and those with premature thelarche. Classically, premature thelarche is self-limited and does not lead to central precocious puberty. However, there are reports of progression to central precocious puberty in a minority of cases, and follow-up for such progression is indicated. Other abnormalities in ovulation and menstruation have been reported following premature thelarche. Recently, girls with fluctuating thelarche were reported as having mutations in the GNAS1 gene, though without other signs of McCune-Albright syndrome.

B. Premature menarche  In rare cases, girls may begin to menstruate at an early age without showing other signs of estrogen effect. An unproved theory suggests that they may be manifesting increased uterine sensitivity to estrogen. In most subjects, menses stop within 1 to 6 years, and normal pubertal progression occurs thereafter.
C. Premature Adrenarche  The term premature adrenarche denotes the early appearance of pubic or axillary hair without other signs of virilization or puberty. This nonprogressive disorder is compatible with then the occurrence of other signs of puberty at the normal age for puberty. Premature adrenarche is more common in girls than in boys, and premature adrenarche is usually found in children over 6 years of age. Sometimes premature adrenarche can overlap with the new age limits of puberty in girls. Plasma and urinary DHEAS levels are elevated to stage 2 pubertal levels, higher than normally found in this age group but well below those seen with. Bone and height ages may be slightly advanced for chronologic age. Patients may have abnormal electroencephalographic tracings without other signs of neurologic dysfunction.

The presenting symptoms of late-onset adrenal hyperplasia may be similar to those of premature adrenarche, and the differential diagnosis may require ACTH stimulation testing (see Chapter 14). This condition may also present in a manner similar to polycystic ovarian syndrome (see Chapter 13). Infants born small for gestational age (SGA) have a predilection to develop premature adrenarche. These girls may also progress to polycystic ovarian syndrome. Daughters of women with PCOS demonstrate elevated androgen concentrations before the age of puberty, and these daughters may progress themselves to develop PCOS.

D. Adolescent gynecomastia  Up to 75% of boys have transient unilateral or bilateral gynecomastia, usually beginning in stage 2 or 3 of puberty and regressing about 2 years later. Serum estrogen and testosterone concentrations are normal, but the estradiol-testosterone ratio may be elevated and SHBG concentrations may be high. Reassurance is usually all that is required, but some severely affected patients with extremely prominent breast development require reduction mammoplasty if psychologic distress is extreme. After 2 years of gynecomastia, the likelihood of spontaneous regression decreases due to the formation of scar tissue. Early studies of aromatase inhibitors in the medical treatment of gynecomastia were disappointing, but more recent evaluation of anastrazole demonstrate promise.

Some pathologic conditions such as Klinefelter and the syndromes of incomplete androgen resistance are also associated with gynecomastia; these disorders should be clearly differentiated from the gynecomastia of normal puberty in males.

Differential Diagnosis of Precocious Puberty  The history and physical examination should be directed toward one of the diagnostic possibilities discussed earlier. Serum gonadotropin and sex steroid concentrations are determined in order to distinguish gonadotropin-mediated secondary sexual development (serum gonadotropin and sex steroid levels elevated to pubertal levels) from autonomous endogenous secretion or exogenous administration of gonadal steroids (serum gonadotropin levels suppressed and sex steroid levels elevated). Gonadotropins must be measured in a third generation assay with pediatric standards as the customary gonadotropin determinations are too insensitive to reveal the small changes of puberty.

Measurement of testosterone or estradiol must be done in an ultrasensitive assay with pediatric standards or, as with gonadotropin assays, the small changes of pubertal development will be missed. Presently highly sensitive high performance liquid chromatography tandem mass spectroscopy (HPLC MS/MS) assays are available at national laboratories for this purpose. Third-generation ultrasensitive immunassays can identify the onset of increased gonadotropin secretion with a single basal unstimulated serum sample. In the past, a GnRH test was required to confirm an increase in LH secretion at puberty because of the overlap of pubertal and prepubertal values of LH in the basal state. These third-generation gonadotropin assays can be applied to urine as well as serum samples; this may someday eliminate the need for GnRH agonist testing or serial serum sampling.

If serum LH concentrations, measured in an assay that cross-reacts with hCG, are quite high in a boy or if a pregnancy screening test (β-hCG) is positive, the likely diagnosis is an extra-pituitary, hCG-secreting tumor. β-LH values are suppressed, so no confusion with hCG levels is possible. If no abdominal or thoracic source of hCG is found, MRI of the brain with particular attention to the hypothalamic-pituitary area is indicated to evaluate the possibility of a germinoma of the pineal gland.

If serum sex steroid levels are very high and gonadotropin levels are low in third-generation assays, an autonomous source of gonadal steroid secretion must be assumed. If plasma gonadotropin and sex steroid levels are in the pubertal range, the most likely diagnosis is complete precocious puberty (Table 15–5).

Differentiation between premature thelarche and central precocious puberty is usually accomplished by physical examination, but determination of serum estradiol or gonadotropins may be required. The evaluation of uterine size by ultrasound may also be useful, because premature thelarche causes no increase in uterine volume while central precocious puberty does and also is associated with an "endometrial stripe." Ovarian size determination is a less useful method of distinguishing between the two possibilities but may reveal pubertal ovarian cysts. As noted earlier, some girls initially thought to have precocious thelarche progress to complete precocious puberty, but there is no way presently to distinguish girls who will progress from those who will not.

The onset of true or complete precocious puberty may indicate the presence of a hypothalamic tumor. Boys more often than girls have central nervous system tumors associated with complete precocious puberty. Skull x-rays are not usually helpful, but CT or MRI scanning is indicated in children with true precocious puberty. The present generation of CT and MRI scanners can make thin cuts through the hypothalamic-pituitary area with good resolution; small hypothalamic hamartomas are now being diagnosed more frequently. Generally, MRI is preferable to CT because of better resolution; the use of contrast may help evaluate possible central nervous system lesions.

Treatment of Precocious Puberty  A. Central precocious puberty  In the past, medical treatment of true precocious puberty involved medroxyprogesterone

acetate or cyproterone acetate—progestational agents that reduce gonadotropin secretion by negative feedback.

However, current treatment for precocious puberty due to a central nervous system lesion involves the use of GnRH agonists that suppress sexual maturation and decrease growth rate and skeletal maturation. Chronic administration of highly potent and long-acting analogs of GnRH has been shown to downregulate GnRH receptors and reduce pituitary gland response to GnRH, thereby causing decreased secretion of gonadotropin and sex steroids and rapidly stopping the progression of sexual precocity. In girls, pubertal enlargement of the ovaries and uterus reverts toward the prepubertal state, and the multicystic appearance of the pubertal ovary regresses as well. This suppressive effect is reversed after therapy is discontinued and puberty progresses. GnRH agonist treatment has been successful for idiopathic precocious puberty and precocious puberty caused by hamartomas of the tuber cinereum, neoplasms of the central nervous system, or long-term androgen exposure. The GnRH agonists were originally given by daily subcutaneous injection or intranasal insufflation. Injection of these agents every 4 weeks in depot preparations has now made treatment much easier and has improved compliance.

Complete suppression of gonadotropin secretion is necessary because an incompletely suppressed patient may appear to have arrested pubertal development while actually secreting low but significant levels of sex steroids. Under these conditions, bone age advances while the growth rate is decreased, leading to even shorter
Males with familial Leydig and germ cell maturation do not initially respond to GnRH agonist therapy, but some have improved with medroxyprogesterone acetate. Affected boys were successfully treated with ketoconazole, an antifungal agent that can block 17,20-lyase and therefore decrease testosterone production. Ketoconazole also suppresses adrenal function as a significant side effect. After initial control with ketoconazole, the boys developed central precocious puberty, because prolonged exposure to androgens led to maturation of their hypothalamic-pituitary axis; treatment with a GnRH agonist then effectively halted this pubertal progression.

Newer therapy for McCune-Albright syndrome in girls is a combination of testolactone (an aromatase inhibitor) and spironolactone (which acts as an antiandrogen). Long-term follow-up demonstrated some decrease in menses, improvement in growth patterns and bone age advancement. Some escaped from control, necessitating the addition of a GnRH agonist, which then suppressed pubertal development. Tamoxifen, an estrogen agonist and antagonist, combined with aromatase inhibitors (such as anastrozole or newer agents such as letrozole) has been successfully used to decrease uterine bleeding and advancement in bone age in clinical trials. Girls with recurrent estrogen-secreting ovarian cyst formation may have a decreased incidence of cysts with medroxyprogesterone acetate therapy. A GnRH agonist may also be effective in such cases. Surgical removal of ovarian cysts may be unnecessary if such medical therapy is first utilized.

Precocious thelarche or adrenarche requires no treatment, as both are self-limited benign conditions. No therapy has been reported for premature menarche. Severe, persistent cases of adolescent gynecomastia have been reportedly treated successfully by testolactone and dihydrotestosterone heptanoate, although surgical removal of breast tissue is often necessary, as noted earlier.

Physical Changes Associated with Puberty

Delayed Puberty and Sexual Infantilism

Seidlmeyer IL, Pahlert MR. Delayed puberty: analysis of a large case series from an academic center. J Clin Endocrinol Metab. 2002;87:1613. [PMID: 11932291]

Sexual Precocity

Throughout pregnancy, the fetal-placental unit secretes protein and steroid hormones that alter the function of every endocrine gland in the mother's body. Both clinically and in the laboratory, pregnancy can mimic hyperthyroidism, Cushing disease, pituitary adenoma, diabetes mellitus, polycystic ovary syndrome, and more.

The endocrine changes associated with pregnancy are adaptive, allowing the mother to nurture the developing fetus. Although maternal reserves are usually adequate, in cases of gestational diabetes or hypertensive disease of pregnancy, a woman may develop overt signs of disease as a direct result of pregnancy.

Aside from creating a satisfactory nutritive environment for fetal development, the placenta serves as an endocrine, respiratory, alimentary, and excretory organ. Measurements of fetal-placental products in the maternal serum provide one means of assessing fetal well being. This chapter will consider the changes in maternal endocrine function in pregnancy and during parturition as well as fetal endocrine development. The chapter concludes with a discussion of some endocrine disorders complicating pregnancy.

## CONCEPTION AND IMPLANTATION

### Fertilization

In fertile women, ovulation occurs approximately 12 to 16 days after the onset of the previous menses. The ovum must be fertilized within 24 to 48 hours if conception is to result. For about 48 hours around ovulation, cervical mucus is copious, nonviscous, slightly alkaline, and forms a gel matrix that acts as a filter and conduit for sperm. Sperm begin appearing in the outer third of the fallopian tube (the ampulla) 5 to 10 minutes after coitus and
continue to migrate to this location from the cervix for about 24 to 48 hours. Of the $200 \times 10^6$ sperm that are deposited in the vaginal fornices, only approximately 200 reach the distal tube. Fertilization normally occurs in the ampulla.

**Implantation and hCG Production**

Embryonic invasion of the uterus occurs during a specific window of implantation 8 to 10 days after ovulation and fertilization, when the conceptus is a blastocyst. Vitronectin, an alpha-v-beta-3 integrin receptor ligand, serves as one of several links between the maternal and embryonic epithelia. The two layers of placental epithelial cells, cytotrophoblasts and syncytiotrophoblasts, develop after the blastocyst invades the endometrium (Figure 16–1). Columns of invading cytotrophoblasts anchor the placenta to the endometrium. The differentiated syncytiotrophoblast, derived from fusion of cytotrophoblasts, is in direct contact with the maternal circulation. The syncytiotrophoblast is the

**FIGURE 16–1** Microanatomy of the human placental bed. Oxygen, nutrients, and waste products are exchanged between the fetus and the mother across this interface. In normal placental development (upper panel), invasive cytotrophoblasts of fetal origin invade the maternal spiral arteries, displacing maternal endothelial cells and transforming the vessels from small-caliber resistance vessels to high-caliber capacitance vessels capable of placental perfusion adequate to sustain fetal growth. In preeclampsia and some cases of fetal growth restriction, cytotrophoblasts fail to adopt an invasive endothelial phenotype. Instead, invasion of the spiral arteries is shallow and they remain small-caliber resistance vessels (lower panel). This can lead to placental ischemia. (Adapted, with permission, from Karumanchi SA, et al. Preeclampsia: a renal perspective. Kidney Int. 2005;67:2101.)
major source of hormone production, containing the cellular machinery needed for synthesis and secretion of both steroid and polypeptide hormones.

In most spontaneously conceived pregnancies, the dates of ovulation and implantation are not known. Weeks of gestation (gestational age) are by convention calculated from the first day of the last menstrual period. Within 24 hours after implantation, or at about 3 weeks of gestation, human chorionic gonadotropin (hCG), produced by syncytiotrophoblasts (see Figure 16–1), is detectable in maternal serum. Under the influence of increasing hCG production, the corpus luteum secretes progesterone and estradiol in increasing quantities.

Ovarian Hormones of Pregnancy

The hormones produced by the corpus luteum include progesterone, 17-hydroxyprogesterone, relaxin, and estradiol. The indispensability of the corpus luteum in early pregnancy has been demonstrated by ablation studies, in which luteectomy or oophorectomy before 42 days of gestation results in precipitous decreases in levels of serum progesterone and estradiol, followed by abortion. Exogenous progesterone will prevent abortion, proving that progesterone alone is required for maintenance of early pregnancy. After about the seventh gestational week, the corpus luteum can be removed without subsequent abortion owing to compensatory progesterone production by the placenta.

Because the placenta does not express the 17α-hydroxylase enzyme (P450C17), it cannot produce appreciable amounts of 17-hydroxyprogesterone; thus, this steroid provides a marker of corpus luteum function. As shown in Figure 16–2, the serum concentrations of estrogens and total progesterone exhibit a steady increase, but the concentration of 17-hydroxyprogesterone rises and then declines to low levels that persist for the duration of the pregnancy. Another marker of corpus luteum function is the polypeptide hormone relaxin, a protein with a molecular mass of about 6000. Pharmacologically, relaxin ripens the cervix, softens the pubic symphysis, promotes decidual angiogenesis, and acts synergistically with progesterone to inhibit uterine contractions.

Symptoms and Signs of Pregnancy

Breast tenderness, fatigue, nausea, absence of menstruation, softening of the uterus, and a sustained elevation of basal body temperature are mostly attributable to hormone production by the corpus luteum and developing placenta.

Fetal-Placental-Decidual Unit

The function of the placenta is to establish effective communication between the mother and the developing fetus while maintaining the immune and genetic integrity of both individuals. Initially, the placenta functions autonomously. By the end of the first trimester, however, the fetal endocrine system is sufficiently developed to complement placental function and to provide some hormone precursors to the placenta. From this time, it is useful to consider the endocrine conceptus as the fetal-placental unit.

The decidua is the endometrium of pregnancy. Decidual cells are capable of synthesizing a variety of polypeptide hormones, including relaxin, prolactin (PRL), and a variety of paracrine factors, in particular insulin-like growth factor (IGF)-binding protein 1. The precise function of the decidua as an endocrine organ has not been established, but its role as a source of prostanoids during labor is certain (see "Endocrine Control of Parturition," later).

POLYPEPTIDE HORMONES

Human Chorionic Gonadotropin

The first marker of trophoblast differentiation and the first measurable product of the placenta is hCG, a glycoprotein consisting of 237 amino acids. It is similar in structure to the pituitary glycoprotein hormones in that it consists of two chains: a common alpha chain and a specific beta chain, which determines receptor interaction and ultimate biologic specificity. The alpha chain is identical in sequence to the alpha chains of thyroid-stimulating hormone (TSH), follicle-stimulating hormone (FSH), and luteinizing hormone (LH). The beta chain has 67% sequence homology with LH and an additional 30 amino acids not found in LH beta.

In early pregnancy (up to 6 weeks), the concentration of hCG doubles every 1.7 to 2 days, and serial measurements provide a sensitive index of early trophoblast function and viability. Maternal plasma hCG peaks during the 10th gestational week and then declines gradually in the third trimester. Peak concentrations correlate temporally with the establishment of maternal blood flow in the intervillous space (see Figure 16–1, upper panel).

The long plasma half-life of hCG (24 hours) allows the tiny mass of cells comprising the blastocyst to produce sufficient hormone to be detected in the peripheral circulation within 24 hours of implantation. Thus, pregnancy can be diagnosed several days before symptoms occur or a menstrual period has been missed. Antibodies to the unique beta-carboxyl terminal segment of hCG do not cross-react significantly with any of the pituitary glycoproteins.

hCG is also produced in gestational trophoblastic neoplasia (GTN) by hydatidiform mole and choriocarcinoma, and the concentration of hCG-beta is used as a tumor marker for diagnosis and for monitoring the success of chemotherapy in these disorders. Women with very high hCG levels due to GTN may become clinically hyperthyroid due to the action of hCG on TSH receptors; they can revert to euthyroidism as hCG is reduced during chemotherapy.

Human Placental Lactogen

A second placental polypeptide hormone, this one with homology to pituitary growth hormone (GH), is human placental lactogen (hPL). hPL is produced by early trophoblasts, but detectable serum concentrations are not reached until 4 to 5 gestational

**FIGURE 16-2 (continued)**
weeks (see Figure 16–2). hPL is a protein of 190 amino acids whose primary, secondary, and tertiary structures are similar to those of GH and PRL. hPL is diabetogenic and lactogenic, but it has minimal growth-promoting activity as measured by standard GH bioassays.

The physiologic role of hPL during pregnancy remains controversial, and normal pregnancy without detectable hPL production has been reported. Although not clearly shown to be a mammotrophic agent, hPL contributes to altered maternal glucose metabolism and mobilization of free fatty acids; causes a hyperinsulinemic response to glucose loads; appears to directly stimulate pancreatic islet insulin secretion; and contributes to the peripheral insulin resistance characteristic of pregnancy. Along with prolonged fasting and insulin-induced hypoglycemia, pre-beta-HDL and apoprotein A-I are two factors that stimulate release of hPL. hPL production is roughly proportionate to placental mass. Actual production rates may reach as much as 1 to 1.5 g/d at term.

Serum hPL concentrations were used historically as a clinical indicator of the health of the placenta, but the range of normal values was wide, and serial determinations were necessary; it is therefore no longer used clinically.

**Other Chorionic Peptide Hormones and Growth Factors**

Other chorionic peptides have been identified, but their functions remain poorly defined. Activin, inhibin, corticotropin-releasing hormone, and multiple peptide growth factors, including fibroblast growth factor (FGF), epidermal growth factor (EGF), platelet-derived growth factor (PDGF), and the IGFs all have been isolated from placental tissue. Placental growth factor (PIGF) and the related vascular endothelial growth factor (VEGF) are suggested to play a role in placental angiogenesis, preeclampsia, and fetal growth.

**STEROID HORMONES**

In contrast to the impressive synthetic capability exhibited in the production of placental proteins, the placenta does not have the ability to synthesize steroids de novo. However, the trophoblasts have remarkable capacity to efficiently interconvert steroids derived from maternal or fetal precursors. This activity is demonstrable even in the early blastocyst, and by the seventh gestational week, when the corpus luteum undergoes involution, the placenta becomes the dominant source of steroid hormones.

**Progesterone**

The placenta relies on maternal cholesterol as its substrate for progesterone production. Fetal death has no immediate influence on progesterone production, suggesting that the fetus is a negligible source of substrate. Enzymes in the placenta cleave the cholesterol side chain, yielding pregnenolone, which in turn is isomerized to progesterone. 250 to 350 mg of progesterone are produced daily by the third-trimester placenta, and most enters the maternal circulation (see Figure 16–2). Whereas exogenous hCG stimulates progesterone production in early pregnancy, hypophysectomy, adrenalectomy, or oophorectomy have no effect on progesterone levels after the luteo-placental shift at 7 to 9 weeks' gestation. Likewise, the administration of adrenocorticotropic (ACTH) or cortisol does not influence placental progesterone secretion.

Progesterone is necessary for establishment and maintenance of pregnancy. Insufficient production of progesterone may contribute to failure of implantation, recurrent pregnancy loss, and preterm delivery. Progesterone, along with relaxin and nitric oxide, maintains uterine quiescence during pregnancy. Clinical trials have indicated that the administration of 17α-hydroxyprogesterone caproate can reliably prevent preterm delivery in high-risk pregnancies. Progesterone also inhibits T cell–mediated allograft rejection. Thus, high local concentrations of progesterone may contribute to immunologic tolerance by the uterus of invading trophoblast tissue from the semiallogeneic fetus.

**Estrogens**

Estrogen production by the placenta also depends on circulating precursors, but in this case both fetal and maternal steroids are important sources. Most of the placental estrogens are derived from fetal androgens, primarily dehydroepiandrosterone (DHEA) sulfate. Fetal DHEA sulfate, produced mainly by the fetal adrenal, is converted by placental sulfatase to free DHEA and then, through enzymatic pathways common to steroid-producing tissues, to androstenedione and testosterone. These androgens are finally aromatized by the placenta to estrone and estradiol, respectively. 17α-Hydroxysteroid dehydrogenase type II prevents fetal exposure to potent estrogens by catalyzing the conversion of estradiol to less potent estrone.

Most fetal DHEA sulfate is metabolized to produce a third estrogen: estriol. Estriol is a weak estrogen with 1/10 the potency of estrone and 1/100 the potency of estradiol. Serum estrone and estradiol concentrations are increased during pregnancy about 50-fold over their maximal prepregnancy values, but estriol increases approximately 1000-fold. The substrate for the reaction is 16α-hydroxy-DHEA sulfate produced in the fetal adrenal and liver, not in maternal or placental tissues. The final steps of desulfation and aromatization to estriol occur in the placenta. Maternal serum or urinary estriol measurements, unlike measurements of progesterone or hPL, reflect fetal as well as placental function. Rising serum or urinary estriol concentrations were once used as biochemical indicators of fetal well-being (see Figure 16–2). Decreased estriol production can result from congenital derangements or iatrogenic intervention. Maternal estriol remains low in pregnancies with placental sulfatase deficiency and in cases of fetal anencephaly. In the first case, DHEA sulfate cannot be hydrolyzed; in the second, little fetal DHEA is produced because fetal adrenal growth stimulation by ACTH is lacking. Maternal administration of glucocorticoids also inhibits fetal ACTH and lowers maternal estriol. Administration of DHEA to the mother during a healthy pregnancy increases estriol production. Placental corticotropin-releasing hormone (CRH) also may be an Important regulator of fetal adrenal DHEA sulfate secretion.
Modern methods of screening for fetal chromosomal aneuploidy, particularly trisomy 21 (Down syndrome), utilize circulating biochemical markers. Screening by maternal age alone (>35 years) led to the prenatal identification of only about 25% of aneuploid fetuses. As an aneuploid chromosome complement affects both fetal and placental tissues, their protein and steroid products have been evaluated. A combination of alpha-fetoprotein (AFP), hCG, inhibin-A and unconjugated estriol concentrations, measured in maternal serum between 15 and 18 weeks’ gestation, can be used to identify fetal Down syndrome and trisomy 18 with a detection rate of 80% over all age groups.

**MATERNAL ADAPTATION TO PREGNANCY**

As a successful *parasite*, the fetal-placental unit manipulates the maternal host for its own gain but normally avoids imposing excessive stress that would jeopardize the pregnancy. The prodigious production of polypeptide and steroid hormones by the fetal-placental unit directly or indirectly results in physiologic adaptations of virtually every maternal organ system. These alterations are summarized in Figure 16–3. Most of the commonly measured maternal endocrine function tests are radically changed. In some cases, true physiologic alteration has occurred; in others, the changes are due to increased production of hormone-binding proteins by the liver or to decreased serum levels of albumin due to the mild dilutional anemia of pregnancy. In addition, some endocrine changes are mediated by altered clearance rates due to increased glomerular filtration, decreased hepatic excretion, or metabolic clearance of steroid and protein hormones by the placenta. The changes in endocrine function tests are summarized in Table 16–1. Failure to recognize normal pregnancy-induced alterations in endocrine function tests can lead to unnecessary diagnostic tests and therapy that may be seriously detrimental to mother and fetus.

**Maternal Pituitary Gland**

The mother’s anterior pituitary gland hormones have little influence on pregnancy after implantation has occurred. The gland itself enlarges by about one-third, with the major component of this increase being hyperplasia of the lactotrophs in response to the high plasma estrogens. PRL, the product of the lactotrophs, is the only anterior pituitary hormone that rises progressively during pregnancy and peaks at the time of delivery. In spite of its high serum concentrations, pulsatile release of PRL and food-induced and nocturnal increases persist. Hence, the normal neuroendocrine regulatory mechanisms appear to be intact in the maternal adenohypophysis. In nonlactating women, maternal PRL decreases to pregestational levels within 3 months of delivery. Pituitary ACTH and TSH secretion remain unchanged. Serum FSH and LH fall to the lower limits of detectability and are unresponsive to GnRH stimulation during pregnancy. GH concentrations are not significantly different from nonpregnant levels, but pituitary response to provocative testing is markedly altered. GH response to hypoglycemia and arginine infusion is enhanced in early pregnancy but thereafter becomes depressed. Established pregnancy can continue in the face of hypophysectomy, and in women hypophysectomized prior to pregnancy, induction of ovulation and normal pregnancy can be achieved with appropriate gonadotropin replacement therapy. In cases of primary pituitary hyperfunction, the fetus is not affected.

**Maternal Thyroid Gland**

The thyroid becomes palpably enlarged during the first trimester, and a subtle bruit may be present. Thyroid iodide clearance and thyroidal $^{131}$I uptake, which are clinically contraindicated in pregnancy, have been shown to be increased. These changes are due in large part to the increased renal clearance of iodide, which causes a relative iodine deficiency. Although total serum thyroxine is elevated as a result of estrogen-stimulated increased thyroid hormone-binding globulin (TBG), free thyroxine and triiodothyronine are normal (see Figure 16–2). High circulating concentrations of hCG, particularly asialo-hCG, which has weak TSH-like activity, contribute to the thyrotropic action of the placenta in early pregnancy. In fact, there is significant, though transient, biochemical hyperthyroidism associated with hCG stimulation in early gestation.

**Maternal Parathyroid Gland**

The net calcium requirement imposed by fetal skeletal development is estimated to be about 30 g by term. This is met by hyperplasia of the maternal parathyroid glands and elevated serum levels of parathyroid hormone. The maternal serum calcium concentration declines to a nadir at 28 to 32 weeks, largely due to the mild hypoalbuminemia of pregnancy but also to fetal bone formation. Ionized calcium is maintained at normal concentrations throughout pregnancy.

**Maternal Pancreas**

The nutritional demands of the fetus require alteration of maternal metabolic homeostatic control, which results in both structural and functional changes in the maternal pancreas. The size of pancreatic islets increases, and insulin-secreting beta cells undergo hyperplasia. Basal levels of insulin are lower or unchanged in early pregnancy but increase during the second trimester as a result of increased secretion rather than decreased metabolic clearance. Thereafter, pregnancy is a hyperinsulinemic state, with resistance to its peripheral metabolic effects. Pancreatic production of glucagon remains responsive to the usual endocrine stimuli and is suppressed by glucose loading, although the degree of responsiveness has not been well evaluated in pregnancy.

The major roles of insulin and glucagon involve the intracellular transport of nutrients, specifically glucose, amino acids, and fatty acids. Insulin is not transported across the placenta, but rather exerts its effects on transportable metabolites. During pregnancy, peak insulin secretion in response to meals is accelerated, and glucose tolerance curves are characteristically altered. Fasting glucose levels are maintained at low-normal levels. Excess
CHAPTER 16 The Endocrinology of Pregnancy

**SYSTEM** | **PARAMETER** | **PATTERN**
--- | --- | ---
Cardiovascular | Heart rate | Gradually increases 20% by 28 wk
 | Blood pressure | Gradually decreases 10% by 34 wk, then increases to prepregnancy values

carbohydrate is converted to fat, and fat is readily mobilized during decreased caloric intake.

**Maternal Adrenal Cortex**

Total plasma cortisol concentrations increase to three times non-pregnant levels by the third trimester. Most of the changes can be explained by increased estrogens causing higher corticosteroid-binding globulin (CBG) production. The actual production of cortisol by the zona fasciculata also is increased in pregnancy. The net effect of these changes increases plasma-free cortisol, which is approximately doubled by late pregnancy. In spite of cortisol concentrations approaching those found in Cushing syndrome, diurnal variation in plasma cortisol is maintained. The elevated free cortisol concentration probably contributes to the insulin resistance of pregnancy and possibly to the appearance of striae, but most signs of hypercortisolism do not occur in pregnancy. It is suggested that high progesterone levels act to antagonize glucocorticoid effects.

Serum aldosterone also is markedly elevated in pregnancy, due to an eight fold increased production rate by the zona glomerulosa. Renin substrate is increased due to the influence of estrogen on hepatic synthesis, and renin also is elevated, leading to increased angiotensin. In spite of these dramatic changes, normal pregnant women show few signs of hyperaldosteronism. There is no tendency toward hypokalemia or hypernatremia, and blood pressure at midpregnancy—when changes in the renin-angiotensin-aldosterone system are maximal—actually tends to be lower than in the nonpregnant state. Progesterone is an effective competitive inhibitor of mineralocorticoids in the distal renal tubules. Thus, increases in renin and aldosterone may simply be an appropriate response to the high gestational levels of progesterone. Elevated angiotensin II does not normally result in hypertension, because of diminished sensitivity of the maternal vascular system to angiotensin. Exogenous angiotensin provokes a smaller increase in blood pressure than in the nonpregnant state. Finally, in patients with preeclampsia, the most common form of pregnancy-related hypertension, serum renin, aldosterone, and angiotensin levels are unchanged or even lower than in normal pregnancy, thus ruling out a primary role for the renin-angiotensin system in this disorder.

In normal pregnancy, the maternal production of androgens is slightly increased but these are buffered by sex hormone-binding globulin (SHBG). Levels of SHBG are increased by estrogens. Testosterone, which binds avidly to SHBG, increases to the normal male range by the end of the first trimester, but free testosterone levels are actually lower than in the nonpregnant state. DHEA sulfate does not bind significantly to SHBG, and plasma concentrations of DHEA sulfate actually decrease during pregnancy.

---

explains growth in placental tissue, amniotic fluid, and fetal weight. Glomerular filtration rate also increases early, then plateaus.
The desulfation of DHEA sulfate by the placenta and the conversion of DHEA to estrogens by the fetal-placental unit are important factors in its increased metabolic clearance.

**FETAL ENDOCRINOLOGY**

Because of the physical inaccessibility of the human fetus, much of our information about fetal endocrinology is derived indirectly. Most early studies of fetal endocrinology relied on observations of infants with congenital disorders or from ablative studies or acute manipulation in experimental animals. The development of effective cell culture methods and sensitive immunoassays, as well as the ability to achieve stable preparations of chronically catheterized monkey fetuses, have increased our understanding of the dynamics of intrauterine endocrine events. The endocrine system is among the first to develop in fetal life, but its study is complicated by its relative physical isolation as well as the multiplicity of sources of the various hormones. Dating of events in fetal development is usually given in fetal weeks, which begin at the time of fertilization. Thus, fetal age is always 2 weeks less than gestational age.

**Fetal Pituitary Hormones**

The characteristic anterior pituitary cell types are discernible as early as 8 to 10 fetal weeks, and all of the hormones of the adult anterior pituitary are extractable from the fetal adenohypophysis by 12 weeks. Similarly, the hypothalamic hormones thyrotropin-releasing hormone (TRH), gonadotropin-releasing hormone (GnRH), and somatostatin are present by 8 to 10 weeks. The direct circulatory connection between hypothalamus and pituitary develops later, with capillary invasion initially visible at about 16 fetal weeks.

The role of the fetal pituitary in organogenesis during the first trimester appears to be negligible. None of the pituitary hormones are released into the fetal circulation in large quantities until after 20 fetal weeks. Even GH appears not to be influential, and in fact total absence of GH is consistent with normal development at birth. Development of the gonads and adrenals during the first trimester appears to be directed by hCG rather than by fetal pituitary hormones, so that these organs initially develop even in the face of anencephaly.

During the second trimester, there is a marked increase in secretion of all of the anterior pituitary hormones, which coincides with maturation of the hypophysial portal system. Female fetuses exhibit higher FSH levels in both pituitary and serum than do males. Differentiation of the gonads is crucial for normal male sexual development and reproductive potential in both sexes. ACTH rises significantly during the second trimester and assumes an increasing role in directing the maturation of the differentiated adrenal, as shown by the anencephalic fetus, in which the fetal zone of the adrenal undergoes atrophy after 20 weeks. Fetal PRL secretion also increases after the 20th fetal week, but its functional significance is unknown. Vasopressin and oxytocin are demonstrable by 12 to 18 weeks in the fetal posterior pituitary gland and correlate with the development of their sites of production, the supraoptic and paraventricular nuclei, respectively.

**Fetal Thyroid Gland**

The fetal thyroid gland develops initially in the absence of detectable TSH. By 12 weeks the thyroid is capable of iodine-concentrating activity and thyroid hormone synthesis, but prior to this time the maternal thyroid appears to be the primary source for $T_4$. This has implications in that infants born to even mildly hypothyroid mothers are reported to have lower IQs and other health problems. The function of the fetal thyroid hormones appears crucial to somatic growth and for successful neonatal adaptation. In particular, auditory maturational events are regulated by thyroid hormones.

During the second trimester, TRH, TSH, and free $T_4$ all begin to rise. The maturation of feedback mechanisms is suggested by the subsequent plateau of TSH at about 20 fetal weeks. Fetal $T_3$ and reverse $T_3$ do not become detectable until the third trimester. The hormone produced in largest amount throughout fetal life is $T_4$, with the metabolically active $T_3$ and its inactive derivative, reverse $T_3$, rising in parallel to $T_4$ during the third trimester. At birth, conversion of $T_4$ to $T_3$ is demonstrable. Goitrogenic agents such as propylthiouracil are transferred across the placenta and may induce fetal hypothyroidism and goiter.

**Fetal Adrenal Cortex**

The fetal adrenal cortex is identifiable as early as 4 weeks of fetal age, and by the seventh week, steroidogenic activity can be detected in the inner zone layers.

During gestation, the adrenal cortex differs anatomically and functionally from the adult gland and occupies as much as 0.5% of total body volume. Most of this tissue is composed of a unique fetal zone that subsequently is transformed into the definitive (adult) zone during the early neonatal period. The inner fetal zone is responsible for the majority of steroids produced during fetal life and comprises 80% of the mass of the adrenal. During the second trimester, the inner fetal zone continues to grow, while the outer zone remains relatively undifferentiated. At about 25 weeks, the definitive (adult) zone develops, ultimately assuming the principal role in steroid synthesis during the early postnatal weeks.

**Fetal Gonads**

The testis is histologically identifiable by about 6 fetal weeks. Primary testis differentiation begins with development of the Sertoli cells at 8 weeks’ gestation. SRY, the sex-determining locus on the Y chromosome directs the differentiation of the Sertoli cells, the sites of anti-Müllerian hormone (AMH) synthesis. AMH, a member of the transforming growth factor-beta family of growth factors, specifically triggers the ipsilateral resorption of the Müllerian tract in males and prevents development of female internal structures. Embryonic androgen production begins in the developing Leydig cells at about 10 weeks, coincident with the peak production of placental hCG. Binding of hCG to fetal testes with stimulation of testosterone release has been demonstrated in the laboratory. Other fetal testicular products of importance are inhibin and the 5α-reduced testosterone metabolite dihydrotestosterone. Dihydrotestosterone is responsible for development of the male external genital structures.
Little is known about early fetal ovarian function, but by 7 to 8 weeks of intrauterine life the ovaries become morphologically recognizable. Oogonia mitosis is active and steroid-producing theca cell precursors are identifiable at 20 weeks. This corresponds with peak gonadotropin levels from the fetal pituitary. Activin and inhibin peptide subunits are expressed in the midtrimester human testis but not in the midtrimester human ovary. In contrast to the male fetus, ovarian steroid production by the fetus is not essential for female phenotypic development (see Chapter 13).

ENDOCRINE CONTROL OF PARTURITION

During the last few weeks of normal pregnancy, two processes herald approaching labor. Sporadic uterine contractions, usually painless, become increasingly frequent, and the lower uterine segment and cervix become softer and thinner, a process known as effacement, or ripening. Although false alarms are not uncommon, the onset of true labor is usually fairly abrupt, with the establishment of regular contractions every 2 to 5 minutes, leading to delivery in less than 24 hours. An extensive literature describes the physiologic and biochemical events that occur during human labor, but the key inciting event has eluded detection. In sheep, the fetus controls the onset of labor. The initial measurable event is an increase in fetal plasma cortisol, which, in turn, alters placental steroid production, resulting in a drop in progesterone. Cortisol reliably induces labor in sheep, but in humans, glucocorticoids do not induce labor and there is no clear drop in plasma progesterone concentrations prior to labor.

Sex Steroids

Progestosterone is essential for maintenance of early pregnancy, and withdrawal of progesterone leads to termination of pregnancy. Progesterone causes hyperpolarization of myometrial cells decreasing the amplitude of action potentials and preventing effective contractions. In various experimental systems, progesterone decreases alpha-adrenergic receptors, stimulates cAMP production, and inhibits oxytocin receptor synthesis. Progesterone also inhibits estrogen receptor synthesis, promotes the storage of prostaglandin precursors in the decidua and fetal membranes, and stabilizes lysosomes containing prostaglandin-synthesizing enzymes. Estrogen opposes progesterone in many of these actions and may have an independent role in ripening the uterine cervix and promoting uterine contractility. It has been shown that an increase in the estrogen-progesterone ratio increases the number of oxytocin receptors and myometrial gap junctions; this finding may explain the coordinated, effective contractions that characterize true labor as opposed to the nonpainful, ineffective contractions of false labor.

Oxytocin

Oxytocin infusion is commonly used to induce or augment labor. Both maternal and fetal oxytocin levels increase spontaneously during labor, but neither has been convincingly shown to increase prior to labor. Data in animals suggest that oxytocin's role in initiation of labor is due to increased sensitivity of the uterus to oxytocin rather than increased plasma concentrations of the hormone. Even women with posterior pituitary failure, manifested as diabetes insipidus, are able to deliver without oxytocin augmentation; thus a maternal source of the hormone is not indispensable. Clinical studies using the oxytocin receptor inhibitor, atosiban, have demonstrated a delay of delivery for 24 to 48 hours but meta-analyses do not show an improvement in fetal outcome.

Prostaglandins

Prostaglandin F2alpha administered intra-amniotically, vaginally, or intravenously is an effective abortifacient as early as 14 weeks of gestation. Prostaglandin E2 administered vaginally induces labor in most women in the third trimester. The amnion and chorion contain high concentrations of arachidonic acid, and the decidua contains active prostaglandin synthetase. Prostaglandins are almost certainly involved in maintenance of labor once it is established. They also probably are important in initiating labor in some circumstances, such as in amnionitis or when the membranes are stripped by the physician. Prostaglandins are believed to be the final common pathway of labor.

PRETERM LABOR/BIRTH

Preterm birth (PTB) is one of the most important problems in obstetrics today as it complicates approximately 12% of all births in the United States and accounts for over 70% of perinatal morbidity and mortality. Approximately 45% to 50% of PTB is idiopathic or spontaneous, defined as regular uterine contractions leading to cervical change prior to 37 weeks of gestation, 30% is related to preterm rupture of membranes and the other 15% to 20% is attributed to medically indicated or elective preterm delivery, typically due to worsening maternal disease or fetal compromise. PTB is a complex disorder with heterogeneous risk factors, genetic and environmental susceptibilities, and pathophysiologic pathways. Risk factors for preterm labor are varied and include history of prior preterm labor, uterine anomalies, multiple gestation, maternal medical complications, low prepregnancy body mass index, gestational bleeding, low socioeconomic status, minority race, behavioral habits such as smoking, alcohol, drug abuse, stressful events, limited or no prenatal care, and infection. The pathophysiology of preterm labor is not well understood but may result from mechanical factors, hormonal changes, infection, or interruption of normal mechanisms responsible for sustaining uterine quiescence. Unfortunately the rate of PTBs continues to increase slightly each year. Despite this, survival rates have improved due to the use of antenatal corticosteroids and improvements in neonatal resuscitation and care.

There is a well-documented racial disparity in rates of PTB with African Americans at 17% versus only 11% in Caucasians. Further, the infant mortality rate for African American babies is 2.5 times higher than Caucasians. Population-based studies indicate that this disparity cannot be explained by socioeconomic status, maternal behavior, marital status, or education alone and likely point to true genetic differences.
Four major mechanistic pathways leading to PTB have been proposed: (1) stress or activation of maternal or fetal hypothalamic-pituitary-adrenal axis, (2) pathologic uterine distention, (3) inflammation/infection, and (4) decidual hemorrhage and coagulation. These are summarized in Figure 16-4. Each of these pathways has different epidemiologic, clinical, and biochemical features, but all are likely to initiate labor via prostaglandin production, myometrial activation, and degradation of extracellular matrix components leading to premature rupture of membranes and cervical dilation. The fetoplacental endocrine unit can trigger labor prematurely, activating CRH release in cases of a hostile intrauterine environment such as stress and chorioamnionitis.

**Maternal/Fetal Stress**

Both exogenous and endogenous maternal stress, ranging from heavy workload to depression, is associated with PTB. The exact mechanism is not well understood, but CRH is thought to play an important role. Maternal CRH levels are elevated in both preterm and term labor and appear to activate the parturition pathway by increasing prostaglandins, inhibiting progesterone, and stimulating fetal cortisol and DHEA production.

**Pathologic Uterine Distention**

Myometrial stretching due to multiple gestations, polyhydramnios, and Mullerian anomalies has been associated with an increased risk of preterm labor. This is thought to occur as distension can induce myometrial contractility, prostaglandin release, collagenase activity, and increased oxytocin receptor expression.

**Infection/Inflammation**

Infection is the only pathologic process for which there is a clear causal link to preterm birth exhibited by the fact that: (1) intrauterine and extrauterine infections are associated with preterm birth; (2) antibiotics for intrauterine infection can prevent preterm birth; and (3) treatment of asymptomatic bacteruria prevents preterm birth. Microbiology studies suggest that infection may account for 25% to 40% of preterm births. Ascending infection is believed to be the most common source of microbial invasion of the amniotic cavity. Endotoxins from bacteria induce proinflammatory mediators such as IL-1 and TNF-alpha from the decidua, which stimulates prostaglandin production. Double knockout mice for IL-1 and TNF-alpha had decreased rates of PTB after administration of microorganisms. Other inflammatory cytokines and chemokines also have been implicated in infection-induced preterm labor.

**Decidual Hemorrhage and Coagulation**

Any vaginal bleeding during pregnancy is a known risk factor for preterm birth. Decidual hemorrhage and uteroplacental ischemia are thought to contribute to preterm labor via generation of thrombin. Thrombin stimulates myometrial contractility in a dose-dependent manner and also binds to protease-activated receptor type 1, which increases expression of metalloproteases leading to cervical ripening and possible subsequent preterm delivery.

**A. Predictors/prevention of preterm labor**

Unfortunately, clinical symptoms to identify women at risk for PTB...
have been shown to be inaccurate and unreliable. Given the clinical, emotional, and financial gravity of preterm birth, multiple tests have been developed over the years to attempt to identify women at risk for preterm delivery. Home uterine activity monitors are not currently recommended as they have not been shown to improve outcome. The presence of bacterial vaginosis (BV) has been associated with preterm delivery independent of other known risk factors, however, there is insufficient data to support screening and treating women with positive cultures. Maternal estradiol and estriol levels have been used to predict activation of the fetal hypothalamic-pituitary-adrenal axis, but trials have failed to establish their clinical usefulness in accurately predicting preterm labor.

Numerous studies have confirmed the association between cervical shortening and subsequent preterm delivery. Transvaginal cervical ultrasonography has been shown to be a reliable and reproducible way to assess the length of the cervix. Despite the usefulness of cervical length determination as a predictor of preterm labor, routine use is not recommended because of the lack of proven treatments affecting outcome.

Fetal fibronectin (fFN) is a basement membrane protein of placental membranes and decidua. Numerous trials have shown that the risk of PTB is increased in the presence of fFN and decreased in its absence. The relationship among fFN, short cervix, BV, and traditional historical risk factors for spontaneous preterm birth suggest the highest associations of preterm birth with positive fFN, followed by cervical length less than 25 mm and a history of preterm birth. A negative fFN test indicates a 95% likelihood of not delivering within 14 days; therefore it is particularly useful in ruling out preterm delivery.

Supplemental progesterone therapy has been shown to reduce the rate of preterm delivery in high-risk populations. Weekly injections of 17α-hydroxyprogesterone caproate from 16 to 20 weeks until 36 weeks of gestation has been found to significantly reduce recurrent preterm birth in women with history of preterm delivery. A recent meta-analysis of 10 placebo-controlled trials found progesterone therapy to significantly reduce the frequency of recurrent preterm birth from 36% to 26%. Given the lack of other available treatments, many providers are using progesterone as preventative therapy in high-risk patients, but progesterone does not reverse established labor.

B. Management of preterm labor

Once preterm labor has been diagnosed, care should be taken to determine if patient warrants tocolysis, expectant management, or delivery. It is important to confirm an accurate gestational age because if less than 34 weeks, glucocorticoids should be administered as they clearly decrease neonatal morbidity and mortality in this population.

Tocolytic therapy is used to attempt to prolong pregnancy to allow time for corticosteroid administration. However, both tocolytic and steroid therapy may result in untoward maternal and fetal consequences and, therefore, their use should be limited to women in true preterm labor at high risk for spontaneous PTB.

In general, tocolytic drugs may prolong pregnancy for 2 to 7 days. There is no first-line tocolytic drug and the choices include beta-mimetics, magnesium sulfate, calcium channel blockers, and NSAIDs (nonsteroidal anti-inflammatory drugs). The tocolytic chosen should be based on maternal/fetal conditions, side effects, and gestational age. Prolonged use of any tocolytic drug is generally not indicated as it may increase maternal-fetal risk. Serious adverse events are rare but potentially life-threatening. Beta-mimetics, magnesium sulfate, and calcium channel blockers are all associated with an increased risk of pulmonary edema. Specifically, beta-mimetics are potent cardiovascular stimulants and can cause maternal myocardial ischemia, metabolic derangements (e.g., hyperglycemia and hypokalemia), and fetal cardiac effects. Magnesium sulfate may cause maternal lethargy, drowsiness, double vision, nausea, and vomiting. NSAIDs can cause fetal oligohydramnios and premature closure of the ductus arteriosus. Calcium channel blockers used as a single agent appear to have a good maternal and fetal safety profile. Combining tocolytic drugs potentially increases maternal morbidity and should be used with caution.

**POSTTERM PREGNANCY**

Postterm pregnancy refers to gestation that has extended to or beyond 42 weeks and is associated with significant risks to the fetus. Most importantly, the perinatal mortality rate (stillbirths plus early neonatal deaths) beyond 42 weeks is twice that at term (4-7 deaths vs 2-3 deaths per 1000 deliveries) and is six fold higher after 43 weeks or more. Potential causes include uteroplacental insufficiency, meconium aspiration, and intrauterine infection. Postterm pregnancy is also a risk factor for low Apgar scores, oligohydramnios, and neonatal complications such as hypoglycemia, seizures, respiratory insufficiency, and increased risk of death within the first year of life. Postterm pregnancy is associated with some complications for the mother including a twofold increased risk of severe perineal injury and cesarean delivery. Because pregnancy past 41 weeks is associated with high costs of antenatal testing and induction of labor, as well as a source of significant anxiety for pregnant women, there has been a movement in obstetrics to effect delivery before 41 completed weeks. The most common cause of a prolonged gestation is incorrect dating; other risk factors include primiparity, prior postterm pregnancy, and male sex of the fetus. Recently, obesity has been identified as a modifiable risk factor. The mechanism for this association is unclear but it is likely due to a derangement in endocrine factors that initiate labor. In rare cases, postterm pregnancy has been associated with placental sulfatase deficiency or fetal anencephaly.

**Management of Postterm Pregnancy**

Standard management of postterm pregnancy focuses on antenatal fetal surveillance and timely initiation of delivery if spontaneous labor does not occur. Although antepartum testing for postterm pregnancies is universally accepted, it has not been validated in prospective trials to decrease perinatal mortality. Given the ethical and medicolegal concerns for a control group, randomized studies to prove benefit will likely never be done. Timing of delivery is
generally recommended when risks to continuing the pregnancy are greater than the benefit to mother or fetus after or during birth. In high-risk cases such as diabetics and hypertensives, pregnancy should not be allowed to progress beyond 41 weeks. However, management of low-risk postterm pregnancy is more controversial. Because delivery cannot always be induced readily, maternal risks and considerations complicate this decision. Factors to consider include gestational age, results of antepartum fetal testing, cervical exam, and maternal preference after counseling regarding the risks, benefits, and alternatives to expectant management with antepartum monitoring versus labor induction.

ENDOCRINOLOGY OF THE Puerperium

Extrication of any active endocrine organ leads to compensatory changes in other organs and systems. Delivery of the infant and placenta causes both immediate and long-term adjustment to loss of the pregnancy hormones. The sudden withdrawal of fetal-placental hormones at delivery permits determination of their serum half-lives and some evaluation of their effects on maternal systems.

Physiologic and Anatomic Changes

Some physiologic and anatomic adjustments that take place after delivery are both hormone dependent and independent. For example, major readjustments of the cardiovascular system occur in response to the normal blood losses associated with delivery and to loss of the low-resistance placental shunt. By the third postpartum day, blood volume is estimated to decline to about 80% of predelivery values. These cardiovascular changes influence renal and liver function, including clearance of pregnancy hormones.

Uterine Changes

The uterus involutes progressively at the rate of about 500 g/wk and continues to be palpable abdominally until about 2 weeks postpartum, after which it reoccupies its position entirely within the pelvis. Nonpregnant size and weight (60-70 g) are reached by 6 weeks postpartum. The reversal of myometrial hypertrophy occurs with a decrease in size of individual myometrial cells rather than by reduction in number. The endometrium, which is sloughed at the time of delivery, regenerates rapidly; by the seventh postpartum day there is restoration of surface epithelium. These rapid regenerative changes do not apply to the area of placental implantation, which requires much longer for restoration and retains pathognomonic histologic evidence of placentation indefinitely.

Endocrine Changes

A. Steroids With expulsion of the placenta, many steroid levels decline precipitously, with half-lives of minutes. Plasma progesterone falls to luteal-phase levels within 24 hours after delivery and to follicular-phase levels within several days. Removal of the corpus luteum results in a fall to follicular levels within 24 hours. Estradiol reaches follicular phase levels within 1 to 3 days after delivery.

B. Pituitary hormones The pituitary gland, which enlarges during pregnancy owing primarily to an increase in lactotrophs, does not diminish in size until after lactation ceases. Secretion of FSH and LH continues to be suppressed during the early weeks of the puerperium, and stimulus with bolus doses of GnRH results in subnormal release of LH and FSH. Over the ensuing weeks, responsiveness to GnRH gradually returns to normal and most women exhibit follicular-phase serum levels of LH and FSH by the third or fourth postpartum week.

C. Prolactin Serum PRL, which rises throughout pregnancy, falls with the onset of labor and then exhibits variable patterns of secretion depending on whether breast-feeding occurs. Delivery is associated with a surge in PRL, which is followed by a rapid fall in serum concentrations over 7 to 14 days in the nonlactating mother. In nonlactating women, the return of normal cyclic function and ovulation may be expected within 3 months, with the initial ovulation occurring at an average of 9 to 10 weeks postpartum. In actively lactating women, PRL can cause a persistence of anovulation. Surges of PRL are believed to act on the hypothalamus to inhibit GnRH secretion. Administration of exogenous GnRH during this time induces normal pituitary responsiveness, and occasional ovulation may occur spontaneously even during lactation.

LACTATION

Development of the breast alveolar lobules occurs throughout pregnancy. This period of mammogenesis requires the concerted participation of estrogen, progesterone, PRL, GH, and glucocorticoids. hPL may also play a role but is not indispensable. Lactation requires PRL, insulin, and adrenal steroids and is associated with further enlargement of the lobules, followed by synthesis of milk constituents such as lactose and casein. Lactopoiesis does not occur until unconjugated estrogens fall to nonpregnant levels at about 36 to 48 hours postpartum. Evidence from GH-deficient and hypothyroid patients suggests that GH and thyroid hormone are not required.

PRL is essential to milk production. Its action involves induced synthesis of large numbers of PRL receptors. These receptors appear to be autoregulated because PRL increases receptor levels in cell culture and bromocriptine, an inhibitor of PRL release, causes a decrease in both PRL and its receptors. In the absence of PRL, milk secretion does not take place. However, even in the presence of high levels of PRL during the third trimester, milk secretion does not take place until after delivery, due to the blocking effect of high levels of estrogen.

Milk secretion requires the additional stimulus of suckling, which activates a neural arc. Milk ejection occurs in response to a surge of oxytocin, which induces a contractile response in the smooth muscle surrounding the gland ductules. Oxytocin release is occasioned by stimuli of a visual, psychologic, or physical nature that prepare the mother for breast-feeding; whereas PRL release is limited to the suckling reflex arc.
Hyperthyroidism in Pregnancy

Pregnancy mimics hyperthyroidism because it causes thyroid enlargement, increased cardiac output, and peripheral vasodilation. Owing to the increase in TBG in pregnancy, total serum thyroxine is in the range expected for hyperthyroidism. Free thyroxine, the free thyroxine index, and TSH levels, however, remain in the normal range (see Chapter 7).

True hyperthyroidism complicates 1 to 2 per 1000 pregnancies. The most common form of hyperthyroidism during pregnancy is Graves disease. Hyperthyroidism is associated with an increased risk of preterm delivery (11%-25%) and may modestly increase the risk of early abortion. In Graves disease, thyroid-stimulating immunoglobulin, a 7S immune gamma globulin, crosses the placenta and may cause fetal goiter and transient neonatal hyperthyroidism.

A. Management of the mother  The treatment of maternal hyperthyroidism is complicated in pregnancy. Radioiodine is strictly contraindicated. Iodide therapy can lead to huge fetal goiter and is contraindicated except as acute therapy to prevent thyroid storm before thyroid surgery. All antithyroid drugs cross the placenta and may cause fetal hyperthyroidism and goiter or cretinism in the newborn. However, propylthiouracil in doses of 300 mg/d or less has been shown to be reasonably safe, although even at low doses about 10% of newborns will have a detectable goiter. A reasonable plan of management is to begin therapy with propylthiouracil in doses high enough to bring the free T4 index into the mildly hyperthyroid range and then to taper the dose gradually. Propranolol has been used to control maternal cardiovascular symptoms but may result in fetal bradycardia, growth restriction, preterm labor, and neonatal respiratory depression. Partial or total thyroidectomy, especially in the second trimester, is a reasonably safe procedure except for the risk of preterm labor.

B. Management of the newborn  Newborns should be observed carefully. In infants of mothers given propylthiouracil, even equivocal evidence of hypothyroidism is an indication for thyroxine replacement therapy. Neonatal Graves disease, which may present as late as 2 weeks after delivery, requires intensive therapy (see Chapter 7).

Hypothyroidism in Pregnancy

Hypothyroidism is uncommon in pregnancy because most women with the untreated disorder are anovulatory. As a practical matter, women taking thyroid medication at the time of conception should be maintained on the same or a slightly higher dose throughout pregnancy, whether or not the obstetrician believes thyroid replacement was originally indicated. Physiologic doses of thyroid hormone replacement are innocuous, but maternal hypothyroidism is hazardous to the developing fetus. Women with a personal or family history of thyroid disease or with symptoms suggestive of hypothyroidism should have TSH tested prior to conception. The correlation between maternal and fetal thyroid status is poor, and hypothyroid mothers frequently deliver euthyroid infants. The strongest correlation between maternal and newborn hypothyroidism occurs in areas where endemic goiter due to iodide deficiency is common. In an iodine-deficient population, treatment with iodine in the first and second trimesters of pregnancy significantly reduces the incidence of cretinism (growth failure, mental retardation, and other neuropsychologic deficits). Overt maternal hypothyroidism has been associated with fetal neurodevelopmental damage and low IQs in the offspring. This is thought to be due to inadequate transplacental supply of thyroxine T4 in early pregnancy as the mother is the only source of T4 for the early developing fetal brain.

Pituitary Disorders in Pregnancy

In women of reproductive age, small tumors of the anterior pituitary are not uncommon (see also Chapter 4). Although many are nonfunctional and asymptomatic, the most common symptom of pituitary microadenomas is amenorrhea, frequently accompanied by galactorrhea. In the past, few affected women became pregnant, but now most can be made to ovulate and to conceive with the aid of clomiphene citrate, recombinant gonadotropins and hCG, or bromocriptine. Before ovulation is induced in any patient, serum PRL should be determined. Modest elevations of PRL warrant checking IGF-1 levels, because hyperprolactinemia occurs in 25% of patients with GH-producing adenomas. If PRL or IGF-1 is elevated, the sella turcica should be evaluated by magnetic resonance imaging. About 10% of women with secondary amenorrhea are found to have adenomas, and 20% to 50% of women with amenorrhea and galactorrhea have detectable tumors.

The effect of pregnancy on pituitary adenomas depends on their size. Microadenomas rarely (1%) lead to visual field defects. However, approximately 20% of macroadenomas may lead to abnormalities in visual fields or other neurologic signs, usually in the first half of pregnancy. These changes almost always revert to normal after delivery, so aggressive therapy for known pituitary adenomas is not indicated except in cases of rapidly progressive visual loss. Monitoring of patients with known PRL-secreting adenomas during pregnancy is primarily based on clinical examination. The normal gestational increase in PRL may obscure an increase attributable to the adenoma, and radiographic procedures are undesirable in pregnancy.

A. Management  Management of the pregnant woman with a pituitary adenoma includes early ophthalmologic consultation for formal visual field mapping and repeat examinations every other month throughout pregnancy. If visual field disturbances are minimal, pregnancy may be allowed to proceed to term. If symptoms become progressively more severe and the fetus is mature, labor should be induced. If symptoms are severe and the fetus is immature, management may consist of transsphenoidal resection
of the adenoma or medical treatment with bromocriptine. Although bromocriptine inhibits both fetal and maternal pituitary PRL secretion, it does not affect decidual PRL secretion. Bromocriptine appears not to be teratogenic, and no adverse fetal effects have been reported. In most cases, it is probably preferable to surgery. The newer, selective dopamine D₂ receptor agonist cabergoline has shown excellent results in normalizing PRL levels, inducing tumor shrinkage, and minimizing side effects. The data available on pregnancies in which cabergoline was used do not show adverse effects; however, because the data are limited compared with the large numbers for bromocriptine safety, the latter is recommended. Both have category B classification for pregnancy. Radiation therapy should not be used in pregnancy, however, focused gamma knife pituitary radiation, with abdominal shielding, is gaining popularity in this setting with less than 0.01% of the radiation dose reaching the uterus.

Lymphocytic hypophysitis is an autoimmune inflammation of the pituitary that classically occurs in women in late pregnancy or during the puerperium. The clinical presentation is difficult to distinguish from that of a large PRL-secreting adenoma. Expectant conservative medical management with corticosteroids is sometimes possible, with vigilant postpartum observation to prevent consequences of pituitary insufficiency.

A. Prognosis and follow-up There appears to be no increase in obstetric complications associated with pituitary adenomas, and no fetal jeopardy. The rate of prematurity increases in women with tumors requiring therapy, but this is probably due to aggressive intervention rather than to direct effects on spontaneous preterm labor. The postpartum period is characterized by rapid relief of even severe symptoms, with less than 4% of untreated tumors developing permanent sequelae. In some cases, tumors improve following pregnancy, with normalization or lowering of PRL relative to prepregnancy values. Management should include imaging and assessment of PRL levels 4 to 6 weeks after delivery. There are no contraindications to breast-feeding.

Obesity and Pregnancy

Obesity is a complicated metabolic and endocrine condition that has been implicated in a number of pregnancy-related complications. Its prevalence has dramatically increased in the United States over the last 20 years. Currently approximately one-third of adult women are obese (body mass index [BMI] >30). This is a particular problem for non-Hispanic black women (49%) and Mexican American women (38%). Obese women are at increased risk for a number of adverse outcomes during pregnancy, including spontaneous abortion, stillbirth, preeclampsia, gestational diabetes, congenital anomalies, cesarean section, venous thromboembolism, and increased surgical morbidity. Complications in pregnancy are generally related to maternal pregravid obesity rather than excessive weight gain during pregnancy. In 1990, the Institute of Medicine published guidelines recommending weight gain of 25 to 35 lb for pregnant women with a normal BMI, 15 to 25 lb for overweight women, and no more than 15 lb for obese women. These were initially designed to help prevent fetal growth restriction. However, most overweight/obese women have mean weight gain exceeding these guidelines. Because of the risks to the fetus, it is recommended that women attempt to lose weight prior to conception.

A. Early pregnancy risks associated with obesity There is a well-documented increased risk of early miscarriage in obese women in both spontaneous pregnancies and after infertility treatments. Maternal obesity is also associated with an increased risk of a range of structural anomalies particularly neural tube defects, heart defects, and omphalocele. As these types of anomalies are also associated with diabetes, it has been suggested that some of these women may be undiagnosed diabetics. To complicates this further, obesity can affect accuracy of diagnostic testing for congenital anomalies. Heavier women have lower AFP levels likely from greater plasma volume and therefore adjustments have to be made for serum screening based on maternal weight. Ultrasound is the primary diagnostic tool for identifying structural abnormalities. Increasing maternal weight is associated with increasing impairment of adequate ultrasound visualization particularly of cardiac and craniomotor abnormalities. For these reasons, it is important to encourage preconception weight loss and perform early screening for diabetes.

B. Late pregnancy risks associated with obesity Maternal obesity in pregnancy is associated with a significantly increased rate of gestational diabetes (GDM), preeclampsia, and stillbirths. In a large prospective study of 16,102 women, obese women and morbidly obese women were 2.5 and 3.2 more likely, respectively, to develop gestational hypertension, and 1.6 and 3.3 times more likely to develop preeclampsia. Given the potential increase in oxidative stress from maternal adipose tissue, antioxidants such as vitamin C and E have been studied in the prevention of preeclampsia in obese women; however, they have yet to show any benefit. Gestational diabetes occurs due to decreased insulin sensitivity and inadequate insulin secretory response. Obese women, in general, are more insulin resistant at baseline; therefore, it is not surprising that they are at higher risk of developing GDM. Overweight and obese women have a 2.0- to 2.4-fold increased risk of unexplained fetal death, respectively. The exact pathophysiology of unexplained intrauterine fetal death in obese women is currently unknown.

C. Peripartum risks associated with obesity Overweight and obese women also have an increased rate of cesarean section and surgical complications, including risks of anesthesia, wound infection, excessive blood loss, endometritis, and deep venous thrombosis. In a recent report, the rate of cesarean section in overweight women was 33.8% and 47% in obese women, compared to only 20.7% in normal weight controls.

D. Long-term risks associated with obesity Maternal obesity is a risk factor for fetal macrosomia. Accumulating evidence indicates fetal macrosomia is associated with adolescent
and adult obesity and metabolic syndrome. A large retrospective study recently found that children born to obese mothers were twice as likely to be obese at 2 years of age. Both maternal obesity and maternal diabetes may independently affect the risk of adolescent obesity in children. Macrosomic infants are also at increased risk of subsequent development of diabetes. Thus, the epidemics of obesity and diabetes may continue to increase further as a result of fetal overgrowth and adiposity in utero.

**Parathyroid Disease and Pregnancy**

Pregnancy is associated with an approximately 25 to 30 g accumulation of calcium in the mother by term. Most of this calcium is used for fetal skeletal development. Elevated levels of 1,25-hydroxyvitamin D from the decidua leads to increased calcium absorption by the maternal gastrointestinal tract. The kidneys also work to conserve calcium during pregnancy by increasing reabsorption. Overall PTH levels are slightly lower throughout pregnancy and calcium is actively transported across the placenta to the fetus against a concentration gradient. The fetus is relatively hypercalcemic, hypercalcitonemic, and hypoparathyroid in comparison to the mother, but this resolves shortly after birth.

**A. Hyperparathyroidism**  
Hyperparathyroidism can be either primary, from an overactive parathyroid gland(s), or a secondary physiologic response to low calcium or vitamin D deficiency. Primary hyperparathyroidism in pregnancy is rare and is due to a solitary or multiple parathyroid adenomas, hyperplasia, or carcinoma. Symptoms of hyperparathyroidism are nonspecific including fatigue, anorexia, nausea, vomiting, constipation, mental status changes, and depression and are generally present when serum calcium levels are over 12 mg/dL. Complications during pregnancy from uncontrolled hyperparathyroidism include nephrolithiasis, pancreatitis, hyperemesis gravidarum, and hypercalcemic crisis. There is an increased incidence of these complications during the postpartum period when the fetal/placental drain of calcium has been removed if the hyperparathyroidism persists after birth of the infant. Fetal complications have been reported to be as high as 80% and include increased risk of spontaneous abortions, intrauterine growth restriction, low birth weight, intrauterine demise, and postpartum neonatal hypocalcemia/tetany due to suppression of the fetal parathyroid glands. In general, neonates do well if supplemental calcium and vitamin D are started promptly and serum biochemistries are closely monitored. If possible, delivery should be delayed until eucalcemia is achieved in order to allow for normal development of the fetal parathyroid glands. Surgical excision of a symptomatic adenoma is generally recommended in pregnancy during the second trimester. Conservative management throughout pregnancy is, however, possible with close maternal and fetal surveillance, if the patient is asymptomatic and only mild elevations in serum calcium are present.

**B. Hypoparathyroidism**  
Hypoparathyroidism in pregnancy is even rarer than hyperparathyroidism and is most commonly due to incidental resection of or damage to the parathyroid glands during thyroidectomy. Symptoms from hypocalcemia include numbness and tingling of fingers and perioral area. If serum calcium levels are maintained within normal limits, pregnancy outcome should not be negatively affected. If not treated, maternal hypocalcemia can lead to hyperparathyroidism in the fetus causing bone demineralization, and labor may be complicated by tetany. Treatment of hypoparathyroidism involves administration of supplemental calcium and vitamin D or its metabolite 1,25-dihydroxyvitamin D.

**PREECLAMPSIA/ECLAMPSIA**

Preeclampsia is an idiopathic multisystem disease seen only in pregnancy and during the peripartum period. The incidence of preeclampsia is approximately 7%. Risk factors include nulliparity, African American race, extremes of age, chronic hypertension, multiple gestation, prior history of preeclampsia, family history of preeclampsia, chronic renal disease, antiphospholipid antibody syndrome, hydramnios, diabetes, and obesity. Preeclampsia is characterized by onset of hypertension and proteinuria after 20 weeks' gestation. Other signs and symptoms include headache, visual disturbances, epigastric pain, nausea/vomiting, thrombocytopenia, abnormal liver and kidney function tests. Eclampsia is the occurrence of seizures that cannot be attributed to other causes in women with preeclampsia and is associated with a maternal mortality rate as high as 10%. Preeclampsia accounts for approximately 15% of maternal deaths in the United States. Deaths occur most frequently from cerebral hemorrhage, renal failure, disseminated intravascular coagulopathy, acute pulmonary edema, or hepatic failure. Preeclampsia is also associated with perinatal fetal death and morbidity, due most commonly to iatrogenic prematurity.

**Pathophysiology**

The exact pathogenesis of preeclampsia remains poorly understood despite a significant amount of research in the field. It likely involves both maternal and placental factors as it is also seen in molar pregnancies with only trophoblastic and no fetal tissue. Abnormalities in placental vasculature development are postulated to result in placental hypoxia, which leads to factors being released that cause hypertension and microangiopathy of target organs. Both epidemiologic and experimental data support the role of the placenta in the etiology of preeclampsia as placental tissue is necessary for the development of the disease and once the placenta is removed its signs and symptoms begin to abate.

In preeclampsia, cytotrophoblast invasion is shallow and only the decidual portion of the spiral arteries is remodeled. In contrast, in normal pregnancies the cytotrophoblasts infiltrate deeper into the muscular tunica media of the spiral arteries, transforming these small muscular arterioles into large vessels with low resistance that facilitate placental blood flow (see Figure 16–1). It is likely that environmental, immunologic, and genetic factors all play a role in this important process.

Hypoperfusion and hypoxia are likely both a cause and effect of abnormal placental vascularization and subsequent preeclampsia. Animal models support this theory as induced preeclampsia generally requires mechanically reduced uteroplacental perfusion.
In addition, maternal medical conditions associated with vascular dysfunction such as hypertension, lupus, and renal disease increase the risk of preeclampsia, as do obstetric conditions that increase placental volume without increasing placental blood flow, such as twins and hydatidiform moles.

Generalized endothelial dysfunction may explain many of the multiple clinical features of preeclampsia. Evidence to support this includes enhanced vascular reactivity to angiotensin II, impaired flow-mediated vasodilation, decreased production of endothelium-derived vasodilators such as nitric oxide and prostacyclin, and increased production of vasoconstrictors like endothelins and thromboxanes.

Extensive placental angiogenesis is required to supply the necessary nutrients and oxygen to the fetus. Normal placental vessel development relies on a balance between proangiogenic factors such as VEGF and placental growth factor (PIGF) and antiangiogenic factors such as soluble fms-like tyrosine kinase 1 (sFlt-1) and soluble endoglin (sEng). It is proposed that free sFlt-1 in the maternal circulation antagonizes the angiogenic activities of VEGF and PIGF, leading to ischemia and vasospasm. sEng from the placenta is elevated in preeclamptic women, and appears to inhibit TGF-beta-1-mediated vasodilation.

Despite extensive research and multiple hypotheses regarding its etiology and pathophysiology, there is still no unifying theory that explains all the features of preeclampsia. It is generally accepted that the basis for the development of preeclampsia occurs early in pregnancy. While the roles of antiangiogenic factors such as sFlt-1 and sEng are convincing with regard to the pathogenesis of preeclampsia, the clinical utility of these biomarkers to predict, diagnose, prevent, or treat this disease remains unknown.

**Clinical Features**

Preeclampsia is classified as mild or severe, the latter designation being applied if any of the following signs or symptoms are present: headache, blurring vision, scotomata, altered mental status, right upper quadrant or epigastric pain, severe hypertension (160/110 mm Hg), pulmonary edema, oliguria (<500 cc/24 h), massive proteinuria (>5 g/24 h), renal failure (creatinine >1 mg/dL over baseline), elevated liver function tests (>2x normal), thrombocytopenia (platelets <100,000), coagulopathy or HELLP syndrome (hemolysis, elevated liver enzymes, low platelets). Despite knowledge of the many risk factors described above, it is still not possible to determine which mothers will ultimately develop preeclampsia and there are no effective preventative treatments. Large clinical trials using low-dose aspirin, calcium, and antioxidant vitamin supplementation revealed minimal to no benefit in preventing the development of preeclampsia. Instead, the current focus of management is for regular prenatal care with screening of blood pressure and proteinuria in hopes of early identification and aggressive monitoring.

**Treatment/Management of Preeclampsia**

The only definitive therapy for preeclampsia is delivery of fetus and placenta. This is straightforward for pregnancies near term. However, pregnancies between 24 to 34 weeks are more complicated as the obstetrician must balance the significant perinatal morbidity and mortality associated with preterm delivery versus the maternal and fetal risk of prolonging these high-risk pregnancies. Antihypertensive medications should be used in setting of severe hypertension to prevent a maternal stroke; however, their use in mild to moderate hypertension has not been shown to improve maternal or fetal outcome. Magnesium sulfate therapy is initiated as the anticonvulsant of choice for preeclamptics during labor, while administering corticosteroids prior to a planned preterm delivery, and for 24 hours postpartum.

THE ENDOCRINE PANCREAS

The pancreas comprises two functionally distinct organs: the exocrine pancreas, the major digestive gland of the body; and the endocrine pancreas, the source of insulin, glucagon, somatostatin, pancreatic polypeptide (PP), and ghrelin. Whereas the major role of the products of the exocrine pancreas (the digestive enzymes) is the processing of ingested foodstuffs so that they become available for absorption, the hormones of the endocrine pancreas modulate every other aspect of cellular nutrition from rate of adsorption of foodstuffs to cellular storage or metabolism of nutrients. Dysfunction of the endocrine pancreas or abnormal responses to its hormones by target tissues cause serious disturbances in nutrient homeostasis, including the important clinical syndromes grouped under the name diabetes mellitus.

ANATOMY AND HISTOLOGY

The endocrine pancreas consists of approximately 1 million small endocrine glands—the islets of Langerhans—scattered throughout the glandular substance of the exocrine pancreas. The exocrine pancreas consists of the enzyme-producing cells organized into acini, and the duct system that delivers those enzymes to the lumen of the duodenum. The islet volume comprises 1% to 1.5% of the total mass of the pancreas and weighs about 1 to 2 g in adult humans. At least five cell types—α, β, δ, ε, and PP—have been identified in the islets (Table 17-1). Each of these islet cell types produces a distinguishing peptide hormone: glucagon, insulin, somatostatin, ghrelin, and PP, respectively. Within individual islets, the different cell types are scattered throughout. A typical human islet is depicted in Figure 17-1.

These cell types are not distributed uniformly throughout the pancreas. The PP cells reside primarily in islets in the posterior portion (posterior lobe) of the head, a discrete lobe of the pancreas separated from the anterior portion by a fascial partition. This lobe originates in the primordial ventral bud as opposed to the dorsal bud. The posterior lobe receives its blood supply from the superior mesenteric artery; the remainder of the pancreas derives most of its blood flow from the celiac artery. The islets themselves are richly vascularized, receiving five to ten times the blood flow of the surrounding exocrine pancreatic tissue. Each islet is surrounded by a lattice of astroglial cells and innervated by sympathetic, parasympathetic, and sensory neurons.

HORMONES OF THE ENDOCRINE PANCREAS

1. INSULIN

Biosynthesis

The human insulin gene resides on the short arm of chromosome 11. A unique set of transcription factors found in the β cell nucleus activates the transcription of the preproinsulin mRNA from the *insulin* gene (Figure 17-2). A precursor molecule, preproinsulin, a peptide of MW 11,500, is translated from the preproinsulin messenger RNA in the rough endoplasmic reticulum of pancreatic β cells (see Figure 17-2). Microsomal enzymes cleave preproinsulin to proinsulin (MW = 9000) almost immediately after synthesis. Proinsulin is transported to the Golgi apparatus, where packaging into clathrin-coated secretory granules takes place. Maturation of the secretory granule is associated with loss of the clathrin coating and conversion of proinsulin into insulin and a smaller connecting peptide, or C peptide, by proteolytic cleavage at two sites along the peptide chain. Mature secretory granules contain insulin and C peptide in equimolar amounts and only small quantities of proinsulin, a small portion of which consists of partially cleaved intermediates.

Biochemistry

Proinsulin (Figure 17-3) consists of a single chain of 86 amino acids, which includes the A and B chains of the insulin molecule plus a connecting segment of 35 amino acids. Two proteins—the prohormone-converting enzymes type 1 and 2 (PCSK1 and PCSK2)—are packaged with proinsulin in the immature secretory granules. These enzymes recognize and cut at pairs of basic amino acids, thereby removing the intervening sequence. After the two pairs of basic amino acids are removed by carboxypeptidase E, the result is a 51 amino acid insulin molecule and a 31 amino acid residue, the C peptide, as shown in Figure 17-3.

A small amount of proinsulin produced by the pancreas escapes cleavage and is secreted intact into the bloodstream, along with insulin and C peptide. Most anti-insulin sera used in the standard immunoassay for insulin cross-react with proinsulin; about 3% to 5% of immunoreactive insulin extracted from human pancreas is actually proinsulin. Because proinsulin is not removed by the liver, it has a half-life three to four times that of insulin. Its long half-life allows proinsulin to accumulate in the blood, where it accounts for 12% to 20% of the circulating immunoreactive insulin in the basal state in humans. Human proinsulin has about 7% to 8% of the biologic activity of insulin. The kidney is the principal site of proinsulin degradation.

FIGURE 17–2 Structural components of the pancreatic β cell involved in glucose-induced biosynthesis and release of insulin. (Modified and reproduced, with permission, from Junqueira LC, Carneiro J, Long JA. Basic Histology. 5th ed. McGraw-Hill; 1986.)

FIGURE 17–3 Structure of human proinsulin C peptides and insulin molecules connected at two sites by dipeptide links.
Of the two major proinsulin split products present in plasma, the one split at arginine 32-33 far exceeds in amount the barely detectable 65-66 split product. In control subjects, concentrations of proinsulin and 32-33 split proinsulin after an overnight fast averaged 2.3 and 2.2 pmol/L, respectively, with corresponding postprandial rises to 10 and 20 pmol/L.

C peptide, the 31 amino acid peptide (MW 3000) released during cleavage of insulin from proinsulin, has no known biologic activity. β Cells release C peptide in equimolar amounts with insulin. It is not removed by the liver but is degraded or excreted chiefly by the kidney. It has a half-life three to four times that of insulin. In the basal state after an overnight fast, the average concentration of C peptide may remain as high as 1000 pmol/L.

Insulin is a protein consisting of 51 amino acids contained within two peptide chains: an A chain, with 21 amino acids; and a B chain, with 30 amino acids. The chains are connected by two disulfide bridges as shown in Figure 17-3. In addition, an intrachain disulfide bridge links positions 6 and 11 in the A chain. Human insulin has a molecular weight of 5808.

Endogenous insulin has a circulating half-life of 3 to 5 minutes. It is degraded chiefly by insulinases in liver, kidney, and placenta. A single pass through the liver removes approximately 50% of the plasma insulin.

Secretion

The human pancreas secretes about 30 units of insulin per day into the portal circulation of normal adults in distinct pulses with a period of approximately 5 minutes. The basal concentration of insulin in the peripheral blood of fasting humans averages 10 μU/mL (0.4 ng/mL, or 61 pmol/L). In normal control subjects, insulin seldom rises above 100 μU/mL (610 pmol/L) after standard meals. After ingestion of food, peripheral insulin concentration increases within 8 to 10 minutes, reaches peak concentrations by 30 to 45 minutes, and then rapidly declines to baseline values by 90 to 120 minutes postprandially.

Basal insulin secretion occurs in the absence of exogenous stimuli, in the fasting state. Plasma glucose levels below 80 to 100 mg/dL (4.4-5.6 mmol/L) do not stimulate insulin release, and most other physiologic regulators of insulin secretion only function in the presence of stimulatory levels of glucose. Stimulated insulin secretion occurs in response to exogenous stimuli. In vivo, ingested meals provide the major stimuli for insulin secretion. Glucose is the most potent stimulant of insulin release. The perfused pancreas releases insulin in two phases in response to glucose stimulation (Figure 17-4). When the glucose concentration increases suddenly, an initial short-lived burst of insulin release occurs (the first phase); if the glucose elevation persists, the insulin release gradually falls off and then begins to rise again to a steady level (the second phase). However, sustained levels of high glucose stimulation (~4 hours in vitro or >24 hours in vivo) result in a reversible desensitization of the β cell response to glucose but not to other stimuli.

The β cell senses glucose through its metabolism (Figure 17-5). Indeed, agents such as 2-deoxyglucose that inhibit the metabolism of glucose block the release of insulin. Glucose enters the pancreatic β cell by passive diffusion, facilitated by membrane proteins termed glucose transporters (see later). Because the transporters function in both directions, and the β cell has an excess of glucose transporters, the glucose concentration inside the β cell is

in equilibrium with the extracellular glucose concentration. The low-affinity enzyme glucokinase catalyzes the subsequent, and rate-limiting, step in glucose metabolism by the pancreatic \( \beta \) cell, the phosphorylation of glucose to glucose-6-phosphate. Glucose catabolism in the \( \beta \) cell causes a rise in the intracellular ATP-ADP ratio. Acting through the sulfonylurea receptor (SUR1), the nucleotide-sensing subunit of the ATP-sensitive potassium channels on the surface of the \( \beta \) cell, the rise in ATP-ADP ratio closes the potassium channels and depolarizes the cell, thereby activating the voltage-sensitive calcium channels and allowing the entry of calcium ions into the cell.

Insulin release requires calcium ion signaling. In addition to the voltage-dependent entry of extracellular \( \mathrm{Ca}^{2+} \) into the \( \beta \) cell as described earlier, glucose also retards \( \mathrm{Ca}^{2+} \) efflux from the \( \beta \) cell and releases \( \mathrm{Ca}^{2+} \) from intracellular compartments (predominantly the endoplasmic reticulum) into the cytosol. Some nonglucose stimuli of insulin release also function through increases in cytoplasmic \( \mathrm{Ca}^{2+} \). The sulfonylurea and meglitinide (such as repaglinide) medications act by closing the ATP-sensitive potassium channels. Secretagogues such as acetylcholine that act through \( \mathrm{G} \) protein–coupled receptors of the \( \mathrm{G}\alpha \_q \) class stimulate the release of intracellular \( \mathrm{Ca}^{2+} \) stored in the endoplasmic reticulum by activating phospholipase C and releasing the intracellular signaling molecule inositol 1,4,5-triphosphate (IP3).

Glucose metabolism in the \( \beta \) cell also generates additional signals that amplify the secretory response to elevations in cytoplasmic \( \mathrm{Ca}^{2+} \) concentration. The exact mechanisms of these amplifying signals remains unknown but involve multiple pathways and include increases in the intracellular signaling molecules diacylglycerol and cAMP. Secretagogues such as the gut hormones glucagon-like peptide-1 (GLP-1) and gastric inhibitory polypeptide (also known as glucose-dependent insulinotropic peptide, GLP) that act via \( \mathrm{G} \) protein–coupled receptors of the \( \mathrm{G}\alpha \_q \) class also stimulate insulin secretion through elevations in cAMP.

Other factors involved in the regulation of insulin secretion are summarized in Table 17–2. These factors can be divided into three categories: direct stimulants, which directly raise cytoplasmic calcium ion concentrations and thus can act in the absence of stimulatory glucose concentrations; amplifiers, which potentiate the response of the \( \beta \) cell to glucose; and inhibitors. Many of the amplifiers are incretins: gastrointestinal hormones that are released in response to the ingestion of meals and stimulate insulin secretion.
The action of the incretins explains the observation that orally ingested glucose provokes a greater insulin secretory response than does the same amount of intravenously administered glucose.

**Insulin Receptors and Insulin Action**

Insulin action begins with the binding of insulin to a receptor on the surface of the target cell membrane. Most cells of the body have specific cell surface insulin receptors. In fat, liver, and muscle cells, binding of insulin to these receptors is associated with the biologic response of these tissues to the hormone. These receptors bind insulin rapidly, with high specificity and with an affinity high enough to bind picomolar amounts.

Insulin receptors, members of the growth factor receptor family (see Chapter 1), are membrane glycoproteins composed of two protein subunits encoded by a single gene. The larger alpha subunit (MW 135,000) resides entirely extracellularly, where it binds the insulin molecule. The alpha subunit is tethered by disulfide linkage to the smaller beta subunit (MW 95,000). The beta subunit crosses the membrane, and its cytoplasmic domain contains a tyrosine kinase activity that initiates specific intracellular signaling pathways.

**Downstream signaling.** On binding of insulin to the alpha subunit, the beta subunit activates itself by autophosphorylation. The activated beta subunit then recruits additional proteins to the complex and phosphorylates a network of intracellular substrates, including insulin receptor substrate-1 (IRS-1), insulin receptor substrate-2 (IRS-2), and others (Figure 17–6). These activated substrates each lead to subsequent recruitment and activation of additional kinases, phosphatases, and other signaling molecules in a complex pathway that generally contains two arms: the mitogenic pathway, which mediates the growth effects of insulin and the metabolic pathway, which regulates nutrient metabolism.

In the metabolic signaling pathway, activation of phosphatidylinositol-3-kinase leads to the activation of serine/threonine kinase AKT/PKB. AKT activation drives the movement of glucose transporter (GLUT) 4-containing vesicles to the cell membrane, increases glycogen and lipid synthesis, and stimulates protein synthesis through the activation of mTOR. In the mitogenic signaling pathway, activation of Ras initiates a cascade of activating phosphorylations via the MAP kinase pathway, leading to cell growth and proliferation.

**Transcriptional regulation.** In addition, the insulin-signaling pathway regulates the activity of several nuclear transcription factors that in turn control the expression of genes involved in metabolism and growth. These include members of the forkhead family of transcription factors, including Foxo1, which is inactivated by phosphorylation by AKT downstream of insulin signaling. Foxo1 coordinates the expression of gene networks involved in nutrient metabolism in multiple tissues, generally activating genes involved in the response to fasting. In this process, Foxo1 works with several other transcriptional regulators including the lipogenic transcription factor SREBP1c, members of the PPAR family of nuclear receptors and the PPAR coactivator PGC1α (Figure 17–7). Foxo1 also inhibits β cell proliferation and survival.

The three members of the PPAR family of nuclear hormone receptors play pleiotropic roles in regulating genes involved in metabolism in many tissues. They may function as targets of insulin signaling, modulators of insulin signaling, or both. Despite overlap in the tissue expression and gene targets of the three PPARs, some general conclusions can be drawn about the function of each. PPARα regulates genes involved in fatty acid catabolism and gluconeogenesis and is most highly expressed in brown fat, heart, liver, kidney, and intestine. PPARβ/δ is broadly expressed and activates gene programs involved in fatty acid oxidation. PPARγ is most highly expressed in adipose tissue, intestine, and immune cells, but also at lower levels in many other tissues. PPARγ drives white adipocyte differentiation and lipid storage and inhibits production of many of the pro-resistance adipokines and pro-inflammatory cytokines in adipose tissue (see section on insulin resistance later). In macrophages, PPARγ acts to promote their alternative activation to the anti-inflammatory M2 state, rather than the pro-inflammatory M1 state.

The PPARs bind to DNA as heterodimers with the 9-cis-retinoic acid receptor (RXR), and recruit a variety of coactivators and corepressors. PGC1α was originally identified as a coactivator interacting with PPARγ, but the interaction is not exclusive. On different genes PPARγ works with different coactivators, and PGC1α interacts with the other PPARs and many other transcription factors. In collaboration with a variety of different transcription factors in various tissues, PGC1α orchestrates the expression of a set of genes involved in metabolism. PGC1α itself is highly regulated by several signaling pathways including insulin signaling, which inhibits PGC1α activity via phosphorylation by AKT.

A number of natural and synthetic lipids and related compounds can act as PPAR ligands, but the endogenous ligands acting in vivo remain a mystery. The fibrate class of lipid-lowering drugs, used clinically to lower circulating triglyceride levels, act as PPARα ligands. The thiazolidinedione class of insulin-sensitizing
Deactivation of insulin signaling. Once activated by binding to insulin, the insulin receptor and downstream signaling cascades rapidly deactivate again by several mechanisms. Insulin can simply disengage from the receptor, or the receptor can be internalized and degraded. The receptor and its tyrosine-phosphorylated substrates can be deactivated by specific protein tyrosine phosphatases such as PTP1b. In addition, inhibitory SOCS (suppressor of cytokine signaling) proteins block interactions between the phosphorylated receptor and interacting IRS proteins, direct the ubiquitination and degradation of the IRS proteins, and terminate the activation of downstream components of the signaling pathway. Finally, serine phosphorylation of the insulin receptor and its active substrates by several different serine/threonine kinases, including components of the insulin-signaling pathway such as AKT, blocks insulin signaling. Many of these mechanisms may play a role in the development of insulin resistance (see later).

Metabolic Effects of Insulin
The major function of insulin is to promote storage of ingested nutrients. Although insulin directly or indirectly affects the function of almost every tissue in the body, the discussion here will be limited to a brief overview of the effects of insulin on the major tissues specialized for energy metabolism: liver, muscle, adipose tissue, and brain. In addition, the paracrine effects of insulin will be discussed briefly.

A. Paracrine effects The effects of the products of endocrine cells on surrounding cells are termed paracrine effects, in contrast to actions that take place at sites distant from the secreting cells, which are termed endocrine effects (see Chapter 1). Paracrine effects of the β and δ cells on the nearby α cells (see Figure 17–1) are of considerable importance in the endocrine pancreas. Insulin directly inhibits α cell secretion of glucagon. In addition, somatostatin, which δ cells release in response to most of the same stimuli that provoke insulin release, also inhibits glucagon secretion.

Because glucose stimulates only β and δ cells (whose products then inhibit α cells) whereas amino acids stimulate glucagon as well as insulin, the type and amounts of islet hormones released during a meal depend on the ratio of ingested carbohydrate to protein. The higher the carbohydrate content of a meal, the lower the amount of glucagon released by any amino acids absorbed. In contrast, a predominantly protein meal results in relatively greater glucagon secretion, because amino acids are less effective at stimulating insulin release in the absence of concurrent hyperglycemia but are potent stimulators of α cells.
**B. Endocrine effects** (Table 17-3)

1. Liver—The first major organ reached by insulin via the bloodstream is the liver. Insulin exerts its action on the liver in two major ways:
   a. **Insulin promotes anabolism**—Insulin promotes glycogen synthesis and storage while inhibiting glycogen breakdown. These effects are mediated by changes in the activity of enzymes in the glycogen synthesis pathway (see below). The liver has a maximum storage capacity of 100 to 110 g of glycogen, or approximately 440 kcal of energy.

   Insulin increases both protein and triglyceride synthesis and very low density lipoprotein (VLDL) formation by the liver. It also inhibits gluconeogenesis and promotes glycolysis through its effects on the function and expression of key enzymes of both pathways.

   b. **Insulin inhibits catabolism**—Insulin acts to reverse the catabolic events of the postabsorptive state by inhibiting hepatic gluconeogenesis, ketogenesis, and gluconeogenesis.

2. Muscle—Insulin promotes protein synthesis in muscle by increasing amino acid transport, as well as by stimulating ribosomal protein synthesis. In addition, insulin promotes glycogen synthesis to replace glycogen stores expended by muscle activity. This is accomplished by increasing glucose transport into the muscle cell, enhancing the activity of glycogen synthase, and inhibiting the activity of glycogen phosphorylase. Approximately 500 to 600 g of glycogen are stored in the muscle tissue of a 70-kg man, but because of the lack of glucose 6-phosphatase in this tissue, it cannot be used as a source of blood glucose, except for a small amount produced when the debranching enzyme releases unphosphorylated glucose from branch points in the glycogen polymer, and the glucose indirectly produced via the liver from lactate generated by muscle.

3. Adipose tissue—Fat, in the form of triglyceride, is the most efficient means of storing energy. It provides 9 kcal/g of stored substrate, as opposed to the 4 kcal/g generally provided by protein or carbohydrate. In the typical 70-kg man, the energy content of adipose tissue is about 100,000 kcal.

   Insulin acts to promote triglyceride storage in adipocytes by a number of mechanisms. (1) It induces the production of lipoprotein lipase in adipose tissue (this is the lipoprotein lipase that is bound to endothelial cells in adipose tissue and other vascular beds), which leads to hydrolysis of triglycerides from circulating lipoproteins, thereby yielding fatty acids for uptake by adipocytes. (2) By increasing glucose transport into fat cells, insulin increases the availability of α-glycerol phosphate, a substance used in the esterification of free fatty acids into triglycerides. (3) Insulin inhibits intracellular lipolysis of stored triglyceride by inhibiting intracellular lipase (also called hormone-sensitive lipase). This reduction of fatty acid flux to the liver is a key regulatory factor in the action of insulin to lower hepatic gluconeogenesis and ketogenesis.

4. Central nervous system—Although the brain is traditionally not considered an insulin-sensitive tissue, and overall glucose utilization by the brain is not acutely regulated by insulin, key regions of the brain can respond to insulin. Insulin signaling via PI3 kinase in key cells in the hypothalamus functions with leptin signaling to decrease appetite and increase energy expenditure (see Chapter 20).

C. AMPK and insulin-independent regulation of nutrient metabolism—Insulin, along with the counter-regulatory hormones and other circulating enhancers and inhibitors of their actions, coordinates nutrient metabolism in response to the overall

Among these mechanisms, adenosine monophosphate protein kinase (AMPK) plays a central role. When energy availability falls, the drop in cellular ATP concentration and rise in AMP trigger a conformational change in the trimeric AMPK complex and the subsequent activation of the catalytic domain by the serine/threonine kinase LKB1/STK11. AMPK then drives the production of ATP by activating catabolic pathways and inhibiting synthetic pathways in the cell (Figure 17–8). In muscle, in response to the rise in AMP during exercise, AMPK increases fatty acid oxidation and insulin-independent glucose uptake while inhibiting mTOR and protein synthesis. In the long term, AMPK also drives mitochondrial biogenesis. In liver cells, AMPK blocks fatty acid and triglyceride synthesis while activating fatty acid oxidation, and also inhibits the gluconeogenic program by blocking cAMP activation of gene expression and inhibiting Foxo1/PGC1α-driven expression of the gluconeogenic genes. In brain, AMPK also functions as an energy sensor and plays a role in the regulation of appetite and energy expenditure by the hypothalamus. AMPK has also been implicated in the regulation of insulin secretion by β cells.

While predominantly an intracellular energy sensor, AMPK increases the sensitivity of cells to insulin, although the mechanisms remain uncertain. AMPK also responds to extracellular signals, and contributes to the regulation of metabolism by many of the adipokines and cytokines (see later) as well as cannabinoids. The biguanide drugs, including metformin, which is used in the treatment of type 2 diabetes, activate AMPK by reducing mitochondrial production of ATP and raising intracellular levels of AMP, and thereby lower blood glucose levels by inhibiting gluconeogenesis.

**Glucose Transporter Proteins**

Glucose oxidation provides energy for most cells and is critical for brain function. Because cell membranes are impermeable to hydrophobic molecules such as glucose, all cells require carrier proteins to transport glucose across the lipid bilayers into the cytosol. Whereas the intestine and kidney have an energy-dependent Na⁺-glucose cotransporter, all other cells utilize non-energy-dependent transporters that facilitate diffusion of glucose from a higher concentration to a lower concentration across cell membranes. Facilitative glucose transporters (GLUTs) comprise a large family including at least 13 members, although some of the recently identified members of the family have not yet been shown to transport glucose. The first four members of the family are the best characterized, and they have distinct affinities for glucose and distinct patterns of expression.

GLUT 1 is present in all human tissues. It mediates basal glucose uptake, because it has a very high affinity for glucose and,

**FIGURE 17–8** Regulation and function of AMPK. Proteins that are directly phosphorylated by AMPK are shown in bold font. The blue arrows indicate stimulation, and the red lines indicate inhibition. Processes activated by AMPK are labeled in blue, while the processes inhibited by AMPK are shown in red. (ACC, acetyl-CoA carboxylase; AKT, AKR mouse tumor 8 kinase; CamKK, calcium/calmodulin-dependent protein kinase kinase; eEF2, eukaryotic translation elongation factor 2; FAS, fatty acid synthase; G6P, glucose-6-phosphatase; GPAT, glycerol-3-phosphate acyltransferase, mitochondrial; HK, hexokinase; HMG-CoA reductase; LKB1, liver kinase B1; MCD, malonyl-CoA decarboxylase; mTOR, mammalian target of rapamycin; PEPCK, phosphoenolpyruvate carboxykinase; PFK2, 6-phosphofructo-2-kinase/fructose-2,6-bisphosphatase; PGC1α, peroxisome proliferator-activated receptor gamma coactivator-1; PKA, protein kinase A; PP2C, protein phosphatase 2C; SREBP1c, sterol regulatory element–binding protein 1c; Tak1, TGF-beta-activated kinase 1; transducer of regulated cAMP response element-binding protein 2; TSC1/2, tuberous sclerosis 1).
therefore, can transport glucose at the relatively low concentrations found in the fasted state. For this reason, its presence on the surface of the endothelial cells of the brain vascular system (blood–brain barrier) ensures adequate transport of plasma glucose into the central nervous system.

GLUT 3, which is also found in all tissues, is the major glucose transporter on neurons. It also has a very high affinity for glucose and is responsible for transferring glucose into neuronal cells at the lower concentrations found in the central nervous system.

In contrast, GLUT 2 has a lower affinity for glucose and thus increases glucose transport when plasma glucose levels rise, such as postprandially. It is a major transporter of glucose in hepatic, intestinal, and renal tubular cells. The low affinity of GLUT 2 for glucose reduces hepatic uptake of glucose during fasting, while its ability to transport glucose equally efficiently in both directions assists in the export of glucose from hepatocytes. GLUT 2 is also expressed on the surface of the β cells in rodents, but it is not detected at significant levels on human β cells.

GLUT 4 is found in two major insulin target tissues: skeletal muscle and adipose tissue. It is sequestered mainly within an intracellular compartment of these cells and thus does not function as a glucose transporter until insulin signaling causes translocation of GLUT 4 to the cell membrane, where it facilitates glucose entry into these tissues after a meal (see Figure 17-6). In muscle, exercise also drives GLUT 4 translocation to the cell surface by activating AMPK.

**Islet Amyloid Polypeptide**

Islet amyloid polypeptide (IAPP), or amylin, is a 37 amino acid peptide produced and stored with insulin in pancreatic β cells but only at a low ratio of approximately one molecule of IAPP to 100 of insulin. β Cells cosecrete IAPP with insulin in response to glucose and other β cell secretagogues. Although it plays a role in regulating gut physiology by decreasing gastric emptying and gut motility after meals, the full physiologic functions of IAPP remain uncertain. A soluble analog of IAPP called pramlintide has been approved for use in patients with type 1 diabetes and insulin-treated type 2 diabetes (see later).

IAPP produces amyloid deposits in pancreatic islets of most patients with type 2 diabetes of long duration. These amyloid deposits are insoluble fibrillar proteins generated from IAPP oligomers that encroach on and may even occur within pancreatic β cells. Islets of nondiabetic elderly persons may contain less extensive amyloid deposits. Whether amyloid fibrils and deposition contributes to the islet dysfunction and β cell loss seen in type 2 diabetes or is simply a consequence of disordered and hyperstimulated islet function remains an unresolved question.

2. **GLUCAGON**

**Biochemistry**

Pancreatic glucagon, along with several other biologically active peptides, derives from the large proglucagon peptide encoded by the preproglucagon gene located on human chromosome 2. Tissue-specific proteases (the prohormone convertases) cleave different sets of peptide products from the proglucagon molecule in the endocrine l-cells of the gut and the α cells in the islet (Figure 17-9). The activity of prohormone convertase 2 in α cells generates the glucagon peptide, along with the amino-terminal glicentin-related peptide, a small central hexapeptide, and a large carboxyl-terminal fragment.

![Figure 17-9](image-url)
Glucagon consists of 29 amino acids in a single-chain polypeptide with a molecular weight of 3485. In healthy humans, the average fasting plasma immunoreactive glucagon level is 75 pg/mL (25 pmol/L). Only 30% to 40% of this is actually pancreatic glucagon, the remainder being a heterogeneous composite of higher-molecular-weight molecules with glucagon immunoreactivity such as proglucagon, glicentin, and oxyntomodulin. Circulating glucagon has a half-life of 3 to 6 minutes due to removal by the liver and kidney.

**Secretion**

In contrast to its stimulation of insulin secretion, glucose inhibits glucagon secretion. Conflicting data surround the question of whether glucose directly inhibits secretion from the α cell or whether it only acts via release of insulin and somatostatin from the β and δ cells, both of which inhibit the α cell directly. In addition, because β cells release gamma-aminobutyric acid (GABA) and α cells express inhibitory GABA receptors, GABA also may participate in the inhibition of α cells during β cell stimulation.

Many amino acids stimulate glucagon release, although they differ in their ability to do so. Some, such as arginine, release both glucagon and insulin; others (eg, alanine) stimulate primarily glucagon release. Leucine, an effective stimulant of insulin release, does not stimulate glucagon. Other substances that promote glucagon release include catecholamines, gastrointestinal hormones (cholecystokinin [CCK], gastrin, and gastric inhibitory polypeptide [GIP]), and glucocorticoids. Both sympathetic and parasympathetic (vagal) stimulation promote glucagon release, especially in response to hypoglycemia. High levels of circulating fatty acids suppress glucagon secretion.

**Action of Glucagon**

In contrast to insulin, which promotes energy storage in a variety of tissues in response to feeding, glucagon provides a humoral mechanism for delivering energy from the liver to the other tissues between meals. The ratio of insulin to glucagon affects key target tissues by regulating the expression and activity of key enzymes controlling nutrient metabolism and, thereby, controlling the flux of these nutrients into or out of storage.

The liver, because of its connection to the pancreas via the portal vein, represents the major target organ for glucagon, with portal vein glucagon concentrations reaching as high as 300 to 500 pg/mL (100-166 pmol/L) during fasting. It is unclear whether physiologic levels of glucagon affect tissues other than the liver. Glucagon signals through the glucagon receptor, a G protein-coupled receptor (GPCR) of the Gaα class found predominantly on the surface of hepatocytes. Binding of glucagon to its receptor in the liver activates adenyl cyclase and the generation of cAMP, which in turn mediates the phosphorylation or dephosphorylation of key enzymes regulating nutrient metabolism. In addition, like insulin, glucagon receptor signaling modifies the activity of a set of cAMP responsive transcriptional regulators that in turn control the expression of the genes encoding these same enzymes.

Glucagon signaling in the liver stimulates the breakdown of stored glycogen, maintains hepatic output of glucose from amino acid precursors (gluconeogenesis), and promotes hepatic output of ketone bodies from fatty acid precursors (ketogenesis). Glucagon facilitates the uptake of the gluconeogenic substrate alanine by liver, and directs fatty acids away from reesterification to triglycerides and toward ketogenic pathways. In sum, glucagon signaling results in the net release of readily available energy stores from the liver in the form of glucose and ketones.

**Glucagon-Related Peptides**

In the intestinal L-cells, found predominantly in the distal ileum and colon, prohormone convertase 1 generates a different set of peptides from the proglucagon molecule, including glicentin, glicentin-related polypeptide (GRPP), oxyntomodulin, and the two glucagon-like peptides GLP-1 and GLP-2 (see Figure 17–9). Several biological activities have been attributed to glicentin and oxyntomodulin based on studies using high concentrations of the peptides, but all these actions can be explained by low-affinity interactions with the receptors for glucagon, GLP-1 and GLP-2. Specific receptors for glicentin and oxyntomodulin have not been identified, and it remains uncertain whether these peptides play any biological role at physiologic concentrations. GRPP also has no clearly established biological activity. The other two gut-derived glucagon-related peptides, GLP-1 and GLP-2, however, play important roles in nutrient metabolism and gastrointestinal physiology (Table 17–4).

There are two active forms of GLP-1: GLP-1(7-36) amide, and GLP-1(7-37). The intestinal L-cells secrete GLP-1 in response to meals, through dietary glucose and lipids and parasympathetic stimulation. The L-cells sense dietary fat in the gut lumen in part through the GPR119 receptor, which binds the long chain fatty acid derivative oleoylthanolamide. GPR119 is also expressed on the surface of the β cells. GLP-1 binds to the GLP-1 receptor, a GPCR similar to the glucagon receptor. The ubiquitous pro tease dipeptidyl peptidase 4 (DPP-4) rapidly inactivates circulating GLP-1 (half-life <2 min) by removing the two amino-terminal amino acids. Pancreatic islets are major targets of GLP-1 action. GLP-1 directly stimulates the production and secretion of insulin and somatostatin, and thereby indirectly inhibits the secretion of glucagon. In addition, GLP-1 protects the β cells from destruction and stimulates β cell growth. Other targets of GLP-1 include the stomach, where the peptide inhibits gastric emptying and gastric acid secretion; the brain, where it inhibits appetite and induces weight loss; and the heart, where it has some protective effects.

Along with GLP-1, intestinal L-cells cosecrete GLP-2 in response to eating; and like GLP-1, GLP-2 binds to a specific GPCR closely related to the glucagon and GLP-1 receptors. DPP-4 also inactivates GLP-2. GLP-2 signaling predominantly targets the intestine, where it stimulates mucosal growth and nutrient absorption and inhibits motility.

The K cells in the duodenum and jejunum produce a related 42 amino acid incretin peptide, GIP, that has both functional and sequential similarity to GLP-1, but is the product of a distinct gene and binds to a distinct receptor, GIPR, which also belongs to
the family of glucagon-related Ga\(_{s}\)-linked receptors. The K cells secrete GIP in response to glucose—via the same pathway used by the \(\beta\) cell (see Figure 17-5)—and lipids. Interestingly, the GIP prepropeptide is also expressed in \(\alpha\) cells, but prohormone convertase 2 in \(\alpha\) cells produces a shorter peptide, GIP\(_{1-30}\), which lacks the 12 carboxyl amino acids present in intestinal GIP\(_{1-42}\). The two forms of GIP appear to function identically. GIP signaling through its receptor has similar effects to those of GLP-1 on the stomach and \(\beta\) cells. \(\alpha\) Cells also express the GIP receptor, through which GIP directly stimulates glucagon secretion; but GIP concomitantly suppresses glucagon secretion indirectly through its stimulation of insulin secretion. The GIP receptor is also expressed in adipose tissue and bone. In adipose tissue, GIP plays an important role in the differentiation of new adipocytes, and also drives lipogenesis and adipokine production in mature adipocytes. In bone, GIP stimulates the osteoblasts and increases bone density.

### 3. SOMATOSTATIN

The pancreatic \(\delta\) cells transcribe the gene for somatostatin on the long arm of chromosome 3. It codes for a 116 amino acid peptide, preprosomatostatin, from whose carboxyl end is cleaved the hormone somatostatin, a 14 amino acid cyclic polypeptide with a molecular weight of 1640 (Figure 17-10). First identified in the hypothalamus, it owes its name to its ability to inhibit the release of growth hormone (GH; pituitary somatotropin). Since that time, somatostatin has been found in a number of tissues, including many areas of the brain and peripheral nervous system, the endocrine \(D\) cells in the epithelial lining of the stomach and intestine, and the \(\delta\) cells in the pancreatic islets. In neurons, gastric \(D\) cells and the islet, somatostatin-14 predominates, but approximately 5% to 10% of the somatostatin-like immunoreactivity in the brain consists of a 28 amino acid peptide, somatostatin-28. Somatostatin-28 consists of an amino terminal region of 14 amino acids and a carboxyl terminal segment containing somatostatin-14. In small intestine, the larger molecule predominates, with 70% to 75% of the hormone in the 28 amino acid form and only 25% to 30% as somatostatin-14. Somatostatin-28 is 10 times more potent than somatostatin-14 in inhibiting growth hormone and insulin secretion, whereas somatostatin-14 is more effective in inhibiting glucagon release.

Most known stimulators of insulin release also promote somatostatin release from \(\delta\) cells. This includes glucose, arginine, gastrointestinal hormones, and sulfonylureas. The importance of circulating somatostatin is unclear; the major action of this peptide appears to be paracrine regulation of the pancreatic islet and the gastrointestinal tract. Physiologic levels of somatostatin in humans seldom exceed 80 pg/mL (49 pmol/L). The metabolic clearance of exogenously infused somatostatin in humans is extremely rapid; the half-life of the hormone is less than 3 minutes.

Molecular cloning has identified five somatostatin receptors (SSTR1-5), all of which are GPCRs. They vary in size from 364 to 418 amino acids (with 105 amino acids invariant) and function in the central nervous system and a wide variety of peripheral tissues, including the pituitary gland, the small intestine, and the pancreas. All five receptors belong to the \(\text{G}_{s}\) class and inhibit the activity of adenylyl cyclase, thereby lowering intracellular levels.
of cAMP and inhibiting cAMP-activated secretion. In addition, however, each of the different somatostatin receptors interacts with additional distinct downstream effectors that modify the cellular consequences of receptor activation. Binding of ligand to SSTR5 on β cells mediates the inhibition of insulin secretion, whereas inhibition of GH release from pituitary somatotrophs as well as glucagon release from α cells of the pancreas works through SSTR2. This explains why an analog of somatostatin, octreotide, which has a much greater affinity for SSTR2 than for SSTR5, is effective in correcting GH excess without having much effect on carbohydrate tolerance when used to treat acromegaly.

Somatostatin acts in several ways to restrain the movement of nutrients from the intestinal tract into the circulation. It prolongs gastric emptying time, decreases gastric acid and gastrin production, diminishes pancreatic exocrine secretion, decreases splanchnic blood flow, and retards xylose absorption.

4. PANCREATIC POLYPEPTIDE

PP is found in PP cells located chiefly in islets in the posterior portion of the head of the pancreas. Similar to the other islet hormones, PP derives from a larger prepropeptide of 85 amino acids that is cleaved to a single 36 amino acid peptide with a molecular weight of 4,200. Circulating levels of the peptide increase in response to a mixed meal; however, intravenous infusion of glucose or lipid does not produce such a rise, and intravenous amino acids induce only a small increase. In contrast, vagotomy abolishes the response to an ingested meal, demonstrating that PP secretion responds predominantly to neural, rather than nutrient signals.

In healthy subjects, basal levels of PP average 24 ± 4 pmol/L and may become elevated owing to a variety of factors including old age, alcohol abuse, diarrhea, chronic renal failure, hypoglycemia, or inflammatory disorders. Values above 300 pmol/L are found in most patients with pancreatic endocrine tumors such as glucagonoma or vasoactive intestinal polypeptide-secreting tumor and in all patients with tumors of the pancreatic PP cell. As many as 20% of patients with insulinoma and one-third of those with gastrinomas also have plasma concentrations of PP that are greater than 300 pmol/L.

Although it has been implicated in the regulation of exocrine pancreatic secretion and gall bladder contraction, the physiologic actions of PP remain uncertain.

5. GHRELIN

The peptide hormone ghrelin was originally identified in extracts from the stomach based on its ability to bind to and activate the growth hormone secretagogue receptor (GHSR) and stimulate growth hormone release from the pituitary. The P/D1 endocrine cells in the gastric mucosa and the ε cells in the islet make ghrelin, as do a few cells in the heart, lung, kidney, immune system, hypothalamus, and pituitary. The human GHRELIN gene comprises four exons, and the major splice product encodes the 117 amino acid preproghrelin peptide. Processing in the ε cells yields the active form of ghrelin: a 28 amino acid peptide (amino acids 24-51 of preproghrelin) with the serine in position 3 modified by the attachment of an octanoyl side chain. Full biological activity requires the n-octanoyl modification. In addition, protease cleavage generates a second peptide, obestatin (amino acids 76-98 of preproghrelin) of less certain biological function.

Initially identified as a stimulator of growth hormone secretion, ghrelin signals through its receptor, the previously identified GHSR, which is a GPCR found in a variety of tissues, including the hypothalamus, pituitary, intestine, and islet. Ghrelin signaling stimulates growth hormone secretion directly through its receptor on pituitary somatotrophs, and also through its stimulation of hypothalamic GHRH secretion. In addition, Ghrelin induces gastric emptying and acid secretion and regulates appetite and energy balance via neurons in the arcuate nucleus of the hypothalamus (see Chapter 20). The role of ghrelin signaling in the pancreas, and the relative contribution of islet-derived ghrelin to the overall actions of ghrelin remains unresolved.
DIABETES MELLITUS

Clinical diabetes mellitus is a syndrome of disordered metabolism with inappropriate hyperglycemia due to an absolute or relative deficiency of insulin. There may also be a defect in insulin action (insulin resistance).

CLASSIFICATION

Diabetes is classified into four main groups based on known pathological and etiologic mechanisms—type 1, type 2, other specific types, and gestational diabetes (Table 17–5). Type 1 diabetes (previously referred to as juvenile-onset or insulin-dependent diabetes mellitus [IDDM]) results from pancreatic islet β cell destruction most commonly by an autoimmune process. These patients are prone to developing ketoacidosis and require insulin replacement. Type 2 diabetes (previously referred to as adult-onset or non-insulin-dependent diabetes mellitus [NIDDM]), the most prevalent form of diabetes, is a heterogeneous disorder most commonly associated with insulin resistance in the presence of an associated impairment in compensatory insulin secretion.

IV. Gestational diabetes mellitus (GDM)

*Patients with any form of diabetes may require insulin treatment at some stage of their disease. Such use of insulin does not, of itself, classify the patient.

bloodstream from their respective storage depots. Furthermore, alterations in fat metabolism lead to the production and accumulation of ketones. This inappropriate persistence of the fasted state postprandially can be reversed by the administration of insulin.

The incidence of type 1 diabetes varies widely in different populations. Scandinavia and northern Europe have the highest incidence of type 1 diabetes: the yearly incidence per 100,000 youngsters 14 years of age or less is as high as 40 in Finland, 31 in Sweden, 22 in Norway, 27 in Scotland, and 20 in England. The incidence of type 1 diabetes generally decreases across the rest of Europe to 11 in Greece and 9 in France. Surprisingly, the island of Sardinia has as high an incidence as Finland, even though in the rest of Italy, including the island of Sicily, the incidence is only 11 per 100,000 per year. The United States averages 16 per 100,000. The lowest incidence of type 1 diabetes worldwide is less than 1 per 100,000 per year in China and parts of South America.

Worldwide incidence of type 1 diabetes continues to increase steadily. In Finland, the incidence has more than tripled since 1953, when it was 12/100,000/year, with an average increase of 2.4% per year. The EURODIAB study group reported recently 0.6% to 9.3% annual increases in incidence of type 1 diabetes in children younger than 15 years in various European countries. The most rapid increases have occurred in low-prevalence countries and in younger patients. Changes in environmental factors most likely explain this increased incidence.

**Latent autoimmune diabetes of adulthood (LADA):** Type 1 diabetes can present at any age, although peaks in incidence occur before school age and again at around puberty. Older adults often present with a more indolent onset that sometimes leads to misdiagnosis and has led to the use of the term latent autoimmune diabetes of adulthood (LADA) to distinguish these patients. These initially unrecognized patients may retain enough β cell function at the outset to avoid ketosis, but develop increasing dependence on insulin therapy over time as their β cell mass diminishes. Islet cell antibody surveys among northern Europeans indicate that up to 15% of patients previously diagnosed with type 2 diabetes may actually have LADA.

### Autoimmunity and Type 1 Diabetes

Most patients with type 1 diabetes at diagnosis have circulating antibodies against β cell proteins: islet cell antibodies (ICA), insulin autoantibodies (IAA), and antibodies to glutamic acid decarboxylase 65 (GAD), tyrosine phosphatase IA2 (ICAI2), and zinc transporter 8 (ZnT8) (Table 17–6). These autoantibodies can often be detected well before the onset of frank hyperglycemia, even decades earlier, providing evidence that the autoimmune process may be prolonged. After diagnosis, autoantibody levels often decline with increasing duration of the disease. Also, once patients are treated with insulin, low levels of IAA develop, even in patients that do not have an autoimmune etiology for their diabetes.

Although useful for diagnosing and predicting type 1 diabetes, antibodies against β cell proteins do not directly cause the destruction of β cells in type 1 diabetes. Instead, it is the cellular immune system, the T lymphocytes, that infiltrate the islets (a process called insulitis) and destroy the β cells. At the time of diagnosis, the islets of patients with type 1 diabetes are extensively infiltrated with both helper and cytotoxic T lymphocytes.

Normally, the thymus deletes autoreactive T cells during development so that the immune system becomes tolerant of self-antigens. In addition, certain specialized T cells, the regulatory T cells, further prevent attacks against healthy tissues by retraining the activity of any autoreactive cytotoxic and helper T cells that escape the thymus. Type 1 diabetes results from a breakdown in these processes of self-tolerance in the immune system.

**Type 1b diabetes:** Approximately 5% of patients with the clinical features of type 1 diabetes lack serum evidence of autoimmunity. Some of these individuals have high risk HLA haplotypes (see later) and may have T-cell–mediated β cell destruction in the absence of measurable levels of the known autoantibodies. Others in this group have low-risk HLA haplotypes, and appear to have a nonautoimmune cause for loss of β cell function. Such nonautoimmune type 1 diabetes has been referred to as type 1b diabetes, but a variety of terms has been used. This probably represents a heterogeneous group of disorders that lead to profound β cell dysfunction or loss, absolute insulin deficiency and a syndrome clinically similar to autoimmune type 1a diabetes. Under the accepted classification system, as specific disorders within this subgroup become defined and the genetic or environmental causes are identified, these disorders become reclassified within the group of “Other Specific Types of Diabetes.”

Included within this group are patients that present with a course of relapsing diabetic ketoacidosis with intervening normoglycemia that eventually progresses to permanent insulin-deficient diabetes. This disorder, ketosis prone diabetes (KPD, see later), has also been referred to as type 1b diabetes, and may result from unknown environmental insults combined with genetic defects in the β cell.

**Autoimmune diabetes and stiff person syndrome:** GAD antibodies, the first identified in type 1 diabetes, remain among the most clinically useful. Human pancreatic β cells produce GAD65, which functions as an enzyme that catalyzes the synthesis of GABA from glutamate. GAD65 and the closely related isoform GAD67 are also found in central nervous system inhibitory neurons that secrete GABA. Some patients with GAD antibodies

develop a rare neurologic condition, **stiff person syndrome**, caused by the depletion of GABA in the central nervous system and characterized by progressive rigidity and fluctuating muscle spasms. Approximately half of the patients with stiff person syndrome develop type 1 diabetes.

The vast majority of patients with type 1 diabetes do not develop symptoms of stiff person syndrome, despite the presence of GAD antibodies. The rare patients that develop the syndrome usually have much higher titers of GAD antibodies than typical patients with type 1 diabetes alone.

### Genetics of Type 1 Diabetes

Family members of patients with type 1 diabetes have an increased lifetime risk of developing type 1 diabetes. The offspring of a mother with type 1 diabetes have a risk of 3%, whereas the risk is 6% for children of affected fathers. The risk in siblings of affected individuals is related to the number of human leukocyte antigen (HLA) haplotypes (see later) that the sibling shares. If one haplotype is shared, the risk is 6% and if two haplotypes are shared, the risk increases to 12% to 25%. Formonozygotic twins, the concordance rate reaches 25% to 50%. Although these data demonstrate a strong genetic contribution to the risk of type 1 diabetes, genetics plays an even larger role in type 2 diabetes, and environment also clearly contributes substantially to the risk of type 1 diabetes.

Genes in the major histocompatibility (MHC) locus on the short arm of chromosome 6 explain at least half of the familial aggregation of type 1 diabetes. Within the MHC locus lie a number of closely packed genes involved in the function and regulation of the immune response. Although a number of genes within the MHC locus have been linked to the risk of developing type 1 diabetes, the most important of these are the genes encoding the HLA class II molecules DQ and DR. The professional antigen-presenting cells—dendritic cells, macrophages and B lymphocytes—use the class II molecules on their cell surface to present peptide antigens to T lymphocytes through the T-cell receptor. T cells activated by antigen-presenting cells carry out the β cell destruction that leads to type 1 diabetes. Although exact mechanisms remain uncertain, the variations in the amino acid sequence of individual HLA class II molecules may impact their ability to present specific self-peptides to T cells either in the process of central or peripheral tolerance or later during the development of the autoimmune response, thereby contributing to the risk of developing type 1 diabetes.

The DR haplotypes DR3 and DR4 are major susceptibility risk factors for type 1 diabetes. As many as 95% of type 1 diabetic patients have a DR3 or a DR4 haplotype—or both—compared with 45% to 50% of Caucasian nondiabetic controls. Individuals who express both a DR3 and a DR4 allele carry the highest risk for type 1 diabetes in the United States.

The high-risk DR genes are generally in linkage disequilibrium with DQ genes that themselves confer high risk, particularly DQA1*0501, DQB1*0201 (coupled with DR3), and DQA1*0301, DQB1*0302 (coupled with DR4). DQ alleles are associated not only with risk for type 1 diabetes but also with dominant protection, often in linkage with HLA-DR2. The most protective of these—and a quite common allele—is DQA1*0102, DQB1*0602. It occurs in over 20% of individuals in the United States but in less than 1% of children who develop type 1 diabetes.

An independent genetic link to chromosome 11 has also been identified in type 1 diabetes. Studies of a polymorphic DNA locus flanking the 5' region of the *insulin* gene on chromosome 11 revealed a small but statistically significant linkage between type 1 diabetes and this genetic locus in a Caucasian population with type 1 diabetes. This polymorphic locus, which consists of a variable number of tandem repeats (VNTRs) with two common sizes in Caucasians, small (26-63 repeats) or large (140-243 repeats), does not encode a protein. An intriguing proposal to explain how the VNTR might influence susceptibility to type 1 diabetes was based on findings that *insulin* gene transcription is facilitated in the fetal thymus gland by the presence of the large allele of the VNTR locus flanking the *insulin* gene. The large VNTR allele might produce a dominant protective effect by promoting negative selection (deletion) by the thymus of insulin-specific T lymphocytes that play a critical role in the immune destruction of pancreatic β cells.

The established genetic association with the MHC region of chromosome 6 contributes much more (about 50%) to the genetic susceptibility to type 1 diabetes than does this locus flanking the *insulin* gene on chromosome 11, which contributes about 10%. Both candidate gene studies and genome-wide association studies (GWAS) have identified a number of additional risk loci that make smaller contributions to the genetic risk of type 1 diabetes. Many of the genes linked to these additional loci also play important roles in the function and regulation of the immune response.

Mutations in two genes involved in T-cell tolerance cause rare syndromes of type 1 diabetes together with other autoimmune diseases. In the autosomal recessive disease autoimmune polyglandular syndrome type 1 (APS1; see Chapter 2), homozygous mutations in the gene encoding the autoimmune regulator (AIRE) prevent the expression of certain self-proteins in the thymus, thus allowing mature autoreactive T cells to leave the thymus. In addition to other autoimmune diseases and mucocutaneous candidiasis, approximately 20% of patients with APS1 develop type 1 diabetes. The second gene, FOXP3, found on the X chromosome, encodes a transcription factor required for the formation of regulatory T cells. Mutations in FOXP3 cause immunodysregulation polyendocrinopathy enteropathy X-linked (IPEX) syndrome. IPEX presents in male patients with very early onset type 1 diabetes, of ten neonatal, combined with other autoimmune endocrinopathies, autoimmune skin disorders, diarrhea secondary to autoimmune enteropathy, and frequent severe infections.

### Environmental Factors in Type 1 Diabetes

While genetic inheritance may play an important role in causing type 1 diabetes, the monozygotic twin studies demonstrate that other causes, stochastic or environmental, are at least as important. Most individuals with type 1 diabetes do not have other family members with the disease. Environmental factors associated with increased risk of type 1 diabetes include viruses (mumps,
congenital rubella, Coxsackie virus B4), toxic chemical agents such as vacor (a nitrophenylurea rat poison), and other destructive cytotoxins such as hydrogen cyanide from spoiled tapioca or cassava root. How these environmental insults lead to type 1 diabetes is unknown; they may directly damage β cells in some cases, or may act as initiators or accelerators of the autoimmune attack on the β cells. In some cases, molecular mimicry, wherein the immune system mistakenly targets β cell proteins that share homologies with certain viral or other foreign peptides may play a role.

Epidemiological studies have demonstrated an association between breast-feeding in the first 6 months of life and protection from type 1 diabetes. While it has been suggested that proteins in cow’s milk may be the culprits, the strongest evidence supports the idea that human breast milk may reduce the risk of autoimmune disease.

Accumulating evidence shows that in the process of modernizing and improving public health, the risk of type 1 diabetes has increased, possibly due to the removal of some protective factors. Type 1 diabetes is almost unheard of in many third-world countries, and has its highest incidence in countries with the best public health systems, such as the Scandinavian countries. In addition, the incidence of the disease has been steadily increasing over the past century in western and westernizing countries and is especially high among the more affluent. This has led to the suggestion that a dirty environment, one with more infections (especially more parasitic diseases) and more antigen exposure, may reduce the risk of type 1 disease.

## TYPE 2 DIABETES

Type 2 diabetes mellitus—previously called non-insulin-dependent diabetes or adult-onset diabetes mellitus—results from relative insulin deficiency, in contrast to the absolute insulin deficiency of patients with type 1 diabetes. Type 2 diabetes is a heterogeneous disorder and probably represents a large number of different primary genetic and environmental insults leading to relative insulin deficiency—a mismatch between insulin production and insulin requirements. Clinically, patients with type 2 diabetes can range from those with severe insulin resistance and minimal insulin secretory defects to those with a primary defect in insulin secretion.

Type 2 diabetes accounts for 80% to 90% of cases of diabetes in the United States. These patients commonly present as adults with some degree of obesity, although increasing rates of obesity are leading to earlier onset of the disease in adolescents and children. At onset, most patients with type 2 diabetes do not require insulin to survive, but over time their insulin secretory capacity tends to deteriorate, and many eventually need insulin treatment to achieve optimal glucose control. Ketonis seldom occurs spontaneously, and if present, it is a consequence of severe stress from trauma or infection.

Most patients with type 2 diabetes, irrespective of weight, have some degree of tissue insensitivity to insulin attributable to several interrelated factors (Table 17-7). These include putative (mostly as yet undefined) genetic factors, which are aggravated in time by further enhancers of insulin resistance such as aging, a sedentary lifestyle, and abdominal visceral obesity. Not all patients with obesity and insulin resistance develop hyperglycemia, however. An underlying defect in the ability of the β cells to compensate for the increased demand determines which patients will develop diabetes in the setting of insulin resistance. Furthermore, both the tissue resistance to insulin and the impaired β cell response to glucose appear to be further aggravated by sustained hyperglycemia, which may impede both insulin signaling and β cell function. Treatment that reduces the blood glucose levels toward normal reduces this acquired defect in insulin resistance and may also improve glucose-induced insulin release to some degree, although the long-term decline in β cell function continues.

Type 2 diabetes frequently goes undiagnosed for many years because the hyperglycemia may develop quite gradually and without initial symptoms. Despite this mild presentation, these patients develop microvascular, and, especially, macrovascular

complications. Furthermore, as noted above, patients with type 2 diabetes suffer from a progressive decline in β cell capacity, leading to worsening hyperglycemia over time.

A. Obesity in type 2 diabetes

The majority of people with type 2 diabetes have excess adiposity, although the prevalence of obesity in association with type 2 diabetes varies among different racial groups. Sixty to eighty percent of North Americans, Europeans, or Africans with type 2 diabetes and close to 100% of individuals with type 2 disease among Pima Indians or Pacific Islanders from Nauru or Samoa have obesity as defined by body mass index (BMI, see Chapter 20), while as few as 30% of Chinese and Japanese patients with type 2 diabetes are obese. However, many of those individuals with type 2 diabetes who do not meet BMI criteria for obesity have a predominantly abdominal distribution of fat, producing an abnormally high waist to hip ratio. Increases in visceral adiposity correlate with increased insulin resistance.

B. Insulin resistance in type 2 diabetes

Insulin resistance can be broadly defined as a decrease in tissue responsiveness to insulin. Clinically it can be assessed directly by measuring the ability of a fixed dose of insulin to promote total body glucose disposal. It can be assessed indirectly by measuring fasting insulin levels. An increase in insulin levels with normal plasma glucose indicates insulin resistance.

As adiposity increases, especially abdominal visceral fat deposits, total body insulin sensitivity decreases. Since adipose tissue only removes a small fraction of plasma glucose, clearly the increased adipose fat stores impact total body insulin sensitivity through effects on other tissues, especially muscle and liver, causing them to decrease insulin-stimulated glucose disposal. The exact means by which fat storage in adipocytes affects the insulin sensitivity of other cells remains uncertain, but experimental evidence suggests several possible mechanisms.

Abnormalities of insulin receptors—in concentration, affinity, or both—affect insulin action. Target tissues downregulate the number of insulin receptors on the cell surface in response to chronically elevated circulating insulin levels, probably by increased intracellular degradation. When insulin levels are low, on the other hand, receptor binding is upregulated. Conditions associated with high insulin levels and lowered insulin binding to the receptor include obesity, high intake of carbohydrates, and chronic exogenous overinsulization. Conditions associated with low insulin levels and increased insulin binding include exercise and fasting. The insulin receptor itself is probably not the major determinant of insulin sensitivity under most circumstances, however. Clinically relevant insulin resistance most commonly results from defects in postreceptor intracellular signaling pathways.

Adipokines.

Adipose tissue can affect the insulin sensitivity of other tissues through the secretion of signaling molecules, adipokines, that inhibit (TNF-α, IL-6, leptin, resistin, and others) or enhance (adiponectin) insulin signaling locally or in distal target tissues (see Chapter 20). Levels of fat storage in adipocytes, along with insulin signaling itself, regulate the production and secretion of many of the adipokines. Some of these mediators of insulin resistance may reduce insulin signaling by blocking access of insulin to target tissues through reduced transendothelial transit. However, most evidence suggests that the secreted adipokines influence insulin signaling in distant tissues through effects on postreceptor intracellular signaling pathways. Potential intracellular effectors include protein tyrosine phosphatases that dephosphorylate the receptor and pathway components, inhibitors such as the SOCS proteins that block receptor–IRS interactions, and serine/threonine kinases that inhibit the receptor and substrates through serine phosphorylation.

Free fatty acids and ectopic lipid storage.

The release of fatty acids by the engorged adipocytes (especially visceral adipocytes, from which fatty acids are more readily mobilized) may play a role in the development of insulin resistance as well. Oxidation of fatty acids by muscle and other tissues could inhibit glycolysis and reduce insulin-stimulated glucose removal (the Randle hypothesis, named after its original proponent). Increased fat storage in adipocytes and release of fatty acids may also eventually cause a shift in lipid storage, increasing lipid uptake and storage in nonadipose tissues such as muscle, liver, and β cells. Ectopic lipid storage in these tissues may lead to a decrease in their insulin sensitivity. In addition, free fatty acids may function directly in a signaling role both locally within the adipose tissue and systemically.

Inflammation.

In addition to adipocytes, adipose tissue contains a variety of other cell types including inflammatory/immune cells, such as macrophages and lymphocytes. Recent evidence implicates these cells in obesity-induced insulin resistance. As adipocyte lipid stores rise, the increased release of free fatty acids and proinflammatory adipokines recruits macrophages to the adipose tissue and activates them. The activated macrophages then release a variety of molecules (TNF-α, IL-6, nitric oxide, and others) that decrease the insulin sensitivity of the adipocytes and further increase their release of proinflammatory fatty acids and peptides, creating a positive feedback loop that maintains a chronic state of local inflammation and insulin resistance. Release of these adipokines and proinflammatory cytokines, along with the increased release of free fatty acids and the development of ectopic lipid accumulation, promotes the development of inflammation and insulin resistance in the other key insulin-target tissues, such as muscle and liver. Similar mechanisms could also lead to inflammation in the islets and contribute to β cell failure.

PPARγ activity in the adipose tissue generally has beneficial effects on systemic insulin signaling through several mechanisms: (1) Promotion of adipose lipid storage, which thereby decreases ectopic lipid storage in nonadipose tissues; (2) Inhibition of the production of adipokines and proinflammatory cytokines, which promote insulin resistance, by adipocytes; (3) Promotion of the alternative activation of macrophages to the anti-inflammatory M2 state, rather than the proinflammatory M1 state; (4) Inhibition of the release of proinflammatory and proresistance cytokines by macrophages. Although it is expressed at much lower levels in muscle than in adipose tissue, PPARγ in myocytes might also have
a direct role in controlling muscle insulin sensitivity; however, these findings remain controversial.

**Tissue heterogeneity in insulin resistance.** Finally, it must be kept in mind that not all tissues necessarily develop insulin resistance in parallel. The combination of local and systemic contributors to obesity-induced insulin resistance may explain the different levels of insulin resistance in different tissues of the same patient. Even in the same cell, insulin resistance may impact different arms of the insulin-signaling pathway discordantly. This heterogeneity leads to changes in tissue energy storage and insulin sensitivity that could explain unique syndromes associated with insulin resistance like hepatic steatosis and polycystic ovary syndrome.

**Other causes of insulin resistance.** Visceral obesity is not the only cause of insulin resistance, although it is far the most common cause in most populations. Other causes of insulin resistance include a variety of genetic and acquired defects that impact the insulin receptors or postreceptor signaling pathways (see Table 17–7).

**Clinical consequences of insulin resistance.** In addition to the impact on glucose metabolism, severe insulin resistance and the resulting elevation in circulating insulin levels can cause other clinical consequences including acanthosis nigricans, pseudoacromegaly, and hyperandrogenism. Acanthosis nigricans appears to be a consequence of very high circulating insulin levels that cross over to bind to IGF receptors on epidermal and melanin-containing cutaneous cells. This leads to local skin hyperplasia with papillomatosis, hyperkeratosis, and hyperpigmentation. The dark, velvety patches of skin most commonly appear on the back of the neck, axillae, and antecubital fossae. In extreme and prolonged cases of insulin resistance, the secondary increase in signaling through the IGF-1 receptor, or possibly residual signaling through the mitogenic arm of the insulin signaling pathway, can cause pseudoacromegaly, a syndrome with all of the bone and soft tissue changes of acromegaly (see Chapter 4), but no elevation in growth hormone or IGF-1. A similar action of extremely high insulin levels on ovarian hilar cells has been implicated in women with insulin resistance who develop hyperandrogenism and hirsutism associated with menstrual irregularities, enlarged cystic ovaries and infertility (polycystic ovary syndrome).

**C. β Cell defects in type 2 diabetes** Although the majority of people with type 2 diabetes have insulin resistance, most people with insulin resistance do not have diabetes because their β cells compensate for the insulin resistance by producing and secreting more insulin. Those individuals with insulin resistance who develop type 2 diabetes have a defect in the compensatory response of their β cells to insulin resistance. Functionally, this defect is revealed by a reduction in first phase insulin secretion and the maximal insulin secretion stimulated by glucose.

While increased insulin secretion per β cell may contribute to the compensatory response to insulin resistance, increases in the number of β cells play a role as well. In the setting of obesity, hyperplasia of pancreatic β cells is often present and probably accounts for the normal or exaggerated insulin responses to glucose and other stimuli seen in obese individuals without type 2 diabetes. Assessment of total β cell mass at autopsy has revealed that β cell mass increases in obesity, but the individuals with type 2 diabetes have decreased β cell mass when compared to non diabetic individuals with the same BMI.

Several possible defects could contribute to the failure of β cell mass compensation in people with type 2 diabetes. Underlying genetic differences in the pathways that drive β cell expansion appear to limit compensation in individuals with high genetic risk of diabetes. In susceptible individuals with obesity, ectopic fat deposition in the islets, local obesity-induced inflammation in the islets, and local and circulating adipokines and inflammatory cytokines may accelerate β cell loss. As β cell failure progresses, levels of glucose and free fatty acids start to rise, which in turn can cause further β cell toxicity. Increased demand on a decreased β cell mass may cause further damage through ER stress and the increased formation of toxic IAPP oligomers. Then, once diabetes is established, all of these mechanisms may further contribute to the progressive decline in β cell function that characterizes type 2 diabetes.

**D. Metabolic syndrome** Patients with visceral obesity and insulin resistance often present with a cluster of abnormalities commonly termed the metabolic syndrome. Hyperglycemia in these patients is frequently associated with hyperinsulinemia, dyslipidemia, and hypertension, which together lead to coronary artery disease and stroke. It has been suggested that this aggregation results from a genetic defect producing insulin resistance, particularly when obesity aggravates the degree of insulin resistance. In this model, impaired action of insulin predisposes to hyperglycemia, which in turn induces hyperinsulinemia. If this hyperinsulinemia is of insufficient magnitude to correct the hyperglycemia, type 2 diabetes is manifest. The excessive insulin level could also increase sodium retention by renal tubules, thereby contributing to or causing hypertension. Increased VLDL production in the liver, leading to hypertriglyceridemia (and consequently a decreased high-density lipoprotein [HDL] cholesterol level), has also been attributed to hyperinsulinism. Moreover, it has been proposed that high insulin levels can stimulate endothelial and vascular smooth muscle cell proliferation—by virtue of the hormone’s action on growth factor receptors—to promote atherosclerosis.

Although there is full agreement on an association of these disorders, the mechanism of their interrelationship remains speculative and open to experimental investigation. Controversy persists about whether or not hypertension is caused by the hyperinsulinism that results from insulin resistance. Moreover, patients with hyperinsulinism due to an insulinoma are generally normotensive, and there is no reduction of blood pressure after surgical removal of the insulinoma restores normal insulin levels.

An alternative unifying hypothesis could be that visceral obesity directly induces the other components of this syndrome. Visceral obesity is an independent risk factor for all of the other components of the metabolic syndrome. In addition to the metabolic effects of visceral obesity, the adipokines and inflammatory cytokines generated from overloaded and inflamed
adipose tissue may contribute to the pathophysiology of the syndrome. Although the full details of the role of these molecules in causation of the metabolic syndrome remain under investigation, the adipocytes and associated macrophages clearly are not just innocent bystanders but play active roles in the development of systemic insulin resistance, hypertension, and hyperlipidemia. Furthermore, thrombi in atheromatous vessels may be more hazardous in patients with visceral obesity because of an associated increase in plasminogen activator inhibitor-1 (PAI-1), a circulating factor produced by omental and visceral adipocytes that inhibits clot lysis. This model emphasizes the importance of measures such as diet and exercise that reduce visceral adiposity in the management of patients with metabolic syndrome and obese type 2 diabetes.

The main value of grouping these disorders as a syndrome, regardless of its nomenclature, is to remind physicians that the therapeutic goals in these patients must not only correct hyperglycemia but also manage the elevated blood pressure and hyperlipidemia that result in considerable cardiovascular morbidity as well as cardiovascular deaths. In addition, it reminds physicians that when choosing antihypertensive agents or lipid-lowering drugs to manage one of the components of this syndrome, their possible untoward effects on other components of the syndrome should be carefully considered. For example, physicians aware of this syndrome are less likely to prescribe antihypertensive drugs that raise lipids (diuretics, beta blockers) or that raise blood glucose (diuretics). Likewise, they may refrain from prescribing drugs that correct hyperlipidemia, but increase insulin resistance with aggravation of hyperglycemia (nicotinic acid).

E. Genetics of type 2 diabetes Type 2 diabetes has a strong genetic link. Depending on the population studied, monozygotic twins have lifetime concordance rates for type 2 diabetes exceeding 90%. In contrast, concordance rates for type 1 diabetes in monozygotic twins are 25% to 50%. Most individuals with type 2 diabetes have other family members with the disease, but the inheritance rarely fits Mendelian patterns, supporting the conclusion that multiple genes with varying degrees of penetrance contribute. Because of the heterogeneous nature of type 2 diabetes, and its complex inheritance, efforts to identify the genes that contribute to the disease have had very limited success in the vast majority of affected patients. There has been considerable success, however, in identifying small subsets of patients with unique monogenic forms of the disease. When the etiologic defect has been defined, these patients have been reclassified within a group designated “Other Specific Types of Diabetes” (see Table 17–5).

Efforts to identify the genes involved in polygenic type 2 diabetes have focused on two approaches: candidate gene testing and genome-wide association studies (GWAS). To date candidate gene and GWAS approaches have identified 19 loci with common variants linked to type 2 diabetes. Although statistically significant and validated in additional populations, these loci independently make very small contributions to type 2 diabetes risk. The highest risk of these common variants is found at a locus adjacent to the gene encoding TCF7L2, a transcription factor involved in Wnt signaling and implicated in β cell turnover. Inheritance of the high-risk TCF7L2 allele increases the probability of developing diabetes by 1.5-fold.

Among the genes identified so far, most are involved in β cell function and turnover. When combined with the predominance of β cell genes implicated in monogenic forms of diabetes (see Other Specific Types of Diabetes), these results reinforce the critical role of the β cell in controlling blood glucose and its involvement in the pathophysiology of type 2 diabetes. Hopefully, with the advent of high-throughput whole genome sequencing technologies, the identification of rarer, but higher risk, variants will further expand our understanding of the genetics of type 2 diabetes in the near future.

F. Environmental factors in type 2 diabetes Despite the critical role of genetics in type 2 diabetes, environment contributes as well, especially in determining the age of onset and severity of the disease. There is generally a low incidence of type 2 diabetes in underdeveloped countries, especially in rural areas. Western countries and westernizing countries suffer from a much higher incidence. Over the past half-century, the incidence of type 2 diabetes has increased rapidly in almost all world populations but especially in emerging third-world countries. This increase correlates with increasing rates of obesity in the same populations and reflects increased access to food with high caloric content and decreased physical activity. This combination inevitably leads to increased adiposity, especially in the more readily mobilized fat stores surrounding the viscera in the abdomen.

One of the most dramatic recent changes in the epidemiology of diabetes has been the growing incidence of type 2 diabetes in children. While rarely seen in children a generation ago, type 2 diabetes is now as common as type 1 diabetes in teenagers in the United States and is seen with increasing frequency, even in younger children. Again, this increase is directly related to increasing visceral adiposity.

OTHER SPECIFIC TYPES OF DIABETES

Autosomal Dominant Genetic Defects of Pancreatic β Cells

MODY: This subgroup of monogenic disorders is characterized by the onset of diabetes in late childhood or before the age of 25 years as a result of a partial defect in glucose-induced insulin release and accounts for up to 5% of diabetes in North American and European populations. A strong family history of early-onset diabetes occurring in one parent and in one-half of the parent’s offspring suggests autosomal dominant transmission. In contrast to most patients with type 2 diabetes, these patients are generally nonobese and lack associated insulin resistance. Instead they exhibit predominantly a defect in glucose-stimulated insulin secretion. However, because they are not ketosis-prone and may initially achieve good glycemic control without insulin therapy, their disease has been called maturity-onset diabetes of the young (MODY). Several distinct types have been described with single-gene defects, and all have been shown to produce a defect in
glucose-induced insulin release. MODY 2 results from an abnormal glucokinase enzyme. Most of the other forms of MODY are due to mutations of nuclear transcription factors that regulate the expression of genes in β cells or β cell precursors (Table 17–8).

MODY 1 includes multiple members of a large pedigree known as the R-W family, descendants of a German couple who immigrated to Michigan in 1861. They were studied prospectively since 1958, and in 1996 the genetic defect was shown to be a nonsense mutation of a nuclear transcription factor found in liver as well as in pancreatic β cells. This gene has been termed hepatocyte nuclear factor-4α (HNF4α), whose gene is located on chromosome 12. This is the most common form of MODY in European populations, with many different mutations having been reported. Like HNF4α, the HNF4α transcription factor is expressed in pancreatic β cells as well as in liver. Also similar to HNF4α, mutations in HNF4α cause a progressive form of diabetes with declining β cell function that often leads to dependence on insulin therapy and high rates of microvascular complications. Noteworthy, early in the course of the disease, these patients may display an exaggerated response to sulfonylureas. Together, HNF4α and HNF4α, along with several other β cell transcription factors including PDX1 (discussed later), form an interacting network of transcription factors. This transcriptional network regulates genes involved in multiple β cell functions, including glucose-sensing and insulin secretion. Target genes include GCK, as well as genes implicated in the formation, maturation and expansion of β cells. Impairment in β cell formation and regeneration may explain the progressive nature of the MODY transcription factor syndromes and reinforces the importance of β cell mass in preventing hyperglycemia.

MODY 4 results from mutation of a pancreatic nuclear transcription factor known as pancreatic and duodenal homeobox-1 (PDX1), whose gene is on chromosome 11. It mediates insulin gene transcription and regulates expression of other β cell-specific genes including GCK. When both alleles of this gene are nonfunctioning, agenesis of the entire pancreas results; but in the presence of a heterozygous mutation of PDX1, a mild form of MODY has been described in which affected individuals developed diabetes at a later age (mean onset at 35 years) than occurs with the other forms of MODY, in whom onset generally occurs before the age of 25 years.

MODY 5 was initially reported in a Japanese family with a mutation of HNF1β, a hepatic nuclear transcription factor closely related in structure and molecular function to HNF1α. The two HNF1 factors, however, are expressed by different cells. HNF1β is expressed early in the development of the liver, pancreas, kidneys, and genitourinary system, and is not found in mature β cells.
Mutations in this gene cause a moderately severe form of MODY with progression to insulin treatment and severe diabetic complications in those affected. Consistent with its expression pattern early in development, HNF1β mutations also frequently cause reduction in the overall size of the pancreas, decreased insulin production, and congenital defects in the kidney and urogenital tract. Patients may also suffer from varying degrees of cholestatic jaundice, hyperuricemia, nephropathy, and hypomagnesemia secondary to renal magnesium wasting.

MODY 6, a milder form of MODY similar to MODY 4, results from mutations in the gene encoding the islet transcription factor NeuroD1. Like PDX1, NeuroD1 plays an important role in the expression of insulin and other β cell genes, and in the formation and maintenance of β cells.

Other MODY genes: The six MODY genes listed above explain the majority of cases of MODY in patients of European ancestry, but less than half of those in non-European populations. Several rare variants in other genes have been implicated in autosomal dominant diabetes in a few families (see Table 17-8); however, a consensus has not yet been reached that these families fit the criteria for MODY and that the reported variants cause the disorder. The causative genes in most non-Europeans with MODY remain unknown.

The identification of mutations in multiple genes encoding pancreatic transcription factors in patients with MODY has led to the screening of other genes encoding pancreatic transcription factors in patients with diabetes. Heterozygous mutations in genes encoding several transcription factors, including Isl1, Pax6, and Pdx6, have been identified in patients with later onset diabetes. The association of diabetes with heterozygous mutations in so many β cell genes highlights the critical importance of optimal β cell function in metabolic regulation. Even modest defects in glucose-induced insulin secretion can result in hyperglycemia.

Insulin mutations: Sequencing of the insulin gene more than 30 years ago led to the first descriptions of heterozygous mutations in the coding sequence of the insulin gene that produce abnormal circulating forms of insulin. Most of these initial cases presented with high circulating levels of insulin, but normal insulin sensitivity and normal glucose levels. Because the abnormal insulins in these cases bind to receptors poorly, they have very low biologic activity and are cleared at a slower rate, leading to accumulation in the blood at higher levels than normal insulin and a subnormal molar ratio of C peptide to immunoreactive insulin. They typically are not associated with hyperglycemia.

However, a mutation in the insulin B chain in one family was associated with decreased circulating levels of both the mutant and normal insulins, and diabetes. Subsequent extensive sequencing of the INS gene has identified several other mutant insulins that produce a similar heterozygous form of diabetes. Modeling of these dominant insulin mutations in mice demonstrates that they lead to the accumulation of abnormally folded proteins in the endoplasmic reticulum, activation of the unfolded protein response in the ER, and β cell apoptosis. Patients with diabetes secondary to INS gene mutations usually present at a younger age than most patients with MODY, often developing the disease as neonates (see later). Because of the profound β cell loss, these patients follow a disease course similar to type 1 diabetes with absolute insulin deficiency and ketosis, and they require insulin therapy.

This syndrome highlights the sensitivity of the β cells to ER stress, which may explain why β cells often fail when presented with the increased insulin demands associated with insulin resistance, the toxicity of IAPP oligomers, or mutations in genes involved in the unfolded protein response pathway (see later).

Mutations in the subunits of the ATP-sensitive potassium channel: β cells sense rising blood glucose concentrations by increasing the production of ATP from glucose. The rising intracellular ATP levels cause the closure of ATP-sensitive potassium channels on the cell surface, which depolarizes the cell and sets off a cascade of events that leads to the secretion of insulin (Figure 17-5). Rare dominant activating mutations in either of the two units of the channel, SUR1 and Kir6.2 (gene names ABCC8 and KCNJ11, respectively), can cause the channels to remain open and prevent glucose-induced depolarization and insulin secretion. Children heterozygous for these mutations present with early-onset diabetes, commonly as neonates, and may have associated neurologic deficits implying a role for these channels in the central nervous system. Depending on the exact mutation, some of these children can still respond to treatment with sulfonylureas, which may also ameliorate the neurologic symptoms.

Other Genetic Defects of Pancreatic β Cells

Autosomal recessive genetic defects: Although less common than the autosomal dominant β cell disorders, mutations in several genes causing autosomal recessive syndromes with defects in β cell function have been identified in patients with diabetes (Table 17-9). Due to the severity of the β cell defect, many of these present with neonatal diabetes. This group of disorders includes homozygous mutations in the MODY genes GCK and PDX1. Homozygous mutations in GCK cause a much more severe syndrome than the mild glucose-sensing defect seen in MODY 2. Patients with homozygous GCK mutations present at birth with severe hyperglycemia and require insulin therapy.

In patients with mutations in both alleles of PDX1, the pancreas fails to form, and they have pancreatic exocrine deficiency as well as diabetes. Homozygous mutations in several other pancreatic transcription factor genes have been described as well, including PTF1A, NEUROG3, RFX6, and GLIS3. Like PDX1, homozygous mutation of PTF1A causes diabetes and pancreatic agenesis, but it also causes cerebellar atrophy as well. The transcription factor Neurog3 drives the formation of the endocrine cells in both the pancreas and gut. In addition to diabetes onset prior to puberty, infants born with homozygous NEUROG3 mutations have severe malabsorption associated with a lack of gut endocrine cells from birth.

Homozygous mutations in RFX6, which encodes a transcription factor that functions downstream of NEUROG3 and upstream of PDX1 in β cell development, cause Mitchell–Riley syndrome in which neonates present with diabetes in association with complete absence of all islet cell types except PP cells, hypoplasia of the pancreas and gall bladder, intestinal atresia, and severe malabsorption.

The zinc finger transcription factor GLI3 is expressed broadly in many tissues and plays a role in the transcription of the insulin gene. Homozygous mutations in GLI3 cause congenital hypothyroidism in addition to neonatal diabetes.

In the autosomal recessive Wolcott-Rallison syndrome, affected children present with neonatal diabetes, epiphyseal dysplasia, and growth retardation together with a variety of progressi ve hepatic, renal, cardiac, and pancreatic exocrine defects and developmental delay. The causative gene, EIF2AK3, encodes a kinase (PKR-like ER kinase [PERK]) activated by the presence of unfolded proteins in the ER. PERK controls one of the three parallel arms of the unfolded protein response; inositol-requiring enzyme 1 (IRE1) and activating transcription factor 6 (ATF6) activate the other two arms. Together these three molecules activate signaling pathways that protect the cell from ER stress but lead to apoptosis when these protective mechanisms fail. Mice lacking PERK have an inadequate response to ER stress, which leads to accelerated β cell apoptosis. With the high load of insulin production in the ER, β cells are uniquely sensitive to ER stress, and this sensitivity probably underlies the damage caused by mutant insulins, IAPP oligomers, and Wolfram syndrome as well.

Wolfram syndrome is an autosomal recessive neurodegenerative disorder first evident in childhood. Patients present with diabetes insipidus, diabetes mellitus, optic atrophy, and deafness—hence the acronym DIDMOAD. Diabetes mellitus usually develops in the first decade together with the optic atrophy, followed by central diabetes insipidus and senile neuronal deafness during the second decade in 60% to 75% of patients. Ureterohydrenephrosis, neurogenic bladder, cerebellar ataxia, peripheral neuropathy, and psychiatric illness develop later in many patients. The diabetes mellitus is nonimmune and not linked to specific HLA antigens, but on autopsy these patients have selective loss of β cells in the pancreas. Genetic studies mapped the causative mutations to a gene called WFS1, which encodes a 100.3-kDa transmembrane protein localized to the endoplasmic reticulum membranes of all cells. WFS1 is expressed at particularly high levels in β cells. Studies in mice have shown that the WFS1 protein forms part of the unfolded protein response downstream of PERK and IRE1 and helps protect the β cells from ER stress and apoptosis, especially during periods of high insulin demand.

Children with thiamine-responsive megaloblastic anemia syndrome carry mutations in the high-affinity thiamine transporter SLC19A2 found on cell and mitochondrial membranes. They develop megaloblastic anemia, diabetes, and sensorineuronal deafness. The diabetes usually presents in the first decade of life. In the absence of SLC19A2, cells and mitochondria can still transport thiamine through lower affinity transporters, and both the anemia and the diabetes respond to pharmacologic treatment with thiamine. However, all patients eventually require insulin replacement despite thiamine therapy. It remains unclear how partial defects in cellular and mitochondrial thiamine transport cause β cell failure.

Mitochondrial DNA mutations: Because sperm do not contain mitochondria, only the mother transmits mitochondrial genes to her offspring. Diabetes due to a mutation of mitochondrial DNA that impairs the transfer of leucine into mitochondrial proteins has now been described in a large number of families, and results from impaired β cell function. The incidence of this disorder is as high as 1% to 3% in patients with diabetes in Japan and Korea, but lower in European populations. Most patients have a mild form of maternally transmitted diabetes with insulin deficiency that responds to oral hypoglycemic agents; however, some patients have a more severe clinical picture similar to type 1a diabetes. As many as 63% of patients with this subtype of diabetes have hearing loss and a smaller proportion (15%) have a syndrome of myopathy, encephalopathy, lactic acidosis, and stroke-like episodes.

Ketosis-Prone Diabetes

First described in young adult African American males from the Flatbush neighborhood in New York City, but since described in a number of populations of both African and non-African ancestry, these patients typically present with diabetic ketoacidosis and absolute insulin deficiency, followed by extended clinical remission of insulin. When tested during remission, however, maximal insulin secretory capacity remains markedly reduced, and these
patients follow a relapsing course of DKA and hyperglycemia with eventual permanent insulin-deficient diabetes. These patients do not have islet cell autoantibodies or increased frequencies of HLA haplotypes associated with risk of autoimmune type 1a diabetes. Although there is often a family history of similar diabetes, the inheritance is not clearly Mendelian. Although KPD patients have been distinguished based on the history of relapsing ß cell dysfunction, it remains controversial as to whether KPD represents a clinical entity distinct from other forms of nonautoimmune type 1b diabetes.

In a study of KPD patients of West African ancestry, linkage was established with coding variants in the PAX4 gene. PAX4 encodes for a transcription factor that functions downstream of NEUROG3 in the formation of ß cells. Fourteen to twenty-one percent of individuals of West African ancestry carry a coding variant that substitutes tryptophan for arginine at position 133 in PAX4 and reduces its ability to repress transcription of target genes. Interestingly, the R133W variant is unique to people of West African ancestry. The R133W allele is approximately twice as frequent in individuals with KPD, and all individuals homozygous for R133W have KPD. An additional PAX4 coding variant with reduced ability to bind to DNA was identified in one patient with KPD. Different coding variants in PAX4 have also been identified in Thai families with MODY (MODY 9) and in Japanese patients (both heterozygous and homozygous) with early onset insulin-deficient diabetes similar to KPD. Taken together, these data suggest that coding variants in the PAX4 gene predispose to insulin-deficient diabetes, but the clinical phenotype may depend on the exact nature of the variant and interactions with other genes and environmental factors.

Genetic Defects of Insulin Action

These are rare and unusual causes of diabetes that result from mutations of the insulin receptor or from other genetically determined postreceptor abnormalities of insulin action. Metabolic abnormalities associated with these disorders may range from hyperinsulinemia and modest hyperglycemia to severe diabetes. Many individuals have acanthosis nigricans, polycystic ovaries with hyperandrogenism, and, in exceptional cases, pseudoacro megaly (see earlier).

Familial forms of insulin resistance associated with acanthosis nigricans, polycystic ovaries, and hyperandrogenism, and, in exceptional cases, pseudoacromegaly (see earlier).

Congenital and acquired forms of lipodystrophy can cause severe insulin resistance. Except in newborns with lipoatrophy secondary to complete loss of insulin receptors (Leprechaunism), alterations in the structure and function of the insulin receptor cannot be demonstrated in patients with insulin-resistant lipodystrophic diabetes, suggesting that the cause of the insulin resistance in these patients must reside in postreceptor pathways. Replacement of the adipokines leptin and adiponectin can reverse insulin resistance in mouse models of severe lipoatrophy, and leptin has been helpful in human cases of generalized lipodystrophy, demonstrating the importance of the adipocyte in regulating insulin function. Also, the loss of adipose storage depots in lipoatrophy leads to very high levels of circulating triglyceride-rich lipoprotein particles and increased deposition of fat in nonadipose tissues such as liver and muscle, which may contribute to dysfunction and insulin resistance in these tissues. The increase in ectopic fat deposition leads to profound hepatic steatosis in affected patients and can progress to cirrhosis and liver failure.

The congenital syndromes can be divided into generalized and partial lipodystrophies with or without dystrophic features in other tissues. The generalized syndromes are often identified in neonates, have severe insulin resistance at diagnosis and rapidly develop hyperglycemia, acanthosis nigricans, hyperandrogenism, and pseudoacromegaly. Recessive mutations causing generalized congenital lipodystrophy have been identified in three genes encoding proteins involved in the formation of lipid droplets (seipin and caveolin-1) and triglyceride (1-acylglycerol-3-phosphate-O-acyltransferase 2 [AGPAT2]).

Two syndromes of familial partial lipodystrophy without associated dysmorphic defects have been described in which the lipoatrophy usually first appears late in childhood, but may be preceded by evidence of insulin resistance. The type 1 syndrome consists of atrophy of limb, gluteal and subcutaneous abdominal fat with sparing or increases of the abdominal visceral, upper trunk, head, and neck fat. In the type 2 syndrome, truncal and visceral fat are also affected and only vulval and head and neck depots are spared.

To date no genetic causes of the type 1 syndrome have been identified. In the type 2 syndrome, dominant mutations have
been found in *LMNA*, the gene encoding the nuclear intermediate filament lamin A/C. In addition, one individual with the type 2 syndrome has been identified with a homozygous nonsense mutation in the gene encoding the lipid droplet protein CIDEC, and one individual was identified with a homozygous truncation of the gene encoding lipase maturation factor 1, a protein required for the maturation of both lipoprotein lipase and hepatic lipase.

Consistent with its known role in adipocytes differentiation, dominant mutations in the gene encoding PPARγ have also been described in patients with familial partial lipodystrophy and insulin resistance. These patients have a pattern of lipoatrophy similar to the type 2 syndrome with *LMNA* mutations, but with less severe subcutaneous fat loss, and have been labeled type 3 familial partial lipodystrophy.

Several syndromes of lipodystrophy associated with other dysmorphic features have been described. Autosomal recessive mutations in *ZMPSTE24*, which encodes a metalloprotease that cleaves prolammin A to produce mature lamin A, cause generalized lipodystrophy associated with mandibulo-acral dysplasia. In patients with partial lipodystrophy combined with mandibulo-acral dysplasia, autosomal recessive mutations have been identified in *LMNA*, but these mutations are distinct from those that cause familial partial lipodystrophy type 2. Remarkably, yet a different set of mutations in *LMNA* cause the autosomal recessive syndrome Hutchinson–Gilford progeria, which includes severe early onset generalized lipodystrophy. Additional distinct mutations in *LMNA* cause several other congenital dysmorphic syndromes, including muscular dystrophies, familial dilated cardiomyopathy, and Charcot-Marie-Tooth disease.

Acquired forms of partial and generalized lipodystrophy with insulin resistance and diabetes can develop secondary to infections, autoimmunity, paraneoplastic syndromes, collagen vascular disorders, drugs, or unknown causes. One common form is seen in patients with HIV infection following treatment with protease inhibitors.

**Neonatal Diabetes**

Neonatal diabetes, defined as diabetes diagnosed before 6 months of age, is rare, occurring in fewer than 1 in 200,000 live births. Children with neonatal diabetes often present with decreased birth weight (intrauterine growth retardation, IUGR) and decreased fat stores in addition to hyperglycemia. Most commonly these children have reduced circulating insulin and C-peptide levels caused by inherited β cells defects, although rare inherited defects in insulin signaling can also present in neonates. In approximately half of cases, neonatal diabetes is transient: the diabetes goes into remission (normoglycemia with no therapy) before 18 months of age, although it usually returns at puberty. In the remainder of cases, the diabetes is permanent.

**Transient neonatal diabetes (TNDM):** Defects in imprinting underlie most cases of TNDM. The most common genetic defect is paternal uniparental isodisomy (replacement of the maternal copy of the region with the paternal copy) of an imprinted region at chromosome 6q24. In this region, the maternal copy of the chromosome is normally silenced by methylation. Simple duplication of the paternal copy of this region, or mutations in ZFP57, a zinc-finger protein required globally for the methylation of imprinted regions, can give the same TNDM phenotype. The affected region of 6q24 contains two genes of uncertain function, but one of them, *ZAC*, has been identified as a tumor suppressor gene and may activate the expression of an inhibitor of cell proliferation. An increase in hypomethylated copies of *ZAC* may lead to the inhibition of β cell proliferation and inadequate β cell mass.

Some autosomal dominant activating mutations in *KCNJ11* and *ABCC8*, the genes encoding the two subunits of the ATP-sensitive potassium channels in β cells (Figure 17–5) and listed among autosomal dominant forms of heritable diabetes (see earlier) can cause TNDM. Autosomal dominant mutations in the MODY 5 gene, *HNF1B*, can also cause TNDM.

**Permanent neonatal diabetes (PNDM):** Autosomal dominant activating mutations in *KCNJ11* and *ABCC8* can also cause PNDM. Some of the autosomal dominant insulin mutations that cause rapid β cell apoptosis will result in permanent diabetes in neonates. In addition, most of the syndromes caused by autosomal recessive genetic defects in β cells (see Table 17–9) present in neonates. These include mutations in the MODY genes *GCK* and *PDX1*, the transcription factor genes *PTF1A*, *GLIS3*, and *RXF6*, and the Wolcott–Rallison syndrome gene *EIF2AK3*. The IPEX syndrome (see Genetics of Type 1 Diabetes above), caused by mutations in *FOXP3*, can also present with accelerated autoimmune type 1 diabetes in neonates. Finally, mutations that cause complete, or nearly complete, loss of insulin signaling (Leprechaunism) also present with PNDM.

Several other syndromes of neonatal diabetes of unknown etiology associated with a variety of other developmental defects have been described. With the advent of rapid whole genome sequencing, the genetic defects that cause these syndromes, as well as later onset diabetes, may soon be identified, providing further insights into the pathogenesis of diabetes and identifying potential therapeutic targets.

**Diabetes due to Diseases of the Exocrine Pancreas**

Any process that diffusely damages or substantially displaces the pancreas can cause diabetes, although individuals with a predisposition to type 2 diabetes are probably more susceptible to developing diabetes with lesser degrees of pancreatic involvement. Because glucagon-secreting α cells are also damaged or removed by these processes, less insulin is usually required for replacement—as compared with most other forms of diabetes that leave α cells intact.

Acquired causes include pancreatitis, trauma, infection, pancreatic carcinoma, and pancreatectomy. Fibrocalculous pancreatitis, a form of acquired pancreatitis with extensive fibrosis and ductal calculi seen commonly in tropical regions, may result from both dietary and genetic contributors, although the exact cause remains obscure. Like chronic pancreatitis from a variety of causes, fibrocalculous involvement of the pancreas may be accompanied by abdominal pain radiating to the back and associated with pancreatic calcifications on x-ray. When extensive enough, hemochromatosis and cystic fibrosis can also displace β cells and
reduce insulin secretion. Autosomal dominant mutations in carboxyl-ester lipase (CEL), an exocrine enzyme, cause accelerated exocrine pancreatic damage and diabetes at a young age, and have been designated as MODY 8 (see Table 17–8).

**Endocrinopathies**

Excess production of certain hormones—GH (acromegaly), glucocorticoids (Cushing syndrome or disease), catecholamines (pheochromocytoma), thyroid hormone (thyrotoxicosis), glucagon (glucagonoma), or pancreatic somatostatin (somatostatinoma)—can produce relative insulin deficiency and diabetes by a number of mechanisms. In all but the last instance (somatostatinoma), peripheral responsiveness to insulin is impaired. In addition, excess of catecholamines or somatostatin decreases insulin release from β cells. Diabetes mainly occurs in individuals with underlying defects in insulin secretion, and hyperglycemia typically resolves when the hormone excess is corrected.

**Drug- or Chemical-Induced Diabetes**

Many drugs are associated with carbohydrate intolerance or frank diabetes mellitus. Some act by interfering with insulin release from the β cells (thiazides, phenytoin, cyclosporine), some by inducing insulin resistance (glucocorticoids, oral contraceptive pills, niacin, and antiviral protease inhibitors), and some by causing β cell destruction (intravenous pentamidine). Patients receiving β interferon have been reported to develop diabetes associated with β cell antibodies and in certain instances severe insulin deficiency. Atypical antipsychotic medications can provoke substantial weight gain and insulin resistance, but the high reported incidence of diabetic ketoacidosis in patients on these drugs suggests that they may also impair β cell function.

Adrenergic drugs impact glucose metabolism in complex and often opposing ways because of differing effects on insulin secretion, glucagon secretion, hepatic glucose output, peripheral insulin sensitivity, and weight gain. In clinical practice, the first generation, nonselective β blockers such as propranolol tend to modestly increase glucose levels, at least in part due to increases in insulin resistance, but potentially by decreasing insulin secretion as well. The second generation, selective β1 blockers also tend to increase blood glucose, but the third generation drugs with combined α and β blockade have minimal effects on blood glucose. In contrast, nonselective α agonist and α2 agonists tend to raise blood glucose, probably due to their combined effects on insulin secretion and hepatic glucose output. However, although β blockers and α2 agonists like clonidine, as well as calcium channel blockers, inhibit glucose-induced insulin release from in vitro preparations of pancreatic β cells, these drugs have minimal or modest effects on blood glucose control at the levels used in standard antihypertensive therapy in humans.

Finally it must be kept in mind that the most common toxin causing diabetes is ethanol. Chronic alcoholic pancreatitis with secondary loss of β cells accounts for approximately 1% of diabetes in the United States.

**Infections Causing Diabetes**

Certain viruses have been associated with direct pancreatic β cell destruction in animals. Diabetes is also known to develop frequently in humans who had congenital rubella, although most of these patients have HLA and immune markers characteristic of type 1 diabetes. In addition, coxsackievirus B, cytomegalovirus, adenovirus, and mumps have been implicated in inducing certain cases of diabetes.

**Uncommon Forms of Immune-Mediated Diabetes**

A severe form of insulin resistance has been reported in patients who developed high titers of antibodies that bind to the insulin receptor and block the action of insulin in its target tissues. As in other states of extreme insulin resistance, these patients often have acanthosis nigricans. In the past, this form of immune-mediated diabetes was termed type B insulin resistance. Most commonly these antibodies are of idiopathic origin, but they have also been described in monoclonal gamopathies and multiple myeloma and in patients with ataxia telangiectasia syndrome.

Several syndromes of altered immune function with multiple endocrine gland involvement have been described. The APS1 and IPEX syndromes are described in the section on the genetics of type 1 diabetes and in Chapter 2. Patients with POEMS, a syndrome of plasma cell dyscrasia associated with polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes, have an increased incidence of diabetes as well as other endocrine disorders. The cause of the diabetes in these patients has not been established.

**Other Genetic Syndromes Sometimes Associated with Diabetes**

More than 50 distinct genetic syndromes involve an increased incidence of diabetes mellitus. These include the chromosomal abnormalities of Down syndrome, Klinefelter syndrome, and Turner syndrome. In addition, a number of complex syndromes associated with neuromuscular pathologies (Freidreich ataxia, Huntington chorea, porphyria, muscular dystrophies) or severe obesity (Laurence-Moon-Biedl, Bardet-Biedl, and Prader-Willi syndromes) have been associated with diabetes.

**CLINICAL FEATURES OF DIABETES MELLITUS**

The principal clinical features of the two major types of diabetes mellitus are listed for comparison in Table 17–10.

**Type 1 Diabetes**

Patients with type 1 diabetes present with symptoms and signs related to hyperglycemia and hyperketonemia. The severity of the insulin deficiency and the acuteness with which the catabolic state develops determine the intensity of the osmotic and ketogenic excess.
A. Symptoms  Increased urination is a consequence of osmotic diuresis secondary to sustained hyperglycemia. This results in a loss of glucose as well as free water and electrolytes in the urine. Nocturnal enuresis due to polyuria may signal the onset of diabetes in very young children. Thirst is a consequence of the hyperosmolar state, as is blurred vision, which often develops as the lenses and retinas are exposed to hyperosmolar fluids.

Weight loss, despite normal or increased appetite, is a common feature of type 1 diabetes when it develops subacutely over a period of weeks. The weight loss is initially due to depletion of water, glycogen, and triglyceride stores. Chronic weight loss due to reduced muscle mass occurs as amino acids are diverted to form glucose and ketone bodies.

Lowered plasma volume produces dizziness and weakness due to postural hypotension when sitting or standing. Total body potassium loss and the general catabolism of muscle protein contribute to the weakness. Paresthesias may be present at the time of diagnosis of type 1 diabetes, particularly when the onset is subacute. They reflect a temporary dysfunction of peripheral sensory nerves and usually clear, as insulin replacement restores glycemic levels closer to normal; thus, their presence suggests neurotoxicity from sustained hyperglycemia.

When insulin deficiency is severe and of acute onset, the above symptoms progress in an accelerated manner. Ketoacidosis exacerbates the dehydration and hyperosmolality by producing anorexia, nausea, and vomiting, thus interfering with oral fluid replacement. As plasma osmolality exceeds 330 mOsm/kg (normal, 285-295 mOsm/kg), impaired consciousness ensues. With progression of acidosis to a pH of 7.1 or less, deep breathing with a rapid ventilatory rate (Kussmaul respiration) occurs as the body attempts to eliminate carbonic acid. With worsening acidosis (to pH 7.0 or less), the cardiovascular system may be unable to maintain compensatory vasoconstriction; severe circulatory collapse may result.

B. Signs  The patient’s level of consciousness can vary depending on the degree of hyperosmolality. When insulin deficiency develops relatively slowly and sufficient water intake is maintained to permit renal excretion of glucose and appropriate dilution of extracellular sodium chloride concentration, patients remain relatively alert and physical findings may be minimal. When vomiting occurs in response to worsening ketoacidosis, dehydration progresses and compensatory mechanisms become inadequate to keep plasma osmolality below 330 mOsm/kg. Under these circumstances, stupor or even coma may occur. Evidence of dehydration in a stuporous patient, with rapid deep breathing and the fruity breath odor of acetone, suggests the diagnosis of diabetic ketoacidosis.

Postural hypotension indicates a depleted plasma volume; hypotension in the recumbent position is a serious prognostic sign. Loss of subcutaneous fat and muscle wasting are features of more slowly developing insulin deficiency. In occasional patients with slow, insidious onset of insulin deficiency, subcutaneous fat may be considerably depleted. An enlarged liver, eruptive xanthomas on the flexor surface of the limbs and on the buttocks, and lipemia retinalis indicate that chronic insulin deficiency has resulted in chylomicronemia, with elevated circulating triglycerides, usually to over 2000 mg/dL (Chapter 19).

Type 2 Diabetes

Patients with type 2 diabetes usually have less severe insulin deficiency than type 1 patients and the symptoms and signs at presentation reflect this difference.

A. Symptoms  Many patients with type 2 diabetes have an insidious onset of hyperglycemia and may be relatively asymptomatic initially. The diagnosis may be made only after glycosuria or hyperglycemia is noted during routine laboratory studies. Chronic skin infections are common. Generalized pruritus and symptoms of candidal vaginitis are frequently the initial complaints of women with type 2 diabetes. Men may complain of an itchy rash of the prepuce. Some patients can remain undiagnosed for many years and the initial presentation may be due to complications such as visual disturbance due to retinopathy or foot pain or infection due to a peripheral neuropathy. Patients with a more severe insulin deficiency have the classical symptoms of polyuria, thirst, blurred vision, paresthesias, and fatigue. This is especially true in individuals who consume large amounts of carbohydrate-rich fluids in response to the thirst.

B. Signs  Many patients are obese or overweight. Even those patients who are not significantly overweight often have a characteristic fat distribution with more fat in the upper part of the body (particularly the abdomen, chest, neck, and face) and relatively less fat on the appendages, which may be quite muscular (the metabolically obese). This centripetal fat distribution has been termed android and is characterized by a high waist circumference. It differs from the more centrifugal gynecoid form of obesity, in which fat is localized more in the hips and thighs and less in the upper parts of the trunk. A larger waist circumference increases the risk for diabetes for any given body mass index (BMI). Thus in patients with the metabolic syndrome, a waist circumference >40 in (102 cm) in men and >35 in (88 cm) in women is associated with an increased risk of diabetes. MRI and CT scans reveal that these patients with increased waist circumference have accumulation of fat in the omental and mesenteric distributions. This visceral fat correlates with insulin resistance,
whereas fat predominantly in subcutaneous tissues of the abdomen has little, if any, association with insulin insensitivity.

Some patients, especially the obese, may have acanthosis nigricans—hyperpigmented, hyperkeratotic skin in the axilla, groin, and back of neck. This sign is associated with significant insulin resistance. Hypertension may be present especially in the obese patient. Eruptive xanthomata on the flexor surface of the limbs and on the buttocks and lipemia retinalis due to hyperchylomicronemia can occur in patients with uncontrolled type 2 diabetes who also have a familial form of hypertriglyceridemia. In women, candidal vaginitis with a reddened, inflamed vulvar area and a profuse whitish discharge may herald the presence of diabetes. In men, candidal infection of the penis may lead to reddish appearance of the penis and/or prepuce with eroded white papules and a white discharge. The occasional patient who has had undiagnosed diabetes for some time may present with retinopathy or peripheral neuropathy.

Patients can also present in hyperglycemic hyperosmolar coma—profoundly dehydrated, hypotensive, lethargic, or comatose without Kussmaul respirations.

**Laboratory Testing in Diabetes Mellitus**

Tests of urine glucose and ketone bodies, as well as whole blood or plasma glucose measured in samples obtained under basal conditions and after glucose administration, are very important in evaluation of the patient with diabetes. Tests for glycosylated hemoglobin have proved useful in both initial evaluation and in assessment of the effectiveness of therapeutic management. In certain circumstances, measurements of insulin or C-peptide levels and levels of other hormones involved in carbohydrate homeostasis (eg, glucagon, GH) may be useful. In view of the increased risk of atherosclerosis in patients with diabetes, determination of serum cholesterol, HDL—cholesterol, triglycerides, and LDL-cholesterol may be helpful.

**Urine Glucose**

Several problems are associated with using urine glucose as an index of blood glucose, regardless of the method employed. First of all, the glucose concentration in bladder urine reflects the blood glucose at the time the urine was formed. Therefore, the first voided specimen in the morning contains glucose that was excreted throughout the night and does not reflect the morning blood glucose at all. Some improvement in the correlation of urine glucose to blood glucose can be obtained if the patient double voids—that is, empties the bladder completely, discards that sample, and then urinates again about one-half hour later, testing only the second specimen for glucose content. However, difficulty in completely emptying the bladder (large residual volumes), problems in understanding the instructions, and the inconvenience impair the usefulness of this test. Self-monitoring of blood glucose has replaced urine glucose testing in most patients with diabetes (particularly those receiving insulin therapy).

Several commercial products are available for determining the presence and amount of glucose in urine. The older and more cumbersome bedside assessment of glycosuria with Clinistix tablets has generally been replaced by the dipstick method, which is rapid, convenient, and glucose specific. This method consists of paper strips (Clinistix, Tes-Tape) impregnated with enzymes (glucose oxidase and hydrogen peroxidase) and a chromogenic dye that is colorless in the reduced state. Enzymatic generation of hydrogen peroxide oxidizes the dye to produce colors whose intensity depends on the glucose concentration. These dipsticks are sensitive to as little as 0.1% glucose (100 mg/dL) but do not react with the smaller amounts of glucose normally present in nondiabetic urine. The strips are subject to deterioration if exposed to air, moisture, and extreme heat and must be kept in tightly closed containers except when in use. False-negative results may be obtained in the presence of alkaptonuria and when certain substances such as salicylic acid or ascorbic acid are ingested in excess. All these false-negative results occur because of the interference of strong reducing agents with oxidation of the chromogen.

Although glycosuria reflects hyperglycemia in more than 90% of patients, two major classes of nondiabetic glycosuria must be considered:

**A. Alterations in renal handling of glucose** Disorders associated with abnormalities in renal glucose handling include Fanconi syndrome, a group of disorders characterized by combined renal wasting of multiple solutes including amino acids, uric acid, phosphate, and bicarbonate as well as glucose and caused by both genetic and acquired defects of the proximal renal tubule. Familial renal glycosuria, a benign inherited disorder manifest only by persistent glycosuria in the setting of euglycemia is caused by mutations in SGLT2, the sodium-glucose cotransporter responsible for the bulk of glucose reabsorption in the proximal tubule.

In addition, glycosuria is relatively common in pregnancy as a consequence of the increased load of glucose presented to the tubules by the elevated glomerular filtration rate during pregnancy. As many as 50% of pregnant women normally have demonstrable sugar in the urine, especially after the first trimester.

**B. Excretion of sugars other than glucose in the urine** Occasionally, a sugar other than glucose is excreted in the urine. Lactosuria during the late stages of pregnancy and the period of lactation is the most common example. Much rarer are other conditions in which inborn errors of metabolism allow fructose, galactose, or a pentose (1-xyllose) to be excreted in the urine. Testing the urine with glucose-specific strips helps differentiate true glucosuria from other glycosurias.

**Microalbuminuria and Proteinuria**

Urine albumin can now be detected in microgram concentrations using high-performance liquid chromatography or immunoassay methodology that is more sensitive than previous available tests. Conventional 24-hour urine collections, in addition to being inconvenient for patients, also show wide variability of albumin excretion, because several factors such as sustained upright posture, dietary protein, and exercise tend to increase albumin excretion rates. For these reasons, it is preferable to measure the
albumin-creatinine ratio in an early morning spot urine collected on awakening—prior to breakfast or exercise—and brought in by the patient for laboratory analysis. A ratio of albumin (mg/L) to creatinine (mg/L) of less than 30 is normal, and a ratio of 30 to 300 indicates abnormal microalbuminuria. Values greater than 300 are referred to as macroalbuminuria.

The minimal detection limit of protein on a standard urine dipstick is 10 to 20 mg/dL. If the dipstick is positive then it is likely that the patient has microalbuminuria and this should be specifically tested. The information from a spot urine sample is adequate for diagnosis and treatment and it is not usually necessary to perform a 24-hour urine collection for protein loss and creatinine clearance.

**Blood Glucose Testing**

**A. Venous blood samples** Venous glucose samples should be collected in tubes containing sodium fluoride, which inhibits enolase and prevents glycolysis in the blood sample that would artifactually lower the measured glucose level. In the absence of fluoride, the rate of disappearance of glucose in the presence of blood cells has been reported to average 10 mg/dL/h—the rate increases with glucose concentration, temperature, and white blood cell count. Fluoride takes about 1 hour to effectively stop glycolysis. Therefore, the rate of decline during the first hour is the same in tubes with or without fluoride. A very high white blood cell count will lower glucose levels even in the presence of fluoride. Ideally the blood should be collected in a sodium fluoride/potassium oxalate tube, placed on ice and the plasma separated from the cells within 60 minutes.

Plasma or serum from venous blood samples has the advantage over whole blood of providing values for glucose that are independent of hematocrit and reflect levels in the interstitial spaces to which body tissues are exposed. For these reasons—and because plasma and serum lend themselves to automated analytic procedures—they are used in most laboratories. The glucose concentration is 10% to 15% higher in plasma or serum than in whole blood because structural components of blood cells are absent. Whole blood glucose determinations are seldom used in clinical laboratories, but are used by patients using home blood glucose monitors.

Glucose levels can be measured in the laboratory using enzymatic methods (such as glucose oxidase or hexokinase), condensation methods (such as o-toluidine), or reducing methods. The reducing methods take advantage of the reducing properties of glucose to change the redox state of a metal ion; however, the method is nonspecific and any strong reducing agent can cross-react to yield spuriously elevated glucose values. In condensation methods, the aldehyde group of glucose undergoes condensation with aromatic compounds to yield a colored product. In the most commonly used condensation reaction, o-toluidine reacts with glucose to form a glucosamine that has an intense green color. The color is measured spectrophotometrically to estimate the glucose concentration. o-Toluidine, however, has the drawback of being highly corrosive and toxic. In the enzymatic method, glucose oxidase reacts with glucose, water, and oxygen to form gluconic acid and hydrogen peroxide. The hydrogen peroxide can then be used to oxidize a chromogen or the consumption of oxygen measured to estimate the amount of glucose present. Current laboratories use enzymatic methods to determine glucose levels.

The range of normal fasting plasma or serum glucose is 70 to 100 mg/dL (3.9–5.5 mmol/L). A plasma glucose level of 126 mg/dL (7.0 mmol/L) or higher on more than one occasion after at least 8 hours of fasting is diagnostic of diabetes mellitus (Table 17–11). Fasting plasma glucose levels of 100 mg/dL (5.6 mmol/L) to 125 mg/dL (6.9 mmol/L) are associated with increased risk for diabetes (impaired fasting glucose).

**B. Capillary blood samples** Capillary blood glucose measurements performed by patients themselves, as outpatients, are extremely useful. In type 1 patients in whom tight metabolic control is attempted, they are indispensable. There are several paper strip (glucose oxidase; hexokinase; glucose dehydrogenase with nicotinamide adenine dinucleotide, glucose dehydrogenase with flavin-adenine dinucleotide, glucose dehydrogenase with pyrroloquinoline quinone) methods for measuring glucose on capillary blood samples. A reflectance photometer or an amperometric system is then used to measure the reaction that takes place on the reagent strip. A large number of blood glucose meters are now available. All are accurate, but they vary with regard to speed, convenience, size of blood samples required, and cost. Popular models include those manufactured by Life-Scan (One Touch), Bayer Corporation (Breeze, Contour), Roche Diagnostics (Accu-Chek), and Abbott Laboratories (Precision, FreeStyle). A Freestyle Flash meter, for example, which requires only 0.3 microliter of blood and gives a result in 5 seconds, is illustrative of the continued progress in this technology area. Various glucometers appeal to a particular consumer need and are relatively inexpensive, ranging from $50.00 to $100.00 each. Test strips remain a major expense, costing 50 to 75 cents each. The meters have memories and can compute blood glucose averages. The data can

* A fasting plasma glucose or HbA1c is diagnostic of diabetes if confirmed by repeat testing. HbA1c test should be performed using an assay certified by the National Glycohemoglobin Standardization program and standardized to the DCCT assay.

* A fasting plasma glucose ≥126 mg/dL is diagnostic of diabetes if confirmed on a subsequent day to be in the diabetic range after an overnight fast.

* Give 75 g of glucose dissolved in 300 mL of water after an overnight fast in subjects who have been receiving at least 150 to 200 g of carbohydrate daily for 3 days before the test. In the absence of unequivocal hyperglycemia, the result should be confirmed by repeat testing.
be downloaded into a computer. In self-monitoring of blood glucose, patients must prick a finger with 26- to 33-gauge lancets. This can be facilitated by a small plastic trigger device such as an Accu-chek multiclix (Roche Diagnostics), Microlet (Boehringer-Mannheim), or one touch lanceting device (Lifescan, Inc.). Some meters such as the FreeStyle (Abbott Laboratories) have been approved for measuring glucose in blood samples obtained at alternative sites such as the forearm and thigh. There is, however, a 5- to 20-minute lag in the glucose response on the arm with respect to the glucose response on the finger. Forearm glucose measurements could therefore result in a delay in detection of rapidly developing hypoglycemia.

The clinician should be aware of the limitations of the self-glucose monitoring systems. First, some meters require input of a code for each batch of strips—failure to enter the code can result in misleading results. Many of the newer meters no longer require this step. Second, increases or decreases in hematocrit can decrease or increase the measured glucose values, respectively. The mechanism underlying this effect is not known, but presumably it is due to the impact of red cells on the diffusion of plasma into the reagent layer. Third, the meters and the test strips are calibrated over glucose concentrations ranging from 60 to 160 mg/dL, and the accuracy is not as good for higher and lower glucose levels. Thus, when the glucose is less than 60 mg/dL, the difference between the meter and the laboratory value may be as much as 20%. Fourth, glucose-oxidase-based amperometric systems underestimate glucose levels in the presence of high oxygen tension. This may be important in critically ill patients who are on supplemental oxygen, and under these circumstances, a glucose dehydrogenase-based system may be preferable. Fifth, glucose-dehydrogenase pyrroloquinoline quinine (GDH-PQQ) systems may report falsely high glucose levels in patients who are receiving parenteral products containing nonglucose sugars such as maltose, galactose, or xylose or their metabolites. Patients have been given insulin based on the falsely high glucose values resulting in life-threatening hypoglycemia. The accuracy of data obtained by glucose monitoring requires education of the patient in sampling and measuring procedures as well as in proper calibration of the instruments. Bedside glucose monitoring in a hospital setting requires rigorous quality control programs and certification of personnel to avoid errors.

**Interstitial Fluid Glucose Samples**

A number of continuous glucose monitoring (CGM) systems are currently available for clinical use. The systems manufactured by Medtronic MiniMed, Abbott Diagnostics, and Dex Com involve inserting a subcutaneous biosensor (rather like an insulin pump cannula) that measures glucose concentrations in the interstitial fluid for 3 to 7 days. The glucose values are available for review by the patient at time of measurement. The systems also display directional arrows indicating rate and direction of change and alerts can be set for dangerously low or high glucose values. Patients still have to calibrate the devices with periodic fingertip glucometer glucose levels; and since there are concerns about the reliability of the measurements, it is still necessary to perform a confirmatory capillary blood glucose measurement before intervening. The individual glucose levels are not that critical—what matters are the direction and the rate at which glucose is changing and the low glucose alerts that allow the user to take corrective action. The user also gains insight into the way particular foods or activities affect their glucose levels. Clinical trials with these systems show that they do enable some patients with type 1 diabetes to improve control without increasing the risk for hypoglycemia. The MiniMed insulin pump marketed in Europe can be programmed to automatically suspend insulin delivery for two hours when the glucose levels on their CGM device falls to a preset level. This feature may help reduce the risk for dangerous hypoglycemia especially when the patient is asleep. They are increasingly being approved by insurance companies. The out of pocket cost of the systems is about $4000 annually.

There is great interest in using the data obtained from these CGM systems to automatically deliver insulin by continuous subcutaneous insulin infusion pump. Algorithms have been devised to link CGM to insulin delivery and preliminary clinical studies appear promising.

**Urine and Serum Ketone Determinations**

In the absence of adequate insulin, three major ketone bodies are formed and excreted into the urine: β-hydroxybutyrate (often the most prevalent in diabetic ketoacidosis), acetoacetate, and acetone. Acetone and acetoacetate react with sodium nitroprusside (nitroferricyanide) in the presence of alkali to produce a purple-colored complex. Acetest tablets, Ketostix, and Keto-Diastix strips utilize this nitroprusside reaction to quantify acetone and acetoacetate levels in urine and plasma. When a few drops of serum are placed on a crushed Acetest tablet, the appearance of a purple color indicates the presence of ketones. A strongly positive reaction in undiluted serum correlates with a serum ketone concentration of at least 4 mmol/L. Although these tests do not detect β-hydroxybutyric acid, which lacks a ketone group, the semiquantitative estimation of the other ketone bodies is nonetheless usually adequate for clinical assessment of ketonuria. Ketostix and Keto-Diastix have short shelf-lives (90 days) once the containers are opened and using expired strips can give false-negative results. It is better therefore to buy individually foil wrapped strips.

Specific enzymatic techniques are available to quantitate each of the ketone acids, but these techniques are cumbersome and are not necessary in most clinical situations. There is also a paper strip method that patients can use to measure capillary blood β-hydroxybutyrate levels (Precision Xtra, Abbott Diagnostics). This technology uses hydroxybutyrate dehydrogenase to catalyse the oxidation of β-hydroxybutyrate to acetoacetate with concomitant reduction of NAD⁺ to NADH. The NADH is reoxidized to NAD⁺ by a redox mediator and a current is generated that is directly proportional to β-hydroxybutyrate concentration. β-Hydroxybutyrate levels >0.6 nmol/L require evaluation. Levels >3.0 nmol/L, which is equivalent to very large urine ketones, will require hospitalization.

Other conditions besides diabetic ketoacidosis may cause ketone bodies to appear in the urine; these include starvation, high-fat diets, alcoholic ketoacidosis, fever, and other conditions in which metabolic requirements are increased.
Glycated Hemoglobin Assays

Ketoamine reactions between glucose and other sugars and free amino groups on the alpha and beta chain lead to glycated forms of hemoglobin. Only glycation of the N-terminal valine of the beta chain imparts sufficient negative charge to the hemoglobin molecule to allow separation by charge-dependent techniques. The charge-separated hemoglobins are collectively referred to as glycated hemoglobin (HbA1c). The major form of HbA1c is hemoglobin A1c (HbA1c), where glucose is the carbohydrate. This form comprises 4% to 6% of total hemoglobin. The remaining HbA1c species contain fructose 1,6-diphosphate (HbA1c1), glucose 6-phosphate (HbA1c2), and an unknown carbohydrate moiety (HbA1c3). The hemoglobin A1c fraction is abnormally elevated in diabetic patients with chronic hyperglycemia. Some laboratories measure the sum of these glycohemoglobins (GHbs) and report the total as hemoglobin A1c, but most laboratories have converted to the highly specific HbA1c assay. Methods for measuring HbA1c include electrophoresis, cation exchange chromatography, boronate affinity chromatography, and immunoassays.

Office-based immunoassays using capillary blood give a result in about 9 minutes, and this allows for immediate feedback to the patients regarding their glycemic control. Because GHbs circulate within red blood cells whose life span lasts up to 120 days, they generally reflect the state of glycaemia over the preceding 8 to 12 weeks, thereby providing an improved method of assessing diabetic control. The HbA1c value, however, is weighted to more recent glucose levels (previous month) and this explains why significant changes in HbA1c are observed with short term (1 month) changes in mean plasma glucose levels. Measurements should be made in patients with either type of diabetes mellitus at 3- to 4-month intervals so that adjustments in therapy can be made if GHb is either subnormal or if it is more than 1% above the upper limits of normal for a particular laboratory. In patients monitoring their own blood glucose levels, GHb values provide a valuable check on the accuracy of monitoring. In patients who do not monitor their own blood glucose levels, GHb values are essential for adjusting therapy.

The various HbA1c assays have been standardized to the assay used in the Diabetes Control and Complications Trial (DCCT) allowing the results to be related to the risks of developing microvascular complications. There is a linear relationship between the HbA1c value and average glucose. A recent study (A1c-Derived Average Glucose) collected 3 months of blood glucose data on 507 subjects—normals, type 1 and type 2 diabetics. The estimated average glucose was calculated by combining weighted results from 2 days of continuous glucose monitoring per month and seven point capillary blood glucose profiles (preprandial, postprandial, and bedtime) for at least 3 d/wk. The HbA1c was measured at the end of the 3 months. The relationship between average glucose and HbA1c based on liner regression analysis was:

\[
\text{Average glucose} = (28.7 \times \text{HbA1c}) - 46.7 \quad (\text{see also Table 17-12})
\]

The accuracy of HbA1c values can be affected by hemoglobin variants or derivatives, the effect depending on the specific hemoglobin variant or derivative and the specific assay used. Immunoassays that use an antibody to the glycated amino terminus of \( \beta \) globin do not recognize the terminus of \( \gamma \) globin of hemoglobin F, and so in patients with high levels of hemoglobin F, immunoassays give falsely low estimates of HbA1c. Cation exchange chromatography separates hemoglobin species by charge differences. Therefore, hemoglobin variants that coelute with HbA1c can lead to an overestimation of the HbA1c value. Chemically modified derivatives of hemoglobin such as carboxymethylated (in renal failure) or acetylated (high-dose aspirin therapy) hemoglobin can, in some methods, coelute with HbA1c.

Any condition that shortens erythrocyte survival or decreases mean erythrocyte age (eg, recovery from acute blood loss, hemoletic anemia) falsely lower HbA1c, irrespective of the assay method used. Alternative methods such as fructosamine (see later) should be considered for these patients. Vitamins C and E are reported to falsely lower test results, possibly by inhibiting glycation of hemoglobin. The National Glycohemoglobin Standardization Program website (www.ngsp.org) has information on the impact of frequently encountered hemoglobin variants and derivatives on the results obtained with the commonly used HbA1c assays.

The American Diabetes Association (ADA) has now endorsed using the HbA1c as a diagnostic test for diabetes (see Table 17-11). A cutoff value of 6.5% was chosen because the risk for retinopathy increases substantially above this value. The advantages of using the HbA1c to diagnose diabetes is that there is no need to fast; it has lower intra-individual variability than the fasting glucose test and the oral glucose tolerance test; and it gives a better picture of glucose control for 2 to 3 months. People with HbA1c levels of 5.7 % to 6.4% should be considered at high risk for developing diabetes (prediabetes). The diagnosis should be confirmed with a repeat HbA1c test, unless the patient is symptomatic with plasma glucose levels >200 mg/dL. This test would not be appropriate to use in populations with high prevalence of hemoglobinopathies or in conditions with increased red cell turnover. Also, the testing

should be performed using a National Glycohemoglobin Standardization Program certified method and standardized to the Diabetes Control and Complications Trial assay.

Serum Fructosamine

Serum fructosamine is formed by nonenzymatic glycosylation of serum proteins (predominantly albumin). Because serum albumin has a much shorter half-life (14-21 days) than hemoglobin, serum fructosamine generally reflects the state of glycemic control for the preceding 2 or 3 weeks. Reductions in serum albumin (e.g., nephrotic state or hepatic disease) lower the serum fructosamine value. When abnormal hemoglobin or hemolytic states affect the interpretation of GHb or when a narrower time frame is required, such as for ascertaining glycemic control at the time of conception in a woman with diabetes who has recently become pregnant, serum fructosamine assays offer some advantage. Normal values vary in relation to the serum albumin concentration and are 200 to 285 μmol/L when the serum albumin level is 5 g/dL. HbA₁c values and fructosamine are highly correlated. The following relationship between fructosamine levels and HbA₁c, has been reported based on linear regression analysis:

\[ \text{HbA₁c} = 0.017 \times \text{fructosamine level (μM/L)} + 1.61. \]

Thus fructosamine levels of 317, 375, and 435 are equivalent to HbA₁c values of 7%, 8%, and 9%, respectively.

In most circumstances, however, glycohemoglobin assays remain the preferred method for assessing long-term glycemic control in patients with diabetes.

Oral Glucose Tolerance Test

It is easy to screen for diabetes using an HbA₁c, or a fasting plasma glucose level (see Table 17–11). The oral glucose tolerance test, therefore, is mostly performed for research studies or when there is a suspicion of the diagnosis but the fasting plasma glucose is less than 126 mg/dL or the HbA₁c level is below 6.5%. The test might be considered, for example, in a woman with a history of delivering an infant above 9 lb (4.1 kg).

In order to optimize insulin secretion and effectiveness, especially when patients have been on a low-carbohydrate diet, a minimum of 150 to 200 g of carbohydrate per day should be included in the diet for 3 days preceding the test. The patient should eat nothing after midnight prior to the test day. Adults are given 75 g of glucose in 300 mL of water; children are given 1.75 g of glucose per kilogram of ideal body weight. The glucose load is consumed within 5 minutes. The test should be performed in the morning because there is some diurnal variation in oral glucose tolerance and patients should not smoke; drink coffee, tea, or alcohol; or be active during the test.

Blood samples for plasma glucose are obtained at 0 and 120 minutes after ingestion of glucose. A fasting plasma glucose value of 126 mg/dL (7 mmol/L) or higher or a 2-hour value of greater than 200 mg/dL (11.1 mmol/L) is diagnostic of diabetes mellitus (see Table 17–11). An oral glucose tolerance test is normal if the fasting venous plasma glucose value is less than 100 mg/dL (5.6 mmol/L) and the 2-hour value falls below 140 mg/dL (7.8 mmol/L). Patients with 2-hour values of 140 to 199 mg/dL have impaired glucose tolerance. False-positive results may occur in patients who are malnourished at test time, bedridden, or afflicted with an infection or severe emotional stress. Diuretics, oral contraceptives, glucocorticoids, excess thyroxine, phenytoin, nicotinic acid, and some of the psychotropic drugs may also cause false-positive results.

Insulin Levels

Normal immunoreactive insulin levels range from 5 to 20 μU/mL in the fasting state. During an oral glucose tolerance test, they reach 50 to 130 μU/mL at 1 hour, and usually return to levels below 30 μU/mL by 2 hours. Insulin measurements are rarely of clinical usefulness. They are principally used in research studies to determine insulin sensitivity.

The homeostasis model of insulin resistance (HOMAᵢᵡ) estimates insulin sensitivity using the following formula:

\[ \text{HOMAᵢᵡ} = \frac{(\text{fasting glucose} \times \text{fasting insulin})}{22.5} \]

The higher the HOMAᵢᵡ value the more resistant the individual. Data from the oral glucose tolerance test can also be used to estimate insulin sensitivity. The Matsuda & DeFronzo Insulin Sensitivity Index is calculated as:

\[ \text{Insulin sensitivity index (ISI)} = \frac{10,000}{\text{square root of } [\text{mean glucose} \times \text{mean insulin during OGTT}]} \]

The lower the ISI the more insulin resistant the subject.

Intravenous Glucose Tolerance Test

The intravenous glucose tolerance test (IVGTT) is performed by giving a bolus of 50 g of glucose per 1.7 m² body surface area (or 0.5 g/kg of ideal body weight) as a 25% or 50% solution over 2 to 3 minutes after an overnight fast. Timing begins with injection and samples for plasma glucose determination are obtained from an indwelling needle in the opposite arm at 0, 10, 15, 20, and 30 minutes. The plasma glucose values are plotted on semilogarithmic paper against time. K, a rate constant that reflects the rate of fall of blood glucose in percent per minute, is calculated by determining the time necessary for the glucose concentration to fall by one-half (t₁/₂) and using the following equation:

\[ K(\text{glucose}) = \frac{0.693}{t_{1/2}} \times 100 \]

The average K value for a nondiabetic patient is approximately 1.72% per minute; this value declines with age but remains above 1.3% per minute. Patients with diabetes almost always have a K value of less than 1% per minute. The disappearance rate reflects the patient’s ability to dispose of a glucose load. Perhaps its most widespread present use is to screen siblings at risk for type 1 diabetes to determine if autoimmune destruction of β cells has reduced first
phase insulin responses (at 1-5 minutes after the glucose bolus) to levels below the normal lower limit of 40 µU/mL.

The IVGTT has been modified by giving a glucose dose of 0.3 g/kg, with more frequent plasma sampling and extending the test to 3 to 4 hours. Also at 20 minutes, a 5-minute infusion of insulin is given (0.03 U/kg for the subject who is likely to be insulin sensitive and 0.06 U/kg for the likely resistant subject). Plasma glucose is sampled at 3, 4, 5, 6, 8, 10, 14, 19, 22, 25, 27, 30, 40, 50, 60, 80, 100, 140, and 180 minutes. Analysis of the time course of glucose and insulin during this frequently sampled IVGTT (FSIVGTT) allows for measurements of insulin sensitivity (Si), that is, fractional glucose clearance per unit insulin concentration; the first phase insulin response (AIRglucose); and glucose effectiveness (Sg), the ability of glucose itself to enhance its own disappearance independent of any change in insulin. The data analysis requires use of specific software (Minmod).

**Lipoproteins in Diabetes**

Levels of circulating lipoproteins are dependent on normal levels and action of insulin, just as is the plasma glucose. In type 1 diabetes, moderately deficient control of hyperglycemia is associated with only a slight elevation of low-density lipoprotein (LDL) cholesterol and serum triglycerides and little if any changes in HDL cholesterol. Once the hyperglycemia is corrected, lipoprotein levels are generally normal. However, patients with type 2 diabetes frequently have a dyslipidemia that is characteristic of the insulin resistance syndrome. Its features are a high serum triglyceride level (300-400 mg/dL), a low HDL cholesterol (<30 mg/dL), and a qualitative change in LDL particles producing a smaller dense LDL whose membrane carries supranormal amounts of free cholesterol. Because low HDL cholesterol is a major feature predisposing to macrovascular disease, the term dyslipidemia has preempted the previous label of hyperlipidemia, which mainly described the elevated triglycerides. Measures designed to correct obesity and hyperglycemia, such as exercise, diet, and hypoglycemic therapy substantially correct the dyslipidemia but most patients require pharmacotherapy. Chapter 19 discusses these matters in detail.

**Clinical Trials in Diabetes**

Findings of the Diabetes Control and Complications Trial (DCCT) and of the United Kingdom Prospective Diabetes Study (UKPDS) have confirmed the beneficial effects of intensive therapy to achieve improved glycemic control in both type 1 and type 2 diabetes, respectively (see later). In addition, with increased understanding of the pathophysiology of both type 1 and type 2 diabetes, large prospective studies—Diabetes Prevention Trial-1 (DPT-1) and the Diabetes Prevention Program (DPP) have been conducted to identify interventions that prevent the onset of these disorders.

**Clinical Trials in Type 1 Diabetes**

**A. The Diabetes Control and Complications Trial (DCCT)** This long-term randomized prospective study of patients with type 1 diabetes reported that lowering of blood glucose levels with intensive insulin therapy delayed the onset and slowed the progression of microvascular and neuropathic complications of diabetes.

More than 1000 patients from 29 medical centers ranging in age from 13 to 39 were divided into two study groups with equal numbers of subjects. Approximately half of the total group had no detectable diabetic complications (primary prevention group), whereas mild background retinopathy was present in the other half (secondary prevention group). Some patients in the latter group also had slightly elevated microalbuminuria and mild neuropathy, but no one with serious diabetic complications was enrolled in the trial. Multiple insulin injections (66%) or insulin pumps (34%) were used in the intensively treated group, and those subjects were trained to modify their therapy in response to frequent glucose monitoring. The conventionally treated group used no more than two insulin injections, and clinical well-being was the goal with no attempt to modify management based on glycated hemoglobin or glucose results.

In the intensively treated subjects, mean glycated hemoglobin of 7.2% (normal, <6%) and a mean blood glucose of 155 mg/dL were achieved, whereas in the conventionally treated group glycated hemoglobin averaged 8.9% and the average blood glucose was 225 mg/dL. Over the study period, which averaged 6.5 years, there was an approximately 60% reduction in risk of diabetic retinopathy, nephropathy, and neuropathy in the intensively treated group. The benefits were seen in both the primary and secondary prevention groups. The intensively treated group also had a nonsignificant reduction in the risk of macrovascular disease of 41% (95% CI, -10%-68%).

Intensively treated patients had a three-fold greater risk of serious hypoglycemia as well as a greater tendency toward weight gain. However, there were no deaths from hypoglycemia in any subjects in the DCCT study, and no evidence of posthypoglycemic neurologic damage was detected.

Subjects participating in the DCCT study were subsequently enrolled in a follow-up observational study (Epidemiology of Diabetes Interventions and Complications [EDIC]). Even though the between group differences in HbA1c narrowed within 4 years, the group assigned to intensive therapy had a lower risk for retinopathy at 4 years and microalbuminuria at 7 to 8 years of post study follow-up. Moreover, by the end of the 11 year follow-up period, the intensive therapy group had significantly reduced risk of any cardiovascular disease events by 42% (95% CI, 9%-23%; p = 0.02). Thus it seems that the benefits of good glycemic control persist even if control deteriorates at a later date.

The general consensus of the ADA is that intensive insulin therapy associated with comprehensive self-management training should become standard therapy in most patients with type 1 diabetes after the age of puberty. Exceptions include those with advanced renal disease and the elderly, because the detrimental risks of hypoglycemia outweigh the benefit of tight glycemic control in these groups. In children under age 7 years, the risk of developing brain damage from hypoglycemia contraindicates attempts at tight glycemic control, particularly because diabetic complications do not seem to occur until some years after the onset of puberty.
B. Diabetes Prevention Trial-1 (DPT-1) This NIH-sponsored multicenter study was designed to determine whether the development of type 1 diabetes could be prevented or delayed by immune intervention therapy. Daily low-dose insulin injections were administered for up to 8 years in first-degree relatives of individuals with type 1 diabetes who were selected as being at high risk for development of type 1 diabetes because of detectable ICAs and reduced early-insulin release. Unfortunately, this immune intervention failed to affect the onset of type 1 diabetes, which was approximately 15% per year in both the treated and control groups. A related study using oral insulin in lower risk first-degree relatives, who had ICAs but whose early insulin release remained intact also failed to show an effect on the onset of type 1 diabetes. After an average of 4.3 years of observation, type 1 diabetes developed in about 35% of persons in both the oral insulin and the placebo groups.

C. Immune intervention trials in new-onset type 1 diabetes At time of diagnosis of type 1 diabetes, patients still have significant β cell function. This explains why soon after diagnosis, patients go into a partial clinical remission (honeymoon) requiring little or no insulin. This clinical remission is short-lived, however, and eventually patients lose all β cell function and have more labile glucose control. Attempts have been made to prolong this partial clinical remission using drugs such as cyclosporine, azathioprine, prednisone, and antithymocyte globulin. These agents, however, have had limited efficacy, and there were concerns about their toxicity and the need for continuous treatment.

More specific strategies for immunosuppression, such as the use of monoclonal antibodies against particular T-cell products, may reduce the hazards of long-term immunotherapy. Phase I/II clinical trials using humanized monoclonal antibodies against CD3, hOKT3y1 (Ala-Ala) (teplizumab), and ChAglyCD3 (orelixizumab) showed efficacy in reducing the decline in insulin production in patients newly diagnosed with type 1 diabetes. The CD3 complex is the major signal transducing element of the T-cell receptor. The anti-CD3 antibodies are believed to modulate the autoimmune response by selectively inhibiting pathogenic T cells and/or by inducing regulatory T cells. Patients were treated with the antibody for 14 days within 6 weeks of diagnosis of type 1 diabetes. One year later, the majority of patients in the treated group had maintained or increased insulin production and improved glycemic control relative to the control group. Larger phase II/III clinical trials are currently in progress.

These and other approaches that selectively modulate the autoimmune T-cell response hold the promise that type 1 diabetes may eventually be preventable without prolonged immunosuppression.

Clinical Trials in Type 2 Diabetes

A. Kumamoto study The Kumamoto study involved a relatively small number of patients with type 2 diabetes (n = 110) who were nonobese and only slightly insulin resistant, requiring less than 30 units of insulin per day for intensive therapy. Over a 6-year period it was shown that intensive insulin therapy, achieving a mean HbA1c of 7.1%, significantly reduced microvascular endpoints compared with conventional insulin therapy, which achieved a mean HbA1c of 9.4%. Cardiovascular events were neither worsened nor improved by intensive therapy, and weight changes were likewise not influenced by either form of treatment.

B. The United Kingdom Prospective Diabetes Study (UKPDS) This multicenter study was designed to determine whether the risk of macrovascular or microvascular complications in patients with type 2 diabetes could be reduced by intensive blood glucose control with oral hypoglycemic agents or insulin and whether any particular therapy was better than the others. Patients aged 25 to 65 years who were newly diagnosed with type 2 diabetes were recruited between 1977 and 1991, and a total of 3867 were studied over 10 years. The median age at baseline was 54 years; 44% were overweight (>20% over ideal weight), and baseline HbA1c was 9.1%. Therapies were randomized to include a control group on diet alone and separate groups intensively treated with insulin, chlorpropamide, glyburide, or glipizide. Metformin was included as a randomization option in a subgroup of 342 overweight patients, and—much later in the study—an additional subgroup of both normal-weight and overweight patients, who were responding unsatisfactorily to sulfonylurea therapy, were randomized to either continue on their sulfonylurea therapy alone or to have metformin combined with it.

After the study was initiated, a further modification was made to evaluate whether tight control of blood pressure with stepwise antihypertensive therapy would prevent macrovascular and microvascular complications in 758 hypertensive patients among this UKPDS population—compared with 390 patients whose blood pressure was treated less intensively. The tight control group was randomly assigned to treatment with either an angiotensin-converting enzyme (ACE) inhibitor (captopril) or a beta blocker (atenolol). Both drugs were stepped up to maximum doses of 100 mg/d, and then, if blood pressure remained higher than the target level of less than 150/85 mm Hg, more drugs were added in the following stepwise sequence—a diuretic, slow-release nifedipine, methyldopa, and prazosin—until the target level of tight control was achieved. In the control group, hypertension was conventionally treated to achieve target levels less than 180/105 mm Hg, but these patients were not given either ACE inhibitors or beta blockers.

Intensive glycemic therapy in the entire group of 3897 patients newly diagnosed with type 2 diabetes patients followed over 10 years showed that intensive treatment with either sulfonylureas, metformin, combinations of these, or insulin achieved mean HbA1c levels of 7.0%. This level of glycemic control decreased the risk of microvascular complications in comparison with conventional therapy (mostly diet alone), which achieved mean levels of HbA1c of 7.9%. Weight gain occurred in intensively treated patients except when metformin was used as monotherapy. There was a trend towards reduction in cardiovascular events (fatal or nonfatal MI; sudden death) with intensive treatment but this did not reach statistical significance (16% reduction, p = 0.052). Hypoglycemic reactions occurred in the intensive treatment
groups, but only one death from hypoglycemia was documented over 27,000 patient-years of intensive therapy.

When therapeutic subgroups were analyzed, some unexpected and paradoxical results were noted. Among the obese patients, intensive treatment with insulin or sulfonylureas did not reduce microvascular complications compared with diet therapy alone. This was in contrast to the significant benefit of intensive therapy with these drugs in the total group. Furthermore, intensive therapy with metformin was more beneficial in the overweight and obese persons than diet alone with regard to reducing myocardial infarctions, strokes, and diabetes-related deaths, but there was no significant reduction of diabetic microvascular complications with metformin as compared with the diet group. Moreover, in the subgroup of obese and non-obese patients in whom metformin was added to sulfonylurea failures, rather than showing a benefit, there was a 96% increase in diabetes-related deaths compared with the matched cohort of patients unsatisfactory glycemic control on sulfonylureas who remained on sulfonylurea therapy. Chlorpropamide also came out poorly on subgroup analysis in that those receiving it as intensive therapy did less well as regards progression to retinopathy than those conventionally treated with diet. The University Group Diabetes Program (UGDP) study was designed to evaluate the effects of glucose-lowering therapies on vascular complications in type 2 diabetes and reported that tolbutamide may increase the risk for cardiovascular deaths. The UKPDS study refutes this concern by failing to confirm any cardiovascular hazard with sulfonylurea treatment.

Intensive antihypertensive therapy to a mean of 144/82 mm Hg had beneficial effects on microvascular disease as well as on all diabetes-related end points, including virtually all cardiovascular outcomes, in comparison with stricter control at a mean of 154/87 mm Hg. In fact, the advantage of reducing hypertension by this amount was substantially more impressive than the benefit that accrued by improving the degree of glycemic control from a mean HbA1c of 7.9% to 7.0%. More than half of the patients needed two or more drugs for adequate therapy of their hypertension, and there was no demonstrable advantage of ACE inhibitor therapy over beta blockers as regards diabetes end points. Use of a calcium channel blocker added to both treatment groups appeared to be safe over the long term in this population with diabetes, despite some controversy in the literature about its safety in such individuals.

The UKPDS researchers, like the DCCT group, performed posttrial monitoring to determine if there were long-term benefits of having been in the intensively treated glucose and blood pressure arms of the study. The between group differences in HbA1c were lost within the first year of follow-up but the reduced risk of development or progression of microvascular complications in the intensively treated group persisted for 10 years (24%, \( p = 0.001 \)). The intensively treated group also had significantly reduced risk for myocardial infarction (15%, \( p = 0.01 \)) and death from any cause (13%, \( p = 0.007 \)) during the follow-up period. The subgroup of overweight or obese subjects who were initially randomized to metformin therapy showed sustained reduction in risk of myocardial infarction and death from any cause in the follow-up period. The between group blood pressure differences disappeared within 2 years of the end of the trial. Unlike the sustained benefits seen with glucose control, there was no sustained benefit from having been in the more tightly controlled blood pressure group. Both blood pressure groups had similar risks for microvascular events and diabetes related end-points in the follow-up period.

Thus, the follow-up of the UKPDS type 2 diabetes cohort showed that, as in type 1 diabetes, the benefits of good glucose control persist even if control deteriorates at a later date. Blood pressure benefits, however, last only as long as the blood pressure is well controlled.

C. Diabetes Prevention Program (DPP) This was a randomized clinical trial in 3234 overweight men and women, aged 25 to 85 years, who showed impaired glucose tolerance. Results from this study indicated that intervention with a low-fat diet and 150 minutes of moderate exercise (equivalent to a brisk walk) per week reduces the risk of progression to type 2 diabetes by 58% as compared with a matched control group. Another arm of this trial demonstrated that use of 850 mg of metformin twice daily reduced the risk of developing type 2 diabetes by 31% but was relatively ineffective in those who were either less obese or in the older age group.

D. The Steno-2 Study This was designed in 1990 to validate the efficacy of targeting multiple concomitant risk factors for both microvascular and macrovascular disorders in type 2 diabetes. A prospective, randomized, open, blinded end-point design was used in which 160 patients with type 2 diabetes and microalbuminuria were assigned to conventional therapy with their general practitioner or to intensive care at the Steno Diabetes Center. In the intensively treated group, stepwise introduction of lifestyle and pharmacologic interventions was aimed at keeping glycated hemoglobin less than 6.5%, blood pressure less than 130/80 mm Hg, total cholesterol less than 175 mg/dL, and triglycerides less than 150 mg/dL. All subjects in the intensively treated group received ACE inhibitors and if intolerant, an angiotensin II receptor blocker. The lifestyle component of intensive intervention included reduction in dietary fat intake to less than 30% of total calories, a smoking cessation program, light to moderate exercise, and a daily vitamin-mineral supplement (vitamins C and E and chromium picolinate). Initially, aspirin was given as secondary prevention to patients with a history of ischemic cardiovascular disease, but later all patients received aspirin.

After a mean follow-up of 7.8 years, 44% of patients in the conventional arm and 24% in the intensive multifactorial arm developed cardiovascular events (myocardial infarction, angioplasties, coronary bypass grafts, strokes, amputations, vascular surgical interventions)—a 53% reduction. Rates of nephropathy, retinopathy, and autonomic neuropathy were also lower in the multifactorial intervention arm—61%, 58%, and 63% of rates in the conventional arm, respectively.

The subjects who participated in this trial were subsequently enrolled in an observational follow-up study for an average of 5.5 years. Even though the significant differences in glycemic control and levels of risk factors for cardiovascular disease between
The data from the UKPDS and this study thus provide support for guidelines recommending vigorous treatment of concomitant microvascular and cardiovascular risk factors in patients with type 2 diabetes.

**E. Accord, Advance, and VADT studies** The ACCORD study was a randomized controlled study designed to determine whether normal HbA1c levels would reduce the risk of cardiovascular events in middle-aged or older individuals with type 2 diabetes. About 35% of the 10,251 recruited subjects had established cardiovascular disease at study entry. The intensive arm of the study was discontinued after 3.5 years of follow-up because of more unexplained deaths in the intensive arm compared to the conventional treatment arm (22%, \( p = 0.020 \)). Analysis of the data at time of discontinuation showed that the intensively treated group (HbA1c 6.4%) had a 10% reduction in cardiovascular event rate compared to the standard treated group (HbA1c 7.5%), but this difference was not statistically significant. The ADVANCE trial randomly assigned 11,140 patients in their 60s with type 2 diabetes to standard or intensive glucose control. The primary outcomes were major macrovascular (nonfatal myocardial infarction or stroke or death from cardiovascular causes) or microvascular events. Thirty-two percent of the subjects had established cardiovascular disease at study entry. After a median follow-up of 5 years, there was a nonsignificant reduction (6%) in major macrovascular event rate in the intensively treated group (HbA1c 6.5%) compared to the standard therapy group (HbA1c 7.3%).

The Veteran Administration Diabetes Trial (VADT) randomly assigned 1791 patients in their 50s and 60s with type 2 diabetes to standard or intensive glucose control. Ninety-seven percent of the subjects were men. The primary outcome was a composite of myocardial infarction, death from cardiovascular causes, congestive heart failure, vascular surgery, inoperable coronary artery disease, and amputation for gangrene. All patients had optimized blood pressure and lipid levels. After a median follow-up of 5.6 years, there was no significant difference in the primary outcome in the intensively treated group (HbA1c 6.9%) compared to the standard therapy (HbA1c 8.4%). Within this larger study, there was an embedded study evaluating the impact of intensive therapy in patients who were categorized as having low, moderate, and high coronary calcium scores on CT scans. Patients with low coronary calcium score showed reduced number of cardiovascular events with intensive therapy.

Thus, the ACCORD, ADVANCE, and VADT results do not provide support for the hypothesis that near-normal glucose control in type 2 diabetes will reduce cardiovascular events. It is, however, important not to over-interpret the results of these three studies. The results do not exclude the possibility that cardiovascular benefits might accrue with longer duration of near-normal glucose control. In the UKPDS, risk reductions for myocardial infarction and death from any cause were only observed during 10 years of posttrial follow-up. Specific subgroups of type 2 diabetes patients may also have different outcomes. The ACCORD, ADVANCE, and VADT studies recruited patients who had diabetes for 8 to 10 years, and a third of them had established cardiovascular disease. Patients in the UKPDS, in contrast, had newly diagnosed diabetes, and only 7.5% had a history of macrovascular disease. It is possible that the benefits of tight glycemic control on macrovascular events are attenuated in patients with longer duration of diabetes or with established vascular disease. Specific therapies used to lower glucose may also affect cardiovascular event rate or mortality. Severe hypoglycemia occurred more frequently in the intensively treated groups of the ACCORD, ADVANCE, and VADT studies; and the ACCORD investigators were not able to exclude undiagnosed hypoglycemia as a potential cause for the increased death rate in their intensive arm group.

A formal meta-analysis performed on the raw trial data from the ACCORD, ADVANCE, VADT, and UKPDS studies found that allocation to more intensive glucose control reduced the risk of MI by 15% (hazard ratio 0.85, 95% CI 0.76-0.94). The benefit appeared to be in patients who did not have preexisting macrovascular disease.

**TREATMENT OF DIABETES MELLITUS**

**Diet**

A well-balanced, nutritious diet remains a fundamental element of therapy for diabetes. However, in more than half of cases, patients with diabetes fail to follow their diets. The American Diabetes Association (ADA) recommends about 45% to 65% of total daily calories in the form of carbohydrates; 25% to 35% in the form of fat (of which less than 7% are from saturated fat), and 10% to 35% in the form of protein. In prescribing a diet, it is important to relate dietary objectives to the type of diabetes. In patients with type 2 diabetes, limiting the carbohydrate intake and substituting some of the calories with monounsaturated fats, such as olive oil, rapeseed (canola) oil, or the oils in nuts and avocados, can lower triglycerides and increase HDL cholesterol. In addition, in those patients with obesity and type 2 diabetes, weight reduction by caloric restriction is an important goal of the diet. Patients with type 1 diabetes or type 2 diabetics who take insulin should be taught carbohydrate counting, so they can administer their insulin bolus for each meal based on its carbohydrate content.

The current recommendations for both types of diabetes continue to limit cholesterol to 300 mg daily, and individuals with LDL cholesterol more than 100 mg/dL should limit dietary cholesterol to 200 mg daily. High protein intake may cause progression of renal disease in patients with diabetic nephropathy; for these individuals, a reduction in protein intake to 0.8 kg/d (or about 10% of total calories daily) is recommended.

Exchange lists for meal planning can be obtained from the American Diabetes Association and its affiliate associations or
from the American Dietetic Association, 216 W. Jackson Blvd., Chicago, IL 60606 (312-899-0040 or http://www.eatright.org).

Special Considerations in Dietary Control

A. Dietary fiber  Plant components such as cellulose, gum, and pectin are indigestible by humans and are termed dietary fiber. Insoluble fibers such as cellulose or hemicellulose increase stool bulk and decrease transit time. Soluble fibers such as gums and pectins, found in beans, oatmeal, or apple skin, can delay glucose absorption and so diminish postprandial hyperglycemia. Although the ADA diet does not require insoluble fiber supplements such as added bran, it recommends foods such as oatmeal, cereals, and beans with relatively high soluble fiber content as stable components of the diet in patients with diabetes. High soluble fiber content in the diet may also have a favorable effect on blood cholesterol levels.

B. Glycemic index  Quantitation of the relative glycemic contribution of different carbohydrate foods has formed the basis of a glycemic index in which the area of blood glucose (plotted on a graph) generated over a 3-hour period following ingestion of a test food containing 50 g of carbohydrate is compared with the area plotted after giving a similar quantity of reference food such as glucose or white bread:

\[
\text{Blood glucose area of test food} \times 100

\text{Blood glucose area of reference food}
\]

White bread is preferred to glucose as a reference standard because it is more palatable and has less tendency to slow gastric emptying by high tonicity, as happens when glucose solution is used. Eating foods with low glycemic index will result in lower glucose levels after meals. Low glycemic index foods have values of 55 or less and include many fruits (apples, oranges) and vegetables, grainy breads, pasta, legumes, milk, and yoghurt. High glycemic index foods have values of 70 and over and include baked potato, white bread, and most white rice. Glycemic index is lowered by the presence of fats and protein when the food is consumed in a mixed meal. Cooking methods can also affect the glycemic index—thus mashed potatoes have a higher glycemic index than baked potato. Since you have to have 50 g of available carbohydrate to measure the glycemic index, you cannot assign glycemic indices to foods which have very little carbohydrate. Even though it may not be possible to accurately predict the impact of the glycemic index of a particular food in the context of a meal, it is still reasonable to choose foods with low glycemic index.

C. Sweeteners  The nonnutritive sweetener saccharin is widely used as a sugar substitute (sweet and low). Aspartame (NutraSweet) consists of two major amino acids, aspartic acid, and phenylalanine, which combine to produce a nutritive sweetener 180 times as sweet as sucrose. A major limitation is its heat lability, which precludes its use in baking or cooking. Sucralose (Splenda) and acesulfame potassium (Sunett, Sweet One, DiabetiSweet) are two other nonnutritive sweeteners that are heat stable and can be used in cooking and baking.

Fructose represents a natural sugar substance that is a highly effective sweetener. It induces only slight increases in plasma glucose levels and does not require insulin for its utilization. However, because of potential adverse effects of large amounts of fructose (up to 20% of total calories) on raising serum cholesterol, triglycerides, and LDL cholesterol, it does not have any advantage as a sweetening agent in the diabetic diet. This does not preclude, however, ingestion of fructose-containing fruits and vegetables or fructose-sweetened foods in moderation.

Sugar alcohols, also known as polyols or polyalcohol, are commonly used as sweeteners and bulking agents. They occur naturally in a variety of fruits and vegetables but are also commercially made from sucrose, glucose, and starch. Examples are sorbitol, xylitol, mannitol, lactitol, isomalt, maltitol, and hydrogenated starch hydrolysates (HSH). They are not as easily absorbed as sugar, so they do not raise blood glucose levels as much as conventional sugars. Therefore, sugar alcohols are often used in food products that are labeled as sugar free, such as chewing gum, lozenges, hard candy, and sugar-free ice cream. However, if consumed in large quantities, they will raise blood glucose and can also cause bloating and diarrhea.

D. Fish oils and other oils  Omega-3 fatty acids in high doses have been shown to lower plasma triglycerides and VLDL cholesterol. They may also reduce platelet aggregation. In the Lyon Diet Heart Study in nondiabetic patients, a high intake of α-linolenic acid was beneficial in secondary prevention of coronary heart disease. This diet, which is rich in vegetables and fruits, also supplies a high intake of natural antioxidants. There is limited clinical information on the use of these oils in patients with diabetes.

AGENTs FOR THE TREATMENT OF HYPERGLYCEMIA

The drugs for treating type 2 diabetes (Table 17-13), other than insulin, fall into several categories. (1) Drugs that act on the sulfonylurea receptor complex of the β cell: sulfonylureas remain the most widely prescribed drugs for treating hyperglycemia. The meglitinide analog repaglinide and the D-phenylalanine derivative nateglinide also bind the sulfonylurea receptor and stimulate insulin secretion. (2) Drugs that principally lower glucose levels by their actions on liver, skeletal muscle, or adipose tissue: metformin works primarily in the liver, and the peroxisome proliferator-activated receptor agonists (PPARs) rosiglitazone and pioglitazone appear to have their main effects on skeletal muscle and adipose tissue. (3) Drugs that principally affect absorption of glucose: the α-glucosidase inhibitors acarbose and miglitol are currently available drugs in this class. (4) Drugs that mimic incretin effects or prolong incretin action: the GLP-1 receptor agonists and the DPP-4 inhibitors fall into this category. (5) Other drugs: these include pramlintide, which lowers glucose by suppressing glucagon and slowing gastric emptying.

</table>
1. DRUGS THAT ACT ON THE SULFONYLUREA RECEPTOR COMPLEX
Sulfonylureas

The sulfonylureas contain a sulfonic acid-urea nucleus that can be modified by chemical substitutions to produce agents that have similar qualitative actions but differ widely in potency. They bind the ATP-sensitive potassium channels (K\textsubscript{ATP}) on the surface of pancreatic β cells, resulting in closure of the channel and depolarization of the β cell. This depolarized state permits calcium to enter the cell and actively promote insulin release (Figure 17-5).

In β cells, the ATP-sensitive channels contain four copies each of two subunits, the regulatory subunit SUR1, which binds ATP, ADP, and sulfonylureas, and the potassium channel subunit Kir6.2. K\textsubscript{ATP} channels composed of the same subunits are found in α cells, GLP-1 secreting intestinal L-cells, and the brain. The SUR1/Kir6.2 complexes are opened by diazoxide and closed by sulfonylureas at low concentrations (IC\textsubscript{50} about 1 nM for glyburide). Inactivating mutations in SUR1 or Kir6.2 cause persistent depolarization of the β cells and have been identified in patients with hyperinsulinemic hypoglycemia of infancy (see Chapter 18). Activating mutations in SUR1 or Kir6.2 prevent depolarization of the β cells and have been identified in patients with neonatal diabetes (see section on Neonatal Diabetes earlier).

K\textsubscript{ATP} channels with different subunit combinations are found in other tissues. The combination of SUR2A/Kir6.2 is found in cardiac and skeletal muscle, and SUR2B/Kir6.1 in vascular smooth muscle. Channel configurations containing SUR2 subunits are insensitive to diazoxide but sensitive to other potassium channel agonists such as pinacidil and cromakalim. Certain channel closers have much higher affinity for SUR1-containing channels than SUR2-containing channels (the sulfonylureas tolbutamide and gliclazide and the meglintides nateglinide and mitiglinide), while others have similar affinities for both of them (glyburide, glimepiride, and repaglinide). It remains uncertain whether the different affinities of these drugs for the two classes of receptors have clinical relevance.

Sulfonylureas are not indicated for use in type 1 diabetes patients since these drugs require functioning pancreatic β cells to produce their effect on blood glucose. These drugs are used in patients with type 2 diabetes, in whom acute administration improves the early phase of insulin release that is refractory to acute glucose stimulation. Sulfonylureas are metabolized by the liver and apart from acetohexamide, whose metabolite is more active than the parent compound, their effect on blood glucose is independent of renal function, tolbutamide is probably the safest agent to use in elderly patients, in whom hypoglycemia would be a particularly serious risk. Prolonged hypoglycemia has been reported rarely, mainly in patients receiving certain drugs (eg, warfarin, phenylbutazone, or sulfonylides) that compete with sulfonylureas for hepatic oxidation, resulting in maintenance of high levels of unmetabolized active sulfonylureas in the circulation.

Tolazamide, acetohexamide, and chlorpropamide are rarely used. Chlorpropamide has a prolonged biologic effect, and severe hypoglycemia can occur especially in the elderly, because their renal clearance declines with aging. Its other side effects include alcohol-induced flushing and hyponatremia due to its effect on vasopressin secretion and action. Tolazamide is comparable to chlorpropamide in potency but is devoid of disulfiram-like or water-retaining effects. Its duration of action may last up to 20 hours, with maximal hypoglycemic effect occurring between the 4th and 14th hours.

Second-generation sulfonylureas: glyburide, glipizide, gliclazide, and glimepiride—these agents have similar chemical structures, with cyclic carbon rings at each end of the sulfonylurea nucleus; this causes them to be highly potent (100- to 200-fold more so than tolbutamide). The drugs should be used with caution in patients with cardiovascular disease as well as in elderly patients, in whom hypoglycemia would be especially dangerous.

a. Glyburide (glibenclamide)—Glyburide is supplied in tablets containing 1.25, 2.5, and 5 mg. The usual starting dose is 2.5 mg/d, and the average maintenance dose is 5 to 10 mg/d given as a single morning dose. If patients are going to respond to glyburide, they generally do so at doses of 10 mg/d or less, given once daily. If they fail to respond to 10 mg/d, it is uncommon for an increase in dosage to result in improved glycemic control. Maintenance doses higher than 20 mg/d are not recommended and may even worsen hyperglycemia. Glyburide is metabolized in the liver into products with such low hypoglycemic activity that they are considered clinically unimportant unless renal excretion is compromised. Although assays specific for the unmetabolized compound suggest a plasma half-life of only 1 to 2 hours, the biologic effects of glyburide clearly persist for 24 hours after a single morning dose in diabetic patients. Glyburide is unique among sulfonylureas in that it not only binds to the pancreatic β cell membrane sulfonylurea receptor but also becomes sequestered within the β cell. This may also contribute to its prolonged biologic effect despite its relatively short circulating half-life.

A formulation of micronized glyburide, which apparently increases its bioavailability, is available in easy to divide tablet sizes of 1.5, 3, and 6 mg.

Glyburide has few adverse effects other than its potential for causing hypoglycemia. It should not be used in patients with liver failure and renal failure because of the risk of hypoglycemia. Elderly patients are at particular risk of hypoglycemia even with relatively small daily doses. For this reason, drugs with a shorter half-life (eg, tolbutamide or possibly glipizide) are preferable in the treatment of type 2
diabetes in the elderly patient. Glyburide does not cause water retention, as chlorpropamide does, and even slightly enhances free water clearance.

b. Glipizide (glydiazinamide)—Glipizide is supplied in tablets containing 5 and 10 mg. For maximum effect in reducing postprandial hyperglycemia, this agent should be ingested 30 minutes before breakfast, because rapid absorption is delayed when the drug is taken with food. The recommended starting dose is 5 mg daily but 2.5-mg dose may be sufficient in elderly patients with early diabetes. The dose can gradually be increased by 2.5 or 5-mg increments. Although as much as 15 mg can be given as a single daily dose before breakfast, most patients do better with divided dosing, taking 5 mg before each meal or taking 10 mg before breakfast and before dinner. The maximum recommended dose is 40 mg/d, although doses above 20 mg probably provide little additional benefit in poor responders. Because of its lower potency and shorter half-life, it is preferable to glyburide in elderly patients. At least 90% of glipizide is metabolized in the liver to inactive products, and only a small fraction is excreted unchanged in the urine. Glipizide therapy is contraindicated in patients with liver failure.

Glipizide is also available as a slow-release preparation (Glucotrol-XL, 2.5, 5, and 10-mg tablets). The medication is enclosed in a nonabsorbable shell that contains an osmotic compartment that expands slowly, thereby slowly pumping out the glipizide in a sustained manner. It provides extended release during transit through the gastrointestinal tract, with greater effectiveness in lowering of prebreakfast hyperglycemia than the shorter duration, immediate-release standard glipizide tablets. However, this formulation appears to have sacrificed glipizide’s reduced propensity for severe hypoglycemia compared with longer acting glyburide without showing any demonstrable therapeutic advantages over glyburide.

c. Gliclazide (not available in the United States)—This drug is another intermediate duration sulfonylurea with a duration of action of about 12 hours. It is available as 80-mg tablets. The recommended starting dose is 40 to 80 mg/d with a maximum dose of 320 mg. Doses of 160 mg and above are given as divided doses before breakfast and dinner. The drug is metabolized by the liver, and the metabolites and conjugates have no hypoglycemic effect. An extended-release preparation is also available.

d. Glimepiride—This sulfonylurea is supplied in tablets containing 1, 2, and 4 mg. It has a long duration of effect with a half-life of 5 hours, allowing once-daily administration. Glimepiride achieves blood glucose lowering with the lowest dose of any sulfonylurea compound. A single daily dose of 1 mg/d has been shown to be effective, and the maximal recommended dose is 8 mg. It is completely metabolized by the liver to relatively inactive metabolic products.

**Meglitinide Analogs**

Repaglinide is supplied as 0.5, 1, and 2-mg tablets. Its structure is similar to that of glyburide but lacks the sulfonic acid-urea moiety. It also acts by binding to the sulfonylurea receptor and closing the ATP-sensitive potassium channel. It is rapidly absorbed from the intestine and then undergoes complete metabolism in the liver to inactive biliary products, giving it a plasma half-life of less than 1 hour. The drug therefore causes a brief but rapid pulse of insulin. The starting dose is 0.5 mg three times a day 15 minutes before each meal. The dose can be titrated to a maximum daily dose of 16 mg. Like the sulfonylureas, repaglinide can be used in combination with metformin. Hypoglycemia is the main side effect. In clinical trials, when the drug was compared with glyburide, a long-acting sulfonylurea, there was a trend toward less hypoglycemia. Like the sulfonylureas, it causes weight gain. Metabolism is by the cytochrome P4503A4 isoenzyme. Other drugs that induce or inhibit this isoenzyme may increase or inhibit the metabolism of repaglinide. The drug may be useful in patients with renal impairment or in the elderly.

Mitiglinide is a benzylsuccinic acid derivative that is very similar to repaglinide in its clinical effects. It binds to the sulfonylurea receptor causing a brief pulse of insulin. It is given as a 5 or 10-mg dose just before a meal and reduces the postprandial rise in blood glucose. It has been approved for use in Japan.

**δ-Phenylalanine Derivative**

Nateglinide is supplied in tablets of 60 and 120 mg. This drug binds the sulfonylurea receptor and closes the ATP-sensitive potassium channel. The drug is rapidly absorbed from the intestine, reaching peak plasma levels within 1 hour. It is metabolized in the liver and has a plasma half-life of about 1.5 hours. Like repaglinide, it causes a brief rapid pulse of insulin, and when given before a meal, it reduces the postprandial rise in blood glucose. The 60-mg dose is used in patients with mild elevations in HbA1c. For most patients, the recommended starting and maintenance dosage is 120 mg three times a day before meals. Like the other insulin secretagogues, its main side effects are hypoglycemia and weight gain.

### 2. DRUGS THAT ACT ON INSULIN TARGET TISSUES

**Metformin**

Metformin (1,1-diethylbiguanide hydrochloride) is used, either alone or in conjunction with other oral agents or insulin, in the treatment of patients with type 2 diabetes.

Metformin acts primarily through AMPK (Figure 17–8), which it activates by uncoupling mitochondrial oxidative phosphorylation and increasing cellular AMP levels. Metformin’s therapeutic effects primarily derive from its effects on the liver, where increased AMPK activity reduces hepatic gluconeogenesis and lipogenesis. Metformin is a substrate for organic cation transporter 1, which is abundantly expressed in hepatocytes and in the gut.

Metformin has a half-life of 1.5 to 3 hours, does not bind to plasma proteins, and is not metabolized in humans, being excreted unchanged by the kidneys.

Metformin is the first-line therapy for patients with type 2 diabetes. The current recommendation is to start this drug at diagnosis. A side benefit of metformin therapy is its tendency to improve both fasting and postprandial hyperglycemia and hyperglycemia in obese patients with diabetes without the weight gain associated with insulin or sulfonylurea therapy. Metformin is ineffective in patients with type 1 diabetes. Patients with renal failure (calculated GFR less than 50 mL/min) should not get this drug because failure to excrete this drug may produce high blood...
and tissue levels of metformin that would stimulate lactic acid overproduction. Likewise, patients with liver failure or abusers of ethanol should not receive this drug; lactic acid production from the gut and other tissues, which rises during metformin therapy, can result in lactic acidosis when defective hepatocytes cannot remove the lactate or when alcohol-induced reduction of nucleotides interferes with lactate clearance. Finally, metformin is relatively contraindicated in patients with cardiorespiratory insufficiency, because they have a propensity to develop hypoxia that would aggravate the lactic acid production already occurring from metformin therapy. The age cutoff for prescribing metformin has not been defined and remains a function of the overall health of the patient. In general, there is concern that after the age of 65 to 70 years the potential for progressive impairment of renal function or development of a cardiac event while taking metformin raises the risk enough to outweigh the benefits of prescribing the drug for patients with type 2 diabetes.

Metformin is dispensed as 500, 850, and 1000-mg tablets. A 500 and 750-mg extended-release preparation is also available. Eighty-five percent of the maximal glucose-lowering effect is achieved by a daily dose of 1500 mg, and there is little benefit from giving more than 2000 mg daily. It is important to begin with a low dose and increase the dosage very gradually in divided doses—to reduce minor gastrointestinal upsets. A common schedule would be one 500-mg tablet three times a day with meals or one 850-mg or 1000-mg tablet twice daily at breakfast and dinner. The maximum recommended dose is 850 mg three times a day. Up to 2000 mg of the extended-release preparation can be given once a day.

The epithelial cells of the gut efficiently absorb metformin, where it accumulates at high concentrations and causes toxicity due to uncoupling of mitochondrial oxidative phosphorylation and increased lactate production. The most frequent side effects of metformin are gastrointestinal symptoms (anorexia, nausea, vomiting, abdominal discomfort, diarrhea), which occur in up to 20% of patients. These effects are dose-related, tend to occur at onset of therapy, and often are transient. However, in 3% to 5% of patients, therapy may have to be discontinued because of persistent diarrheal discomfort. In a retrospective analysis, it has been reported that patients who switched from immediate-release metformin to a comparable dose of extended-release metformin experienced fewer gastrointestinal side effects.

Absorption of vitamin B₁₂ appears to be reduced during chronic metformin therapy but usually the vitamin B₁₂ levels remain in the normal range. Screening of serum vitamin B₁₂ levels should be considered if the patient develops a macrocytic anemia or if the patient develops peripheral neuropathy symptoms. Hypoglycemia does not occur with therapeutic doses of metformin, which permits its description as a euglycemic or anhypoglycemic drug rather than an oral hypoglycemic agent. Dermatologic or hematologic toxicity is rare.

Lactic acidosis has been reported as a side effect but is uncommon with metformin in contrast to phenformin. Metformin both increases lactate production by uncoupling mitochondrial oxidative phosphorylation, especially in the gut, and reduces lactate removal by the liver by blocking gluconeogenesis. At therapeutic doses of metformin, serum lactate levels rise only minimally if at all, since other organs such as the kidney can remove the slight excess. However, if tissue hypoxia occurs, the metformin-treated patient is at higher risk for lactic acidosis due to compromised lactate removal. Similarly, when kidney function deteriorates, affecting not only lactate removal by the kidney but also metformin excretion, plasma levels of metformin rise far above the therapeutic range and can increase lactate production and block hepatic uptake sufficiently to provoke lactic acidosis even in the absence of other causes of increased lactic acid production. Acute renal failure can occur rarely following radiocontrast administration. Metformin therapy should therefore be temporarily halted on the day of radiocontrast administration and restarted a day or two later after confirmation that renal function is normal. Almost all reported cases of lactic acidosis have involved subjects with associated risk factors that should have contraindicated its use (kidney, liver, or cardiorespiratory insufficiency, alcoholism, advanced age).

**Peroxisome Proliferator–Activated Receptor Agonists**

Thiazolidinediones are insulin sensitizers exerting their antidiabetic effects through the activation of PPARγ (see discussion on PPAR nuclear receptors in insulin action and insulin resistance earlier). Observed effects of thiazolidinediones include increased glucose transporter expression (GLUT 1 and GLUT 4); decreased free fatty acid levels; decreased hepatic glucose output; increased adiponectin and decreased resistin release from adipocytes; and increased differentiation of preadipocytes into adipocytes. They have also been demonstrated to decrease levels of plasminogen activator inhibitor type 1, matrix metalloproteinase 9, C-reactive protein, and interleukin-6. Like the biguanides, this class of drugs does not cause hypoglycemia. Pioglitazone, the first drug in this class to go into widespread clinical use, was withdrawn from clinical use because of drug-associated fatal liver failure.

Two other drugs in the same class are available for clinical use: *rosiglitazone* and *pioglitazone*. Both are effective as monotherapy and in combination with sulfonylureas, metformin, or insulin. When used as monotherapy, these drugs lower HbA₁c by about 1 to 2 percentage points. When used in combination with insulin, they can result in a 30% to 50% reduction in insulin dosage, and some patients can come off insulin completely. The combination of a thiazolidinedione and metformin has the advantage of not causing hypoglycemia. Patients inadequately managed on sulfonylureas can do well on a combination of sulfonylurea and rosiglitazone or pioglitazone. About 25% of patients in clinical trials fail to respond to these drugs, presumably because they are significantly insulinopenic.

In addition to glucose-lowering, the thiazolidinediones have effects on lipids and other cardiovascular risk factors. Rosiglitazone therapy is associated with increases in total cholesterol, LDL cholesterol (15%), and HDL cholesterol (10%). There is a reduction in free fatty acids of about 8% to 15%. The changes in triglycerides were generally not different from placebo. Pioglitazone in clinical trials lowered triglycerides (9%) and increased HDL cholesterol (15%) but did not cause a consistent change in total cholesterol.
cholesterol and LDL cholesterol levels. A prospective randomized comparison of the metabolic effects of pioglitazone and rosiglitazone in patients who had previously taken troglitazone (now withdrawn from clinical use) showed similar effects on HbA1c and weight gain. Pioglitazone-treated subjects, however, had lower total cholesterol, LDL cholesterol, and triglyceride levels when compared with rosiglitazone. A study in patients with type 2 diabetes who were not on lipid-lowering therapy has recently confirmed this difference in lipid-lowering effects of the two thiazolidinediones. Small prospective studies have also shown that treatment with these drugs leads to improvement of biochemical and histological features of nonalcoholic fatty liver disease. The thiazolidinediones also may limit vascular smooth muscle proliferation after injury and there are reports that troglitazone and pioglitazone reduce neointimal proliferation after coronary stent placement. Also, in one double-blind, placebo-controlled study, rosiglitazone was shown to be associated with a decrease in the ratio of urinary albumin to creatinine.

The dosage of rosiglitazone is 4 to 8 mg daily and of pioglitazone 15 to 45 mg daily, and the drugs do not have to be taken with food. Rosiglitazone is primarily metabolized by the CYP 2C8 isoenzyme and pioglitazone is metabolized by CYP 2C8 and CYP 3A4.

Safety concerns and some troublesome side effects have emerged about this class of drugs that limit their use.

A meta-analysis of 42 randomized clinical trials with rosiglitazone suggested that this drug increases the risk of angina pectoris or myocardial infarction. A meta-analysis of clinical trials with pioglitazone did not show a similar finding. Although conclusive data are lacking, the European Medicines Agency has suspended the use of rosiglitazone in Europe. In the United States, the FDA has mandated that it can be prescribed to new patients only if they are unable to achieve glucose control on other medications or are unable to take pioglitazone.

Edema occurs in about 3% to 4% of patients receiving monotherapy with rosiglitazone or pioglitazone. The edema occurs more frequently (10%-15%) in patients receiving concomitant insulin therapy and may result in congestive heart failure. The drugs are contraindicated in diabetic individuals with New York Heart Association class III and IV cardiac status. Thiazolidinediones have also rarely been reported as being associated with new onset or worsening macular edema which resolved or improved once the drug was discontinued.

In experimental animals, rosiglitazone stimulates bone marrow adipogenesis at the expense of osteoblastogenesis resulting in a decrease in bone mineral density. An increase in fracture risk in women (but not men) has been reported with both rosiglitazone and pioglitazone. The fracture risk is in the range of 1.9 per 100 patient-years with the thiazolidinedione. In at least one study of rosiglitazone, the fracture risk was increased in premenopausal as well as postmenopausal women. This increased risk for fractures is perhaps the most important reason for limiting the use of this class of drugs.

Other side effects include anemia, which occurs in 4% of patients treated with these drugs; it may be due to a dilutional effect of increased plasma volume rather than a reduction in red cell mass. Weight gain occurs, especially when the drug is combined with a sulfonylurea or insulin. Some of the weight gain is fluid retention, but there is also an increase in total fat mass. In preclinical studies with pioglitazone, bladder tumors were observed in male rats receiving clinically relevant doses of the medication. In a planned five-interim analysis of data from a long term observational cohort there was no overall increased risk of bladder cancer with pioglitazone therapy. However, increased bladder cancer risk was observed with increasing dose and duration of pioglitazone use, reaching statistical significance after 24 months of exposure.

Troglitazone, the first drug in this class, was withdrawn from clinical use because of drug-associated fatal liver failure. The two currently available agents, rosiglitazone and pioglitazone, have thus far not caused hepatotoxicity. The FDA has, however, recommended that patients should not initiate drug therapy if there is clinical evidence of active liver disease or pretreatment elevation of the alanine aminotransferase (ALT) level that is 2.5 times greater than the upper limit of normal. Obviously, caution should be used in initiation of therapy in patients with even mild ALT elevations. Liver biochemical tests should be performed prior to initiation of treatment and periodically thereafter.

3. DRUGS THAT AFFECT GLUCOSE ABSORPTION

Alpha-Glucosidase Inhibitors

Drugs of this family are competitive inhibitors of intestinal brush border α-glucosidases. Two of these drugs, acarbose and miglitol, are available for clinical use in the United States. Voglibose, another α-glucosidase inhibitor, is available in Japan, Korea, and India. Acarbose and miglitol are potent inhibitors of glucoamylase, α-amylase, and sucrase. They are less effective on isomaltase and are ineffective on trehalase or lactase. Acarbose binds 1000 times more avidly to the intestinal disaccharidases than do products of carbohydrate digestion or sucrose. A fundamental difference exists between acarbose and miglitol in their absorption. Acarbose has the molecular mass and structural features of a tetrascarhide, and very little (~2%) crosses the microvillar membrane. Miglitol, however, is structurally similar to glucose and is absorbable. Both drugs delay the absorption of carbohydrates and reduce postprandial glycemic excursion.

a. Acarbose is available as 50 and 100-mg tablets. The recommended starting dose is 50 mg twice daily, gradually increasing to 100 mg three times daily. For maximal benefit on postprandial hyperglycemia, acarbose should be given with the first mouthful of food ingested. In diabetic patients it reduces postprandial hyperglycemia by 30% to 50%, and its overall effect is to lower the HbA1c by 0.5% to 1%. The principal adverse effect, seen in 20% to 30% of patients, is flatulence. This is caused by undigested carbohydrate reaching the lower bowel, where gases are produced by bacterial flora. In 3% of cases, troublesome diarrhea occurs. This gastrointestinal discomfort tends to discourage excessive carbohydrate consumption and promotes improved compliance of patients with type 2 diabetes with their diet prescriptions.

When acarbose is given alone, there is no risk of hypoglycemia. However, if combined with insulin or sulfonylureas, it may increase risk of hypoglycemia from these agents. A slight rise in hepatic aminotransferases has been noted in clinical trials (5% vs 2% in placebo controls, and
particularly with doses >300 mg/d). This generally returns to normal on stopping this drug. In the UKPDS, approximately 2000 patients on diet, sulfonylurea, metformin, or insulin therapy were randomized to acarbose or placebo therapy. By 3 years, 60% of the patients had discontinued the drug, mostly because of gastrointestinal symptoms. In the 40% of patients who remained on the drug, acarbose was associated with a 0.5% lowering of HbA1c compared with placebo.

b. Miglitol is similar to acarbose in terms of its clinical effects. It is indicated for use in diet- or sulfonylurea-treated patients with type 2 diabetes. Therapy is initiated at the lowest effective dosage of 25 mg three times a day. The usual maintenance dose is 50 mg three times a day, although some patients may benefit from increasing the dose to 100 mg three times a day. Gastrointestinal side effects occur as with acarbose. The drug is not metabolized and is excreted unchanged by the kidney. Theoretically, absorbable α-glucosidase inhibitors could induce a deficiency of one or more of α-glucosidases involved in cellular glycogen metabolism and biosynthesis of glycoproteins. This does not occur in practice because—unlike the intestinal mucosa, which is exposed to a high concentration of the drug—circularizing plasma levels are 200-fold to 1000-fold lower than those needed to inhibit intracellular α glucosidases. Miglitol should not be used in renal failure because its clearance is impaired in this setting.

4. INCRETINS

The gut makes several incretins, gut hormones that amplify postprandial insulin secretion, including glucagon-like peptide-1 (GLP-1, Figure 17−9) and glucose-dependent insulinoctropic polypeptide (GIP). Therapeutic drugs in this class include GLP-1 receptor agonists and dipeptidyl peptidase 4 (DPP-4) inhibitors, which increase levels of both GLP-1 and GIP.

When GLP-1 is infused in patients with type 2 diabetes, it stimulates insulin secretion and lowers glucose levels. GLP-1, unlike the sulfonylureas, has only a modest insulin stimulatory effect under normoglycemic conditions. This means that GLP-1 administration has a lower risk of causing hypoglycemia than the sulfonylureas. GLP-1, in addition to its insulin stimulatory effect, also has a number of other pancreatic and extrapancreatic effects (see Table 17−4).

GLP-1 Receptor Agonists

GLP-1 is rapidly proteolyzed by DPP-4 and by other enzymes such as endopeptidase 24.11. It is also cleared rapidly by the kidney. As a result, the half-life of GLP-1 is only 1 to 2 minutes. The native peptide, therefore, cannot be used therapeutically. Instead, the approach taken has been to develop metabolically stable analogs or derivatives of GLP-1 that are not subject to the same enzymatic degradation or renal clearance. Two GLP-1 receptor agonists, exenatide and liraglutide, are currently available for clinical use.

a. Exenatide or exendin 4 is a GLP-1 receptor agonist isolated from the saliva of the Gila monster (a venomous lizard) that is resistant to DPP-4 action and is cleared from the plasma by glomerular filtration. When given to patients with type 2 diabetes by subcutaneous injection twice a day, this compound lowers blood glucose and HbA1c levels. Exenatide appears to have the same effects as GLP-1 on glucagon suppression and gastric emptying. In clinical trials, adding exenatide to the therapeutic regimen of patients with type 2 diabetes who are already taking metformin or a sulfonylurea (or both) further lowered the HbA1c value by 0.4% to 0.6% over a 30-week period. These patients also lost 3 to 6 lb in weight. In an open-label extension study up to 80 weeks, the HbA1c reduction was sustained, and there was further weight loss (to a total loss of −10 lb).

The main side effect was nausea, affecting over 40% of patients. The nausea was dose-dependent and declined with time. The risk of hypoglycemia was higher in subjects on sulfonylureas. The delay in gastric emptying may affect the absorption of some other drugs; therefore, antibiotics and oral contraceptives should be taken 1 hour before exenatide doses. Low-titer antibodies against exenatide develop in over one-third (38%) of patients, but the clinical effects are not attenuated. High-titer antibodies develop in a subset of patients (~6%), and in about half of these cases, an attenuation of glycemic response has been seen.

The FDA has received 30 postmarketing reports of acute pancreatitis in patients taking exenatide. The pancreatitis was severe (hemorrhagic or necrotizing) in six instances and two of these patients died. Many of the patients had other risk factors for pancreatitis, but the possibility remains that the drug was causally responsible for some cases. Patients taking exenatide should be advised to seek immediate medical care if they experience unexplained, persistent, severe abdominal pain. The drug should be discontinued if pancreatitis is suspected. The FDA also reported 16 cases of renal impairment and 62 cases of acute renal failure in patients taking exenatide. Some of these patients had preexisting kidney disease and others had one or more risk factors for kidney disease. A number reported nausea, vomiting, and diarrhea and it is possible that these side effects cause volume depletion and contributed to the development of renal failure.

Exenatide is dispensed as two fixed-dose pens (5 and 10 μg). It is injected 60 minutes before breakfast and before dinner. Patients should be prescribed the 5-μg pen for the first month and then, if tolerated, the dose should be increased to 10 μg twice daily. The drug is not recommended in patients with glomerular filtration rate less than 30 mL/min.

b. Liraglutide is a soluble fatty acid acylated GLP-1 analog—with replacement of lysine with arginine at position 34 and the attachment of a C16 acyl chain to a lysine at position 26. The fatty-acyl GLP-1 retains affinity for GLP-1 receptors, but the addition of the C16 acyl chain allows for noncovalent binding to albumin, both hindering DPP-4 access to the molecule and contributing to a prolonged half-life and duration of action. The half-life is approximately 12 hours allowing the drug to be injected once a day.

In clinical trials lasting 26 and 52 weeks, adding liraglutide to the therapeutic regimen (metformin, sulfonylurea, thiazolidinedione) of patients with type 2 diabetes further lowered the HbA1c value. Depending on the dose and design of the study, the HbA1c decline was in the range of 0.6% to 1.5%. The patients had sustained weight loss of 1 to 6 lb.

Like exenatide, the most frequent side effect is nausea and vomiting affecting approximately 10% of subjects. There was also an increase in incidence of diarrhea. About 2% to 5% of subjects withdrew from the studies because of the GI symptoms. Pancreatitis may also occur—in the clinical trials there were seven cases of pancreatitis in the liraglutide-treated group with one case in the comparator group (2.2 vs 0.6 cases per 1000 patient-years). Liraglutide
stimulates C-cell neoplasia and causes medullary thyroid carcinoma in rats. Human C cells express very few GLP-1 receptors and the relevance to human therapy is unclear but because of the animal data, the drug should not be used in patients with personal or family history of medullary thyroid carcinoma or multiple endocrine neoplasia syndrome type 2.

The dosing is initiated at 0.6 mg daily increased after 1 week to 1.2 mg daily. An additional increase in dose to 1.8 mg is recommended if needed for optimal glycemic control. Titration should of course be based on tolerability. There is limited experience using the drug in renal failure but no dose adjustment is recommended.

DPP-4 Inhibitors

An alternative to the use of GLP-1 receptor agonists involves inhibition of the enzyme DPP-4 with prolongation of the action of endogenously released GLP-1 and GIP. Two oral DPP-4 inhibitors, sitagliptin and saxagliptin, are available for the treatment of type 2 diabetes in the United States. An additional DPP-4 inhibitor, Vildagliptin, is available in Europe.

a. Sitagliptin in clinical trials was shown to be effective in lowering glucose when used alone and in combination with metformin and pioglitazone. In various clinical trials, improvements in HbA1c ranged from 0.5% to 1.4%. The usual dose of sitagliptin is 100 mg once daily, but the dose is reduced to 50 mg daily if the calculated creatinine clearance is 30 to 50 mL/min and to 25 mg for clearances less than 30 mL/min. Unlike exenatide, sitagliptin does not cause nausea or vomiting. It also does not result in weight loss. The main adverse effect appears to be a predisposition to nasopharyngitis or upper respiratory tract infection. A small increase in neutrophil count of approximately 200 cells/mL has also occurred. Since its FDA approval and clinical use, there have been reports of serious allergic reactions to sitagliptin, including anaphylaxis, angioedema, and exfoliative skin conditions, including Stevens-Johnson syndrome. There have also been reports of pancreatitis (88 cases including two cases of hemorrhagic or necrotizing pancreatitis). The frequency of these events is unclear. DPP-4 is a pleiotropic enzyme that inactivates a variety of peptide hormones, neuropeptides, and chemokines and DPP-4 inhibitors have been shown to prolong the action of neuropeptide Y and substance P. Whether its inhibition over a long-term period will have negative consequences is not known.

b. Saxagliptin when added to the therapeutic regimen (metformin, sulfonylurea, thiazolidinedione) of patients with type 2 diabetes further lowered the HbA1c value by about 0.7% to 0.9%. The dose is 2.5 or 5 mg once a day. The 2.5-mg dose should be used in patients with calculated creatinine clearance less than 50 mL/min. It lowers HbA1c by about 0.6% when added to metformin, glyburide, or thiazolidinedione in various 24-week clinical trials. The drug is weight neutral. The main adverse reactions were upper respiratory tract infection, nasopharyngitis, headache, and urinary tract infection. There is also small reversible dose-dependent reduction in absolute lymphocyte count which remains within normal limits. Hypersensitivity reactions such as urticaria and facial edema occurred in 1.5% of patients on the drug compared to 0.4% with placebo. The metabolism of saxagliptin is through CYP 3A4/5; so strong inhibitors or inducers of CYP 3A4/5 will affect the pharmacokinetics of saxagliptin and its active metabolite.

c. Vildagliptin, like the other DPP-4 inhibitors, lowers HbA1c by about 0.5% to 1.0% when added to the therapeutic regimen of patients with type 2 diabetes. The dose is 50 mg once a day or twice a day. The adverse reactions include upper respiratory tract infections, nasopharyngitis, dizziness, and headache. Rare cases of hepatic dysfunction including hepatitis have been reported. Liver function testing is recommended, quarterly the first year, and periodically thereafter.

5. OTHERS

Pramlintide is a synthetic analog of islet amyloid polypeptide (IAPP) that when given subcutaneously (1) delays gastric emptying, (2) suppresses glucagon secretion, and (3) decreases appetite. It is approved for use both in type 1 and insulin-treated type 2 patients. In 6-month clinical studies with type 1 and insulin-treated type 2 patients, those on the drug had approximately a 0.4% reduction in HbA1c and lost about 1.7 kg compared to placebo. The HbA1c reduction was sustained for 2 years, but some of the weight was regained. The drug is given immediately before the meal by injection. Hypoglycemia is the most concerning adverse event, and it is recommended that the short-acting or premixed insulin doses be reduced by 50% when the drug is started. Since the drug slows gastric emptying, recovery from hypoglycemia can be a problem because of delay in absorption of the fast-acting carbohydrate. Nausea was the other main side effect, affecting 30% to 50% of subjects. It tended to improve with time. In patients with type 1 diabetes, pramlintide is initiated at the dose of 15 µg before each meal and titrated by 15 µg increments to a maintenance dose of 30 or 60 µg before each meal. In patients with type 2 diabetes, the initiation dose is 60 µg premeals increased to 120 µg in 3 to 7 days if no significant nausea occurs.

A combination of pramlintide and recombinant human leptin (metreleptin) is currently being evaluated in clinical trials for weight loss.

Drug Combinations

A number of drug combinations, glyburide-metformin (Glucomave), glipizide-metformin (Metaglip), repaglinide-metformin (Prandi-Met), rosiglitazone-metformin (Avandamet), pioglitazone-metformin (ACTOplus Met), sitagliptin-metformin (Janumet), saxagliptin-metformin extended release (kombiglyze XR), rosiglitazone-glimepiride (Avandaryl), and pioglitazone-glimepiride (Duetact) are available. These combinations, however, limit the clinician's ability to optimally adjust dosage of the individual drugs and for that reason are of questionable merit.

6. INSULIN

Insulin is indicated for individuals with type 1 diabetes as well as for those with type 2 diabetes whose hyperglycemia does not respond to diet therapy and other diabetes drugs.

Human insulin is now produced by recombinant DNA techniques (biosynthetic human insulin). Animal insulins are no longer
available in the United States. With the availability of highly purified human insulin preparations, immunogenicity has been markedly reduced, thereby decreasing the incidence of therapeutic complications such as insulin allergy, immune insulin resistance, and localized lipoatrophy at the injection site. The insulins are also quite stable and refrigeration while in use is not necessary. During travel, reserve supplies of insulin can be readily transported without significant loss of potency, provided they are protected from extremes of heat or cold.

Insulins in Europe and United States are available only in a concentration of 100 U/mL (U100). Low-dose (0.3 mL) disposable insulin syringes allow for accurate dosing of as low as 1 or 2 U. If extremely low doses of insulin are needed, diluted insulin can be prepared using diluent available from the insulin manufacturer. For use in rare cases of severe insulin resistance in which large quantities of insulin are required, a U500 (500 U/mL) regular human insulin is available from Eli Lilly.

Insulin preparations differ with regard to their time of onset and duration of biologic action (Figure 17–11; Table 17–14).

The short-acting preparations are regular insulin and the rapidly acting insulin analogs (Table 17–15). They are dispensed as clear solutions at neutral pH and contain small amounts of zinc to improve their stability and shelf life. The long-acting preparations are neutral protamine hagedorn (NPH) insulin and the long-acting insulin analogs. NPH insulin is dispensed as a turbid suspension at neutral pH with protamine in phosphate buffer. The long-acting insulin analogs are dispensed as clear solutions; insulin glargine is at acidic pH and insulin detemir is at neutral pH. The rapidly acting insulin analogs and the long-acting insulins are designed for subcutaneous administration, while regular insulin can also be given intravenously. While insulin aspart has been approved for intravenous use (eg, in hyperglycemic emergencies), there is no advantage in using insulin aspart over regular insulin by this route.

It is important to recognize that values given for time of onset of action, peak effect, and duration of action are only approximate and that there is great variability in these parameters from patient to patient and even in a given patient depending on the size of the

*All types of insulin available in the United States are recombinant human or human insulin analog origin. All the insulins are dispensed at U100 concentration. There is an additional U500 preparation of regular insulin.

**FIGURE 17–11** Extent and duration of action of various types of insulin (in a fasting diabetic). Duration of action may be extended considerably when the dose of a given insulin formulation increases above the average therapeutic doses depicted here.
Another desirable feature of rapidly acting insulin analogs is that aspart A. Regular insulin are administered. Intravenous infusions of regular insulin are particularly useful in the treatment of diabetic ketoacidosis and during the perioperative management of insulin-requiring diabetics. Regular insulin is indicated when the subcutaneous insulin requirement is changing rapidly, such as after surgery or during acute infections—although the rapidly acting insulin analogs may be preferable in these situations.

For very insulin-resistant subjects who would otherwise require large volumes of insulin solution, a U500 preparation of human regular insulin is available. Because a U500 syringe is not available, a U100-insulin syringe or tuberculin syringe is used to measure doses. The physician should carefully note dosages in both units and volume to avoid overdosage.

B. Rapidly acting insulin analogs Insulin lispro (Humalog) is an insulin analog produced by recombinant technology, wherein two amino acids near the carboxyl terminal of the B chain have been reversed in position; proline at position B28 has been moved to B29 and lysine has been moved from B29 to B28. Insulin aspart (Novolog) is a single substitution of proline by aspartic acid at position B28. Insulin glulisine (Apidra) differs from human insulin in that the amino acid asparagine at position B3 is replaced by lysine and the lysine in position B29 by glutamic acid. These changes reduce the tendency to form hexamers in these three analogs, in contrast to human insulin. When injected subcutaneously, the analogs quickly dissociate into monomers and are absorbed very rapidly, reaching peak serum values in as soon as 1 hour—in contrast to regular human insulin, whose hexamers require considerably more time to dissociate and become absorbed. The amino acid changes in these analogs do not interfere with their binding to the insulin receptor, with the circulating half-life, or with their immunogenicity, which are all identical to those of human regular insulin.

Clinical trials have demonstrated that the optimal times of preprandial subcutaneous injection of comparable doses of the rapidly acting insulin analogs and of regular human insulin are 20 minutes and 60 minutes before the meal, respectively. Although this more rapid onset of action has been welcomed as a great convenience by patients with diabetes who object to waiting as long as 60 minutes after injecting regular human insulin before they can begin their meal, patients must be taught to ingest adequate absorbable carbohydrate early in the meal to avoid hypoglycemia during the meal. Another desirable feature of rapidly acting insulin analogs is that their duration of action remains at about 4 hours irrespective of dosage. This contrasts with regular insulin, whose duration of action is prolonged when larger doses are used.

The rapidly acting analogs are also commonly used in pumps. In a double-blind crossover study comparing insulin lispro with regular insulin in insulin pumps, persons using insulin lispro had lower HbA1c values and improved postprandial glucose control with the same frequency of hypoglycemia. The concern remains that in the event of pump failure, users of the rapidly acting insulin analogs will have more rapid onset of hyperglycemia and ketosis.

The structural differences between insulin lispro and human insulin may be sufficient to prevent insulin lispro from binding to human insulin antibodies in some patients, and there have been case reports of successful use of insulin lispro in those rare patients who have a generalized allergy to human insulin or who have severe antibody-mediated insulin resistance.

Long-Acting Insulin Preparations

a. Neutral Protamine Hagedorn (NPH), or isophane, insulin is an intermediate-acting insulin in which the onset of action is delayed by combining two parts of soluble crystalline zinc insulin with one part protamine zinc insulin. The mixture has equivalent concentrations of protamine and insulin, so that neither is in excess (isophane). Its onset of action is delayed by 2 to 4 hours, and its peak response is generally reached in about 8 to 10 hours. Because its duration of action is often less than 24 hours (with a range of 10-20 hours), most patients require at least two injections daily to maintain a sustained insulin effect.

Flocculation of suspended particles may occasionally frost the sides of a bottle of NPH insulin or clump within bottles from which multiple small doses are withdrawn over a prolonged period. This instability is a rare phenomenon and might occur less frequently if NPH human insulin were refrigerated when not in use and if bottles were discarded after 1 month of use. Patients should be vigilant for early signs of frosting or clumping of the NPH insulin, because it indicates a pronounced loss of potency. Several cases of diabetic ketoacidosis have been reported in patients with type 1 diabetes who had inadvertently injecting this denatured insulin.

b. Insulin glargine is an insulin analog in which the asparagine at position 21 of the A chain of the human insulin molecule is replaced by glycine and two arginines are added to the carboxyl terminal of the B chain. The arginines raise the isoelectric point of the molecule close to neutral, making it more soluble in an acidic environment. In contrast, human insulin has an isoelectric point of pH 5.4. Insulin glargine is a clear insulin that, when injected into the neutral pH environment of the subcutaneous tissue, forms micro-precipitates that slowly release the insulin into the circulation. It lasts for about 24 hours without any pronounced peaks and is given once a day to provide basal coverage. This insulin cannot be mixed with the other insulins because of its acidic pH. When this insulin was given as a single injection at bedtime to type 1 diabetes patients, fasting hyperglycemia was better controlled when compared with bedtime NPH insulin. The clinical trials also suggest that there may be less nocturnal hypoglycemia with this insulin when compared with NPH insulin.

In one clinical trial involving patients with type 2 diabetes, insulin glargine was associated with a slightly more rapid progression of retinopathy when compared with NPH
insulin. The frequency was 7.5% with the analog and 2.7% with the NPH. This observation was not confirmed in a 5-year open-label prospective study of 1024 subjects randomized to NPH or insulin glargine. There was no increase in the risk of progression of retinopathy with the analog insulin.

In in vitro studies, insulin glargine has a sixfold greater affinity for the IGF-1 receptor compared with the human insulin. There has also been a report that insulin glargine has increased mitogenicity compared with human insulin in a human osteosarcoma cell line. Circulating levels of insulin glargine, however, are low, and the clinical significance of these observations is not yet clear. An observational study from Germany of 127,031 patients who had exposure to regular insulin, short-acting insulin analogs, and insulin glargine reported a strong correlation between increased insulin dose and cancer risk. Moreover, insulin glargine, dose for dose, appeared to carry a higher risk than regular insulin. Additional studies are needed to confirm or refute this observation. Because of lack of safety data, use of insulin glargine during pregnancy is not recommended.

c. Insulin detemir is an insulin analog in which the tyrosine at position 30 of the B chain has been removed and a 14-C fatty acid chain (tetradecanoic acid) is attached to the lysine at position 29 by acylation. The fatty acid chain makes the molecule more lipophilic than native insulin, and the addition of zinc stabilizes the molecule and leads to formation of hexamers. After injection, self-association at the injection site and albumin binding in the circulation via the fatty acid side chain lead to slower distribution to peripheral target tissues and prolonged duration of action. The affinity of insulin detemir is four- to fivefold lower than that of human soluble insulin and, therefore, the U100 formulation of insulin detemir has a concentration of 2400 nmol/mL compared to 600 nmol/mL for NPH. The duration of action for insulin detemir is about 17 hours at therapeutically relevant doses. It is recommended that the insulin be injected once or twice a day to achieve a stable basal coverage. Apparently this insulin has been reported to have lower within-subject pharmacodynamic variability compared to NPH insulin and insulin glargine. In vitro studies do not suggest any clinically relevant albumin binding interactions between insulin detemir and fatty acids or protein-bound drugs. Because there is a vast excess (~400,000) of albumin-binding sites available in plasma per insulin detemir molecule, it is unlikely that hypoalbuminemic disease states will affect the ratio of bound to free insulin detemir.

With increasing use of rapid-acting insulin analogs as a preprandial insulin, it has become evident that combination with an intermediate-acting or long-acting insulin is essential to maintain postabsorptive glycemic control. It has been demonstrated that insulin lispro can be acutely mixed with NPH insulin without affecting its rapid absorption. Premixed preparations of insulin lispro and NPH insulin however are unstable because of exchange of insulin lispro with the human insulin in the protamine complex. Consequently, over time, the soluble component becomes a mixture of regular and insulin lispro at varying ratios. In an attempt to remedy this, an intermediate insulin composed of isophane complexes of protamine with insulin lispro was developed and given the name NPL (neutral protamine lispro). Premixed combinations of NPL and insulin lispro are now available for clinical use (Humalog Mix 75/25 and Humalog Mix 50/50). These mixtures have a more rapid onset of glucose-lowering activity compared with 70% NPH/30% regular human insulin mixture and can be given within 15 minutes before or after starting a meal. Similarly, a 70% insulin aspart protamine/30% insulin aspart (NovoLog Mix 70/30) is now available. The main advantages of these new mixtures are that (1) they can be given within 15 minutes of starting a meal and (2) they are superior in controlling the postprandial glucose rise after a carbohydrate-rich meal. These benefits have not translated into improvements in HbA1c levels when compared with the usual 70% NPH/30% regular mixture.

The longer-acting insulin analogs (insulin glargine or insulin detemir) cannot be acutely mixed with either regular insulin or the rapid-acting insulin analogs.

Methods of Insulin Administration

a. Insulin syringes and needles—Disposable plastic syringes with needles attached are available in 1-mL, 0.5-mL, and 0.3-mL sizes. Their finely honed 30- to 31-gauge attached needles have greatly reduced the pain of injections. They are light, not susceptible to damage, and convenient when traveling. Moreover, their clear markings and right plungers allow accurate measurement of insulin dosage. The 

low-dose syringes have become increasingly popular, because most patients take less than 30 U at one injection and also it is available with half unit markings. Two lengths of needles are available: short (8 mm) and long (12.7 mm). Long needles are preferable in obese patients to reduce the variability of insulin absorption.

b. Sites for injection—Any part of the body covered by loose skin can be used as an injection site, including the abdomen, thighs, upper arms, flanks, and upper-outter quadrants of the buttocks. In general, regular insulin is absorbed more rapidly from upper regions of the body such as the deltoid area or the abdomen rather than from the thighs or buttocks. Exercise appears to facilitate insulin absorption when the injection site is adjacent to the exercising muscle. Rotation of sites continues to be recommended to avoid delayed absorption when fibrosis or lipohypertrophy occurs due to repeated use of a single site. However, considerable variability of absorption rates from different regions, particularly with exercise, may contribute to the instability of glycemic control in certain patients with type 1 diabetes if injection
sites are rotated indiscriminately over different areas of the body. Consequently, diabetologists recommend limiting injection sites to a single region of the body and rotating sites within that region. It is possible that some of the stability of glycemic control achieved by infusion pumps may be related to the constancy of the region of infusion from day to day. For most patients, the abdomen is the recommended region for injection because it provides a considerable area in which to rotate sites, and there may be less variability of absorption with exercise than when the thigh or deltoid areas are used. The effect of anatomic regions appears to be much less pronounced with the analogs.

c. Insulin pen injector devices—Insulin pens eliminate the need for carrying insulin vials and syringes. Cartridges of insulin lispro, insulin aspart, and insulin glargine are available for reusable pens (Lilly, Novo Nordisk, and Owen Mumford). Disposable prefilled pens are also available for insulin lispro, insulin aspart, insulin glulisine, insulin detemir, insulin glargine, NPH, 70% NPH/30% regular, 75% NPL/25% insulin lispro, and 70% insulin aspart protamine/30% insulin aspart. Thirty-one-gauge needles (5, 6, and 8-mm long) for these pens make injections almost painless.

d. Insulin pumps—Several small portable open loop pumps for the delivery of insulin are in the market. These devices contain an insulin reservoir and a pump programmed to deliver regular insulin subcutaneously; they do not contain a glucose sensor. With improved methods for self-monitoring of blood glucose at home (see later), these pump systems are becoming increasingly popular. In the United States, Medtronic MiniMed, Insulet, Animas, and Roche insulin infusion pumps are available for subcutaneous delivery of insulin. These pumps are small (about the size of a pager) and easy to program. They have many features, including the ability to record a number of different basal rates throughout a 24-hour period and adjust the time over which bolus doses are given. They are able also to detect pressure build-up if the catheter is kinked. The catheter connecting the insulin reservoir to the subcutaneous cannula can be disconnected so the patient can remove the pump temporarily (eg, for bathing). Ominpod (Insulet Corporation) is an insulin infusion system in which the insulin reservoir and infusion set are integrated into one unit (pod), so it does not use a catheter. The pod, placed on the skin, delivers subcutaneous basal and bolus insulin based on wirelessly transmitted instructions from a personal digital assistant.

The great advantage of continuous subcutaneous insulin infusion (CSII) is that it allows for establishment of a basal profile tailored to the patient. The patient, therefore, is able to eat with less regard to timing because the basal insulin infusion should maintain a constant blood glucose level between meals. Also, the ability to adjust the basal makes it easier for the patient to manage glycemic excursions that occur with exercise. The pumps also have software that can assist the patient to calculate boluses based on glucose reading and carbohydrates to be consumed. They also keep track of the time elapsed since last insulin bolus and the patient is reminded of this when he or she attempts to give additional correction bolus before the effect of the previous bolus has worn off (insulin on board feature). This feature reduces the risk of overcorrecting and subsequent hypoglycemia.

CSII therapy is appropriate for patients who are motivated, mechanically adept, educated about diabetes (diet, insulin action, treatment of hypo- and hyperglycemia), and willing to monitor their blood glucose four to six times a day. Known complications of CSII include ketoacidosis, which can occur when insulin delivery is interrupted, and skin infections. Another major disadvantage is the cost and the time demanded of physicians and staff in initiating therapy. Almost all patients use the rapid-acting insulin analogs in their pumps. Clinical trials have shown that when compared with regular insulin, subjects using rapid-acting insulin analogs in pumps had lower HbA1c values and improved post-prandial glucose control with the same frequency of hypoglycemia. There does remain a concern that in the event of pump failure, the insulin analogs could result in more rapid onset of hyperglycemia and ketosis.

e. Inhaled insulin—Exubera, the first inhaled insulin preparation approved by the FDA is no longer available; the manufacturer stopped marketing it because of lack of demand. In clinical trials, Exubera was as effective as subcutaneous regular insulin in controlling postprandial glucose excursions. Physicians, however, were reluctant to prescribe Exubera for a number of reasons, including a lack of long-term safety data on pulmonary function, availability of other insulin delivery systems, cost, lack of insurance coverage, and awkward dosing. The manufacturer also subsequently reported that there were six cases of lung cancer in patients who were on inhaled insulin and one case in the comparator-treated patients. All the patients who developed lung cancer had a history of prior cigarette smoking. There is currently only one pharmaceutical company that is still conducting clinical trials with inhaled insulin (Technosphere insulin, MannKind Corporation).

f. Pancreas transplantation—This transplantation done at the time of renal transplantation is becoming more widely accepted. Patients undergoing simultaneous pancreas and kidney transplantation have an 85% chance of pancreatic graft survival and a 92% chance of renal graft survival after 1 year. About 1200 pancreas transplants are performed yearly in the United States. About 75% of the transplants are performed at the same time as the kidney transplant with both organs from the same donor. About 15% of the pancreas transplants are performed after a previously successful kidney transplant and 10% are performed without a kidney transplant. Solitary pancreatic transplantation in the absence of a need for renal transplantation should be considered only in those rare patients who fail all other insulin therapeutic approaches and who have frequent severe hypoglycemia or who have life-threatening complications related to their lack of metabolic control.

Islet cell transplantation—This is a minimally invasive procedure, and investigators in Edmonton, Canada, reported initial insulin independence in a small number of patients with type 1 diabetes, who underwent this procedure. Using islets from multiple donors and steroid-free immunosuppression, percutaneous transhepatic portal vein transplantation of islets was achieved in more than 20 subjects. Several centers around the world have successfully replicated this experience. Unfortunately, although all of the initial cohorts achieved insulin independence posttransplantation, some for more than 2 years of follow-up, a decline in insulin secretion occurred with time, and the subjects have again required supplemental insulin. However, patients with successful transplants had complete correction of severe hypoglycemic reactions, leading to a marked improvement in overall quality of life. Islet transplant trials with different immunosuppressive regimens are currently underway. Even if long-term insulin independence is demonstrated, wide
application of this procedure for the treatment of type 1 diabetes is limited by the dependence on multiple donors and the requirement for potent long-term immunotherapy.

**STEPS IN THE MANAGEMENT OF THE DIABETIC PATIENT**

**History and Examination**

A complete history is taken and a physical examination is performed for diagnostic purposes and to rule out the presence of coexisting or complicating disease. Nutritional status should be noted, particularly if catabolic features such as progressive weight loss are present despite a normal or increased food intake. The family history should include not only the incidence but also the age at onset of diabetes in other members of the family, and it should be noted whether affected family members were obese, whether they required insulin, and whether they developed complications from their diabetes. Other factors that increase cardiovascular risk, such as a smoking history, presence of hypertension or hyperlipidemia, or oral contraceptive pill use should be documented.

A careful physical examination should include baseline height and weight, pulse rate, and blood pressure. If obesity is present, it should be characterized as to its distribution, and a waist-to-hip ratio should be recorded. All peripheral arterial pulses should be examined, noting whether bruits or other signs of atherosclerotic disease are present. Neurologic and ophthalmologic examinations should be performed, with emphasis on investigation of abnormalities that may be related to diabetes, such as neovascularization of the retina or stocking/glove sensory loss in the extremities.

**Laboratory Diagnosis**

See also Laboratory Testing in diabetes mellitus earlier. Laboratory diagnosis should include documentation of the presence of fasting hyperglycemia (plasma glucose ≥126 mg/dL [7 mmol/L]), postprandial (post-glucose tolerance test) values consistently ≥200 mg/dL (11.1 mmol/L) or HbA1c ≥6.5%. An attempt should be made to characterize the diabetes as type 1 or type 2, based on the clinical features present and on whether ketonuria accompanies the glycosuria. For the occasional patient, measurement of ICA, ICA 512, GAD, and insulin antibodies can help in distinguishing between type 1 and type 2 diabetes. Many newly diagnosed patients with type 1 diabetes still have significant endogenous insulin production, and C-peptide levels may not reliably distinguish between type 1 and type 2 diabetes. Other baseline laboratory measurements that should be made part of the record include hemoglobin A1c, lipid profile, serum creatinine and electrolytes, complete blood count, electrocardiogram, and urine albumin measurement (type 2 patient).

**Patient Education and Self-Management Training**

Since diabetes is a lifelong disorder, education of the patient and the family is probably the most important obligation of the clinician who provides initial care. The best persons to manage a disease that is affected so markedly by daily fluctuations in environmental stress, exercise, diet, and infections are the patients themselves and their families. It must be remembered that education is necessary not only for patients with newly diagnosed diabetes and their families, but also for patients with diabetes of any duration who may never have been properly educated about their disorder or who may not be aware of advances in diabetes management. The teaching curriculum should include explanations by the physician or nurse of the nature of diabetes and its potential acute and chronic hazards and how they can be recognized early and prevented or treated. Self-monitoring of blood glucose should be emphasized, especially in insulin-requiring diabetic patients, and instructions must be given on proper testing and recording of data. Patients must also be helped to accept the fact that they have diabetes; until this difficult adjustment is made, efforts to cope with the disorder are likely to be futile. Counseling should be directed at avoidance of extremes such as compulsive rigidity or self-destructive neglect.

Patients on insulin should have an understanding of the actions of basal and bolus insulins. They should be taught how to determine whether the basal dose is appropriate and how to adjust the rapidly acting insulin dose for the carbohydrate content of a meal. Patients and their families or friends should also be taught to recognize signs and symptoms of hypoglycemia and how to institute appropriate therapy for hypoglycemic reactions. Strenuous exercise can precipitate hypoglycemia, and patients should know how much to reduce their insulin dosage in anticipation of strenuous activity or to take supplemental carbohydrate. Injection of insulin into a site farthest away from the muscles most involved in exercise may help ameliorate exercise-induced hypoglycemia, since insulin injected in the proximity of exercising muscle may be more rapidly mobilized. Exercise training also increases the effectiveness of insulin and insulin doses should be adjusted accordingly. Because infections, particularly pyogenic ones with fever and toxemia, provoke a marked increase in insulin requirements, patients must be taught how to appropriately administer supplemental rapid-acting insulin as needed to correct hyperglycemia during infections.

Type 2 diabetes on noninsulin medications should be informed about the time of onset, peak action, duration of action, and any adverse effects of pharmacologic agents being used. They should also learn to inquire about possible drug interactions whenever any new medications are added to their regimens.

The targets for blood glucose control should be elevated appropriately in elderly patients since they have the greatest risk if subjected to hypoglycemia and the least long-term benefit from more rigid glycemic control. Patients should be provided advice on personal hygiene, including detailed instructions on foot and dental care. All infections (especially pyogenic ones) provoke the release of high levels of insulin antagonists such as catecholamines or glucagon and thus bring about a marked increase in insulin requirements. Patients who are oral agents may decompensate and temporarily require insulin. All patients receiving therapy that can cause hypoglycemia should wear a MedicAlert bracelet or necklace that clearly states that insulin or an oral sulfonylurea drug is being taken. Patients should be told about community agencies, such as
American Diabetes Association chapters, that can serve as a continuing source of instruction.

Finally, vigorous efforts should be made to persuade new diabetics who smoke to give up the habit, since large vessel peripheral vascular disease and debilitating retinopathy are less common in nonsmoking diabetic patients.

**Specific Therapy**

With the publication of data from the DCCT and the UKPDS, there has been a shift in the guidelines regarding acceptable levels of control. The ADA recommends that for patients with either type 1 and type 2 diabetes, the goal is to achieve preprandial blood glucose values of 80 to 120 mg/dL and an average bedtime glucose of 100 to 140 mg/dL and HbA1c of <7% (nondiabetic range: 4%-6%). Obviously, these goals should be modified by taking into account the patient’s ability to carry out the treatment regimen, the risk of severe hypoglycemia, and other patient factors that may reduce the benefit of such tight control.

A. Type 1 diabetes  Patients with type 1 diabetes require replacement therapy with exogenous insulin. This should be instituted under conditions of an individualized diabetic diet with multiple feedings and normal daily activities so that an appropriate dosage regimen can be developed.

At the onset of type 1 diabetes, many patients recover some pancreatic β cell function and may temporarily need only low doses of exogenous insulin to supplement their own endogenous insulin secretion. This is known as the honeymoon period. Within 8 weeks to 2 years, however, most of these patients show either absent or negligible pancreatic β cell function. At this point, these patients should be switched to a more flexible insulin regimen with a combination of rapid-acting insulin analogs or regular insulin together with intermediate-acting or long-acting insulin. At a minimum, the patient should be on a three-injection regimen and frequently changing the insulin mixtures cannot maintain near-normalization of blood glucose without hypoglycemia (particularly at night) and are not recommended. Self-monitoring of blood glucose levels is required for determining the optimal adjustment of insulin dosage and the modulation of food intake and exercise in type 1 diabetes.

Certain caveats should be kept in mind regarding insulin treatment. Considerable variations in absorption and bioavailability exist, even when the same dose is injected in the same region on different days in the same individual. Such variation often can be minimized by injecting smaller quantities of insulin at each injection and consequently using multiple injections. Furthermore, a given insulin dosage may demonstrate considerable variability in pharmacokinetics in different individuals, either because of insulin antibodies that bind insulin with different avidity or for other as yet unknown reasons. A properly educated patient should be taught to adjust insulin dosage by observing the pattern of recorded self-monitored blood glucose levels and correlating it with the approximate duration of action and the time to peak effect after injection of the various insulin preparations (see Table 17–14).

A combination of rapid-acting insulin analogs and long-acting insulins (insulin glargine or insulin detemir) allows for more physiologic insulin replacement. In clinical studies, combinations of rapid-acting insulin analogs (insulin lispro or insulin aspart) with meals together with intermediate-acting (NPH) or long-acting insulin (insulin glargine) for basal coverage have now been shown to have improved HbA1c values with less hypoglycemia when compared with a regimen of regular insulin with meals and NPH at night. Table 17–16 illustrates some regimens that might be appropriate for a 70-kg person with type 1 diabetes eating meals of standard carbohydrate intake and moderate to low fat content.

Multiple injections of NPH insulin can be mixed in the same syringe as the insulin lispro, insulin aspart, and insulin glulisine. Insulin glargine is usually given once in the evening to provide 24-hour coverage. This insulin should not be mixed with any of the other insulins and must be given as a separate injection. There are occasional patients in whom insulin glargine does not seem to last for 24 hours, and in such cases it needs to be given twice a day.

Continuous subcutaneous insulin infusion by portable battery-operated open loop devices currently provides the most flexible approach, allowing the setting of different basal rates throughout the 24 hours and permitting patients to delay or skip meals and vary meal size and composition (see Methods of Insulin Administration, earlier). The dosage is usually based on providing 50% of the estimated insulin dose as basal and the remainder as intermittent boluses prior to meals. For example, a 70-kg man requiring 35 U of insulin per day may require a basal rate of

*Assumes that patient is consuming approximately 75 g carbohydrate at breakfast, 60 g at lunch, and 90 g at dinner.

The dose of rapid-acting insulin analogs can be raised by 1 or 2 U if extra carbohydrate (15-30 g) is ingested or if premeal blood glucose is >170 mg/dL. The rapid-acting insulin analogs can be mixed in the same syringe with NPH insulin.

Insulin glargine cannot be mixed with any of the available insulins and must be given as a separate injection.
adjustments to basal and bolus dosages would depend on the 
when 0.8 U/h might be appropriate (for the dawn phenomenon). The meal bolus would depend on the carbohydrate content of the meal and the premeal blood glucose value. One unit per 15 g of carbohydrate plus 1 U for 50 mg/dL of blood glucose above a target value (eg, 120 mg/dL) is a common starting point. Further adjustments to basal and bolus dosages would depend on the results of blood glucose monitoring. Most patients use the rapid-acting insulin analogs in the pumps.

One of the more difficult therapeutic problems in managing patients with type 1 diabetes is determining the proper adjustment of insulin dose when the early morning blood glucose level is high before breakfast (Table 17–17). Prebreakfast hyperglycemia is sometimes due to the Somogyi effect, in which nocturnal hypoglycemia evokes a surge of counterregulatory hormones to produce high blood glucose levels by 7 AM. However, a more common cause of prebreakfast hyperglycemia is the waning of the evening or bedtime insulin and/or the dawn phenomenon. That is, reduced tissue sensitivity to insulin between 5 AM and 8 AM (dawn), due to spikes of growth hormone released hours before, at onset of sleep. Table 17–17 shows that diagnosis of the cause of prebreakfast hyperglycemia can be facilitated by self-monitoring of blood glucose at 3 AM in addition to the usual bedtime and 7 AM measurements. This is required for only a few nights, and when a particular pattern emerges from monitoring blood glucose levels overnight, appropriate therapeutic measures can be taken. Prebreakfast hyperglycemia due to the Somogyi effect can be treated by reducing the dose of either intermediate- or long-acting insulin analog at bedtime. For hyperglycemia due to waning of overnight basal insulin and/or dawn phenomenon, an increase in the evening dose of the basal insulin or shifting it from dinnertime to bedtime (or both) can be effective. A bedtime dose either of insulin glargine or insulin detemir provides more sustained overnight insulin levels than human NPH and may be effective in managing refractory prebreakfast hyperglycemia. If this fails, insulin pump therapy may be required with a higher basal insulin infusion rate (eg, from 0.8 U/h to 0.9 U/h from 6 AM until breakfast).

**B. Type 2 diabetes** Therapeutic recommendations are based on the relative contributions of β cell insufficiency and insulin insensitivity in individual patients. The possibility that the individual patient has a specific etiological cause for their diabetes should always be considered, especially when the patient does not have a family history of type 2 diabetes or does not have any evidence of central obesity or insulin resistance. Such patients should be evaluated for other types of diabetes such as LADA or MODY. Patients with LADA should be prescribed insulin when their disease is diagnosed and treated like patients with type 1 diabetes. It is also important to note that many type 2 patients have a progressive loss of β cell function and will require additional therapeutic interventions with time.

**Weight reduction**—One of the primary modes of therapy in the obese patient with type 2 diabetes is weight reduction. Normalization of glycemia can be achieved by reducing adipose stores, with consequent restoration of tissue sensitivity to insulin. A combination of caloric restriction, increased exercise, modification of behavior, and consistent reinforcement of good eating habits is required if a weight reduction program is to be successful. Knowledge of the symptoms of diabetes and an understanding of the risks and complications of diabetes often increase the patient’s motivation for weight reduction. Even so, significant weight loss is seldom achieved and is even more difficult to maintain in the morbidly obese patient. Weight control is variable in moderately obese patients, depending on the enthusiasm of the therapist and the motivation of the patient.

For selected patients, medical or surgical options for weight loss should be considered (also see Chapter 20). Sibutramine, a combined serotonin-norepinephrine reuptake inhibitor, is moderately effective in promoting weight loss. It has however been associated with increased risk of heart attack and stroke and has been withdrawn from clinical use.

Orlistat is a reversible inhibitor of gastric and pancreatic lipases and prevents the hydrolysis of dietary triglycerides. These triglycerides are then excreted in the feces. In a 1-year study in obese patients with type 2 diabetes, those taking orlistat had lost more weight, had lower HbA1c values, and had improved lipid profiles. The main adverse reactions were gastrointestinal, with oily spotting, oily stool, flatus, and fecal...
urgency and frequency. Malabsorption of fat-soluble vitamins also occurs. Patients should take a multivitamin tablet containing fat-soluble vitamins at least 2 hours before or 2 hours after the administration of orlistat. Cases of severe liver injury have been reported with this drug although a cause and effect relationship has not been established.

Bariatric surgery (Roux-en-Y, gastric sleeve, biliopancreatic diversion/duodenal switch, or gastric banding) typically result in substantial weight loss, and long-term follow-up has shown that many patients with diabetes who undergo these procedures maintain the weight reduction.

Nonobese patients with type 2 diabetes frequently have increased visceral adiposity—the so-called metabolically obese normal-weight patient. There is less emphasis on weight loss but exercise remains an important aspect of treatment.

Antihyperglycemic agents—The current recommendation is to start metformin therapy at diagnosis and not wait to see if the patient can achieve target glycemic control with weight management and exercise. Metformin is advantageous because, apart from lowering glucose without the risk of hypoglycemia, it also lowers triglycerides and promotes some modest weight loss. The drug, however, cannot be used in patients with renal failure, and some patients have gastrointestinal side effects at even the lowest doses. Under these circumstances the choice of the initial agent depends on a number of factors, including comorbid conditions, adverse reactions to the medications, ability of the patient to monitor for hypoglycemia, drug cost, and patient and physician preferences. Sulfonylureas have been available for many years, and their use in combination with metformin is well established. They do, however, have the propensity to cause hypoglycemia and weight gain. Thiazolidinediones improve peripheral insulin resistance and lower glucose without causing hypoglycemia. They also have been reported to improve nonalcoholic fatty liver disease. In addition, they have beneficial effects on the lipid profile and some other cardiovascular risk factors. They decrease microalbuminuria, and reduce neointimal tissue hyperplasia after coronary artery stent placement. Thiazolidinediones, however, can cause fluid retention and are contraindicated in patients with heart failure. They also very commonly increase weight, which patients find distressing, affecting adherence. The drugs are associated with increased fracture risk in women and this adverse effect significantly limits their use. Pioglitazone is the preferred choice because of concerns regarding rosiglitazone and the risk of ischemic heart disease. Both drugs are contraindicated in patients with active liver disease and in patients with liver enzyme levels ≥2.5 times the upper limit of normal. The α-glucosidase inhibitors have modest glucose-lowering effects and have gastrointestinal side effects. They have a lower risk of hypoglycemia than the sulfonylureas and promote weight loss. The GLP-1 receptor agonists (exenatide and liraglutide) have a lower risk of hypoglycemia than the sulfonylureas, and they promote weight loss. However, they need to be given by injection, cause nausea, may cause pancreatitis, and are contraindicated in patients with gastroparesis. The DPP-4 inhibitors (sitagliptin and saxagliptin) also have a low risk of hypoglycemia, and they do not cause nausea or vomiting. They can also be used in patients with kidney impairment. There are, however, reports of serious allergic reactions, including anaphylaxis, angioedema, and Stevens-Johnson syndrome. There is concern that sitagliptin, like the GLP-1 receptor agonists, may cause pancreatitis.

When patients are not well controlled on their initial therapy (usually metformin) then a second agent should be added. In those patients where the problem is hyperglycemia after a carbohydrate-rich meal (such as dinner), a short-acting secretagogue before meals may suffice to put the glucose levels into the target range. Patients with severe insulin resistance or non-alcoholic fatty liver disease or microalbuminuria may be candidates for pioglitazone. Subjects who are very concerned about weight gain may benefit from a trial of a GLP-1-receptor agonist or DPP-4 inhibitor. If two agents are inadequate, then a third agent is added, although data on efficacy with such combined therapy are limited. When the combination of oral agents (and injectable GLP-1 receptor agonists) fail to achieve target glycemic control in patients with type 2 diabetes or if there are contraindications to their use, then insulin treatment should be instituted. Various insulin regimens may be effective. One proposed regimen is to continue the oral combination therapy and then simply add a bedtime dose of NPH or long-acting insulin analog (insulin glargine or insulin detemir) to reduce excessive nocturnal hepatic glucose output and improve fasting glucose levels. If the patient does not achieve target glucose levels during the day, then daytime insulin treatment can be initiated. A convenient insulin regimen under these circumstances is a split dose of 70/30 NPH/regular mixture (or Humalog Mix 75/25 or NovoLogMix 70/30) before breakfast and before dinner. If this regimen fails to achieve satisfactory glycemic goals or is associated with unacceptable frequency of hypoglycemic episodes, then a more intensive regimen of multiple insulin injections can be instituted as in patients with type 1 diabetes. Metformin principally reduces hepatic glucose output, and it is reasonable to continue with this drug when insulin therapy is instituted. The thiazolidinediones, which improve peripheral insulin sensitivity, can be used together with insulin, but this combination is associated with more weight gain and peripheral edema. The sulfonylureas also have been shown to be of continued benefit. There is limited information on the benefits of continuing the GLP1-receptor agonists or the DPP-4 inhibitors once insulin therapy is initiated. Weight-reducing interventions should continue even after initiation of insulin therapy and may allow for simplification of the therapeutic regimen in the future.

IMMUNOPATHOLOGY OF INSULIN THERAPY

At least five molecular classes of insulin antibodies are produced during the course of insulin therapy: IgA, IgD, IgE, IgG, and IgM. Human insulin is much less antigenic than the older formulations of animal (especially beef) insulins, but because of its hexameric presentation at therapeutic injection doses, it is also treated as a foreign substance by the immune system and results in detectable—albeit low—titers of insulin antibodies in most patients.

A. Insulin allergy

Insulin allergy, a hypersensitivity reaction of the immediate type, is a rare condition in which local or systemic urticaria occurs immediately after insulin injection. This reaction is due to histamine release from tissue mast cells sensitized by adherence of IgE antibodies to their surface. In severe cases, anaphylaxis can occur. The appearance of a subcutaneous
nodule at the site of insulin injection, occurring several hours after
the injection and lasting for up to 24 hours, has been attributed to
an IgG-mediated complement-binding Arthus reaction. Because
sensitivity was often due to noninsulin protein contaminants, the
highly purified insulins have markedly reduced the incidence of
insulin allergy, especially of the local variety. Antihistamines,
corticosteroids, and even desensitization may be required, espe-
cially for systemic hypersensitivity in an insulin-dependent
patient. A protocol for allergy testing and insulin desensitization is
available from the Lilly Company. A trial of insulin analogs should
also be considered. There is a case report of successful use of insu-
lin lispro in the face of generalized allergy to human insulin.

B. Immune insulin resistance  All patients who receive
insulin (including insulin analogs) develop a low titer of circulating
IgG antibodies, and this neutralizes the rapid action of insulin
to a small extent. With the animal insulins, a high titer of circulating
antibodies is sometimes developed, resulting in extremely high
insulin requirements, often to more than 200 U/d. This is now
very rarely seen with the switch to the highly purified human
insulins and has not been reported with use of the analogs.

C. Lipodystrophy at injection sites  Rarely, a disfiguring
atrophy of subcutaneous fatty tissue occurs at the site of insulin
injection. Although the cause of this complication is obscure, it
seems to represent a form of immune reaction, particularly
because it occurs predominantly in females and is associated with
lymphocyte infiltration in the lipoatrophyic area. This complica-
tion has become even less common because of the development of
highly purified insulin preparations of neutral pH. Injection of
highly purified preparations of insulin directly into the atrophic
area often results in restoration of normal contours.

Lipohypertrophy, on the other hand, is not a consequence of
immune responses; rather, it seems to be due to the pharmacologic
effects of depositing insulin in the same location repeatedly. It is
prevented by rotation of injection sites. There is a case report of a
male patient who had intractable lipohypertrophy (fatty infiltration
of injection site) with human insulin but no longer had the problem
when he switched to insulin lispro.

ACUTE COMPLICATIONS OF DIABETES MELLITUS

Hypoglycemia

Hypoglycemic reactions (see later and Chapter 18) are the most
common complications that occur in patients with diabetes who
are treated with insulin. Hypoglycemia may result from delay in
taking a meal, from unusual physical exertion without supplemental
calories, or from an increase in insulin dose. In addition, it can
occur in any patient taking oral agents that stimulate pancreatic
β cells (eg, sulfonylureas, meglitinide, D-phenylalanine analogs),
particularly if the patient is elderly, has renal or liver disease, or is
taking certain other medications that alter metabolism of the sul-
fonylureas (eg, phenylbutazone, sulfonamides, or warfarin). It
occurs more frequently with the use of long-acting sulfonylureas.

The signs and symptoms of hypoglycemia may be divided into
those resulting from stimulation of the autonomic nervous system
and those arising from neuroglycopenia (insufficient glucose for
normal central nervous system function). When the blood glucose
falls to around 54 mg/dL, the patient starts to experience both
sympathetic (tachycardia, palpitations, sweating, tremulousness)
and parasympathetic (nausea, hunger) nervous system symptoms.
If these autonomic symptoms are ignored and the glucose levels
fall further (to around 50 mg/dL), then neuroglycopenic symp-
toms appear, including irritability, confusion, blurred vision,
tiredness, headache, and difficulty speaking. A further decline in
glucose (below 30 mg/dL) can then lead to loss of consciousness
or even a seizure.

With repeated episodes of hypoglycemia, there is adaptation
and autonomic symptoms do not occur until the blood glucose
levels are much lower and so the first symptoms are often due
to neuroglycopenia. This condition, which is referred to as
hypoglycemic unawareness, results from failure of the sympa-
thetic nervous system to respond to hypoglycemia (Table 17-18).
This adaptation of the central nervous system to recurrent hypogly-
cemic episodes is due to upregulation of the GLUT 1 transport-
ers at the blood-brain barrier and increased glucose transport
into the brain despite subnormal levels of plasma glucose. It has
been shown that hypoglycemic unawareness can be reversed by
keeping glucose levels high for a period of several weeks. Except
for sweating, most of the sympathetic symptoms of hypoglycemia
are blunted in patients receiving β-blocking agents for angina
pectoris or hypertension. Though not absolutely contraindicated,
these drugs must be used with caution in insulin-requiring diabet-
ics, and β1-selective blocking agents are preferred.

Hypoglycemia in insulin-treated patients with diabetes occurs
as a consequence of three factors: behavioral issues, impaired
counterregulatory systems, and complications of diabetes.

| TABLE 17-18 Hypoglycemic “unawareness” in type 1 diabetes mellitus. |
| --- | --- |
| I. Sleeping patient (nocturnal hypoglycemia) |
| II. Hypoglycemia with unawareness while awake |
| A. Manifestations |
| a. Neuroglycopenic symptoms first (weakness, lethargy, confusion, incoordination, blurred vision) |
| b. Autonomic symptoms are delayed and blunted (tremor, anxiety, palpitations, sweating, hunger) |
| B. Mechanisms |
| 1. Defective autonomic response: |
| a. Adaptation to chronic hypoglycemia (increased brain glucose transporter 1) |
| b. Due to diabetic autonomic neuropathy |
| C. Management |
| 1. Identify patients at risk and reevaluate glycemic goals |
| 2. Advise frequent self-monitoring of blood glucose; use of continuous glucose monitoring systems |
| 3. Learn to detect subtle symptoms of neuroglycopenia |
| 4. Avoid recurrent hypoglycemia |
| 5. Injectable glucagon made available to family |
Behavioral issues include injecting too much insulin for the amount of carbohydrates ingested. Drinking alcohol in excess, especially on an empty stomach, can also cause hypoglycemia. In patients with type 1 diabetes, hypoglycemia can occur during or even several hours after exercise, and so glucose levels need to be monitored and food and insulin adjusted. Some patients do not like their glucose levels to be high, and they treat every high glucose level aggressively. These individuals who stack their insulin, that is, give another dose of insulin before the first injection has had its full action, can develop hypoglycemia.

Counterregulatory issues resulting in hypoglycemia include impaired glucagon response and impaired sympatho-adrenal responses (Table 17–19). Patients with diabetes of greater than 5 years duration lose their glucagon response to hypoglycemia. As a result, they are at a significant disadvantage in protecting themselves against falling glucose levels. Once the glucagon response is lost, their sympatho-adrenal responses take on added importance. Unfortunately, aging, autonomic neuropathy, or hypoglycemic unawareness due to repeated low glucose levels further blunts the sympatho-adrenal responses. Occasionally, Addison disease develops in persons with type 1 diabetes mellitus; when this happens, insulin requirements fall significantly, and unless insulin dose is reduced, recurrent hypoglycemia will develop.

Complications of diabetes that increase the risk for hypoglycemia include autonomic neuropathy, gastroparesis, and renal failure. The sympathetic nervous system is an important system alerting the individual that the glucose level is falling by causing symptoms of tachycardia, palpitations, sweating, and tremulousness. Failure of the sympatho-adrenal responses increases the risk of hypoglycemia. In patients with gastroparesis, insulin given before a meal promotes maximal glucose uptake into cells before the food is absorbed, causing the glucose levels to fall. Finally, in renal failure, hypoglycemia can occur presumably because of decreased insulin clearance as well as loss of the renal contribution to gluconeogenesis in the postabsorptive state.

### Table 17–19 Counterregulatory responses to hypoglycemia.

</tr>
</tbody>
</table>

*Type 2 diabetics are less well characterized as to their defective counterregulation of glucagon loss, but appear to have the same frequency and causes of adrenergic loss as do type 1 diabetics.

### Treatment

To treat insulin-induced hypoglycemia, the diabetic patient should carry glucose tablets or juice at all times. For most episodes, ingestion of 15 g of carbohydrate is sufficient to reverse the hypoglycemia. The patient should be instructed to check the blood glucose in 15 minutes and treat again if the glucose level is still low.

A parenteral glucagon emergency kit (1 mg) should be provided to every patient with diabetes who is on insulin therapy. Family or friends should be instructed how to inject it subcutaneously or intramuscularly into the buttock, arm, or thigh in the event that the patient is unconscious or refuses food. The drug can occasionally cause vomiting and the unconscious patient should be turned on his or her side to protect the airway. Glucagon mobilizes glycogen from the liver raising the blood glucose by about 36 mg/dL in about 15 minutes. After the patient recovers consciousness additional oral carbohydrate should be given. Glucagon is contraindicated in sulfonylurea-induced hypoglycemia where it paradoxically causes insulin release. People with diabetes on hypoglycemic drug therapy should also wear a MedicAlert bracelet or necklace or carry a card in his or her wallet.

Medical personnel treating severe hypoglycemia can give 50 mL of 50% glucose solution by rapid intravenous infusion. If intravenous therapy is not available, 1 mg of glucagon can be injected intramuscularly. If the patient is stuporous and glucagon is not available, small amounts of honey or maple syrup or glucose gel (15 g) can be inserted within the buccal pouch, although, in general, oral feeding is contraindicated in unconscious patients. Rectal administration of maple syrup or honey (30 mL per 500 mL of warm water) has been effective.

Most patients who arrive at emergency departments in hypoglycemic coma appear to recover fully; however, profound hypoglycemia or delays in therapy can result in permanent neurologic deficit or even death. Furthermore, repeated episodes of hypoglycemia may have a cumulative adverse effect on intellectual functioning. The physician should carefully review with the patient the events leading up to the hypoglycemic episode. Associated use of other medications, as well as alcohol or narcotics, should be noted. Careful attention should be paid to diet, exercise pattern, insulin or sulfonylurea dosage, and general compliance with the prescribed diabetes treatment regimen. Any factors thought to have contributed to the development of the episode should be identified and recommendations made in order to prevent recurrences of this potentially disastrous complication of diabetes therapy.

If the patient is hypoglycemic from use of a long-acting oral hypoglycemic agent (eg, chlorpropamide or glyburide) or from high doses of a long-acting insulin, admission to hospital for treatment with continuous intravenous glucose and careful monitoring of blood glucose is indicated.
Coma

Coma is a medical emergency calling for immediate evaluation to determine its cause so that proper therapy can be started. Patients with diabetes may be comatose because of hypoglycemia, diabetic ketoacidosis, hyperglycemic hyperosmolar coma, or lactic acidosis. When evaluating a comatose diabetic patient, these must be considered in addition to the myriad causes included in the differential diagnosis of coma (e.g., cerebrovascular accidents, head trauma, intoxication with alcohol, or other drugs).

After emergency measures have been instituted (airway protection; laboratory tests; intravenous dextrose unless fingerstick blood glucose shows hyperglycemia), a careful history (from family, friends, or paramedics), physical examination, and laboratory evaluation are required to resolve the differential diagnosis. Patients in deep coma from a hyperosmolar nonketotic state or from hypoglycemia are generally flaccid and have quiet breathing—in contrast to patients with acidosis, whose respirations are rapid and deep if the pH of arterial blood has dropped to 7.1 or below. When hypoglycemia is a cause of the coma, the state of hydration is usually normal. Although the clinical laboratory remains the final arbiter in confirming the diagnosis, a rapid estimate of blood glucose and ketones can be obtained by the use of bedside glucose and ketone meters (see Laboratory Findings in diabetes mellitus, earlier). Table 17–20 is a summary of some laboratory abnormalities found in diabetic patients with coma attributable to diabetes or its treatment.

1. DIABETIC KETOACIDOSIS

This acute complication of diabetes mellitus may be the first manifestation of previously undiagnosed type 1 diabetes or may result from increased insulin requirements in type 1 diabetes patients during the course of infection, trauma, myocardial infarction, or surgery. The National Data Group reports an annual incidence of five to eight episodes of diabetic ketoacidosis per 1000 diabetic patients. In all cases, precipitating factors such as infection should be searched for and treated appropriately. Poor compliance, either for psychological reasons or because of inadequate patient education, is probably the most common cause of diabetic ketoacidosis, particularly when episodes are recurrent. In adolescents with type 1 diabetes, recurrent episodes of severe ketoacidosis often indicate the need for counseling to alter this behavior.

Diabetic ketoacidosis has been found to be one of the more common serious complications of insulin pump therapy, occurring in approximately 1 per 80 patient-months of treatment.

Patients with type 2 diabetes may also develop ketoacidosis under severe stress such as sepsis, trauma, or major surgery.

Pathogenesis

Acute insulin deficiency results in rapid mobilization of energy from stores in muscle and fat depots, leading to an increased flux of amino acids to the liver for conversion to glucose and of fatty acids for conversion to ketones (acetoacetate, β-hydroxybutyrate, and acetone). In addition to this increased availability of precursor, there is a direct effect of the low insulin-glucagon ratio on the liver that promotes increased production of ketones as well as glucose. In response to both the acute insulin deficiency and the metabolic stress of ketosis, the levels of insulin-antagonistic hormones (corticosteroids, catecholamines, glucagon, and GH) are consistently elevated. Furthermore, in the absence of insulin, peripheral utilization of glucose and ketones is reduced. The combination of increased production and decreased utilization leads to an accumulation of these substances in blood, with plasma glucose levels reaching 500 mg/dL (27.8 mmol/L) or more and plasma ketones reaching levels of 8 to 15 mmol/L or more. β-Hydroxybutyrate is the predominant ketone and its ratio to acetoacetate increases from 1:1 to as much as 5:1.

The hyperglycemia causes osmotic diuresis leading to depletion of intravascular volume. As this progresses, impaired renal blood flow reduces the kidney's ability to excrete glucose, and hyperosmolality worsens. Severe hyperosmolality (>330 mOsm/kg) correlates closely with central nervous system depression and coma.

In a similar manner, impaired renal excretion of hydrogen ions aggravates the metabolic acidosis that occurs as a result of the accumulation of the ketoacids, β-hydroxybutyrate, and acetoacetate.

*A small degree of ketonuria may be present if the patient is severely stressed or has not been eating because of illness.

*APatient may be acidic if there is severe volume depletion with cardiovascular collapse or if sepsis is present.

*Leftover urine in bladder might still contain sugar from earlier hyperglycemia.
The accumulation of ketones may cause vomiting, which exacerbates the intravascular volume depletion. In addition, prolonged acidosis can compromise cardiac output and reduce vascular tone. The result may be severe cardiovascular collapse with generation of lactic acid, which then adds to the already existing metabolic acidosis.

**Clinical Features**

**A. Symptoms and signs**  
The appearance of diabetic ketoacidosis is usually preceded by a day or more of polyuria and polydipsia associated with marked fatigue, nausea, and vomiting. Eventually, mental stupor ensues and can progress to frank coma. On physical examination, evidence of dehydration in a stuporous patient with rapid and deep respirations and the fruity breath odor of acetone strongly suggest the diagnosis. Postural hypotension with tachycardia indicates profound dehydration and salt depletion. Abdominal pain and even tenderness may be present in the absence of abdominal disease, and mild hypothermia is usually present.

**B. Laboratory findings**  
Typically, the patient with moderately severe diabetic ketoacidosis has a plasma glucose of 350 to 900 mg/dL (19.4-50 mmol/L), serum ketones are positive at a dilution of 1:8 or greater, hyperkalemia of 5 to 8 mEq/L, slight hypernatremia of approximately 130 mEq/L, hyperphosphatemia of 6 to 7 mg/dL, and an elevated blood urea nitrogen and creatinine. Acidosis may be severe (pH ranging from 6.9-7.2 with a bicarbonate concentration ranging from 5-15 mEq/L); pCO₂ is low (15-20 mm Hg) secondary to hyperventilation.

The fluid depletion is typically about 100 mL/kg. The hyperkalemia occurs despite total body potassium depletion, because of the shift of potassium from the intracellular to extracellular spaces in systemic acidosis. The average total body potassium deficit resulting from osmotic diuresis, acidosis, and gastrointestinal losses is about 3 to 5 mEq/kg body weight. Similarly despite the elevated serum phosphate, total body phosphate is generally depleted. Serum sodium is generally reduced, due to loss of sodium ions by polyuria and vomiting (7-10 mEq/kg), and because severe hyperglycemia shifts intracellular water into the interstitial compartment (for every 100 mg/dL of plasma glucose above normal, serum sodium decreases by 1.6 mEq/L). Serum osmolality can be directly measured by standard tests of freezing point depression or can be estimated by calculating the molarity of sodium, chloride, and glucose in the serum. A convenient formula for estimating effective serum osmolality is:

\[ m\text{Osm/kg} = 2(\text{measured Na}^+) + \frac{\text{Glucose (mg/dL)}}{18} \]

The effective serum osmolality in humans is generally between 280 and 300 mOsm/kg. These calculated estimates are usually 10 to 20 mOsm/kg lower than values recorded by standard cryoscopic techniques. Central nervous depression or coma occurs when the effective serum osmolality exceeds 320 to 330 mOsm/L.

Blood urea nitrogen and serum creatinine are invariably elevated because of dehydration. Urea exerts an effect on freezing point depression as measured in the laboratory, but it is freely permeable across cell membranes and therefore not included in calculations of effective serum osmolality. Serum creatinine may also be falsely elevated due to interference from acetocetate with some automated creatinine assays. However, most laboratories can correct for these interfering chromogens by using a more specific method, if asked to do so.

The nitroprusside reagents (Acetest and Ketostix) used for the bedside assessment of ketoacidemia and ketoaciduria measure only acetocetate and its by-product, acetone. The sensitivity of these reagents for acetone, however, is quite poor, requiring over 10 mmol/L, which is seldom reached in the plasma of ketoacidotic subjects—although this detectable concentration is readily achieved in urine. Thus, in the plasma of ketotic patients, only acetocetate is measured by these reagents. The more prevalent β-hydroxybutyrate has no ketone group and is therefore not detected by the conventional nitroprusside tests. This takes on special importance in the presence of circulatory collapse during diabetic ketoacidosis, wherein an increase in lactic acid can shift the redox state to increase β-hydroxybutyrate at the expense of the readily detectable acetocetate. Bedside diagnostic reagents would then be unreliable, suggesting no ketonemia in cases where β-hydroxybutyrate is a major factor in producing the acidosis. Under these circumstances, β-hydroxybutyrate can be directly measured at the bedside using the Precision Xtra meter (Abbott Diagnostics). Many clinical laboratories now offer β-hydroxybutyrate measurement.

In about 90% of cases, serum amylase is elevated. However, this often represents salivary as well as pancreatic amylase and correlates poorly with symptoms of pancreatitis, such as pain and vomiting. Therefore, in patients with diabetic ketoacidosis, an elevated serum amylase does not justify a diagnosis of acute pancreatitis; serum lipase may be useful if the diagnosis of pancreatitis is being seriously considered.

**Treatment**

Patients with mild DKA are alert and have pH between 7.25 and 7.30; those with moderate DKA have pH between 7.0 and 7.24 and are alert or slightly drowsy; and those with severe DKA are stuporous and have pH <7.0. Those with mild DKA can be treated in the emergency room, but those with moderate or severe DKA require admission to the intensive care unit or step-down unit.

The therapeutic goals are to restore plasma volume and tissue perfusion; reduce blood glucose and osmolality toward normal; correct acidosis; replenish electrolyte losses; and identify and treat precipitating factors. Gastric intubation is recommended in the comatose patient to prevent vomiting and aspiration that may occur as a result of gastric atony, a common complication of diabetic ketoacidosis. In patients with preexisting cardiac or renal failure or those in severe cardiovascular collapse, a central venous pressure catheter or a Swan-Ganz catheter should be inserted to evaluate the degree of hypovolemia and to monitor subsequent fluid administration.
Plasma glucose should be recorded hourly and electrolytes and pH at least every 2 to 3 hours during the initial treatment period. A bedside glucose meter should be used to titrate the insulin therapy.

1. **Fluid replacement.** In most adult patients, the fluid deficit is 4 to 5 L. Once the diagnosis of diabetic ketoacidosis is established in the emergency department, administration of at least 2 L of isotonic saline (0.9% saline solution) in an adult patient in the first 2 to 3 hours is necessary to help restore plasma volume and stabilize blood pressure while acutely reducing the hyperosmolar state. In addition, by improving renal plasma flow, fluid replacement also restores the renal capacity to excrete hydrogen ions, thereby ameliorating the acidosis as well. After the first 2 L of fluid have been given, the fluid should be changed to 0.45% saline solution given at a rate of 300 to 400 mL/h, because water loss exceeds sodium loss in uncontrolled diabetes with osmotic diuresis. Failure to give sufficient volume replacement (at least 3-4 L in 8 hours) to restore normal perfusion is one of the most serious therapeutic shortcomings affecting satisfactory recovery. In the same way, excessive fluid replacement (>5 L in 8 hours) may contribute to acute respiratory distress syndrome or cerebral edema. When blood glucose falls to approximately 250 mg/dL, the fluids should be changed to a 5% glucose solution to maintain plasma glucose in the range of 250 to 300 mg/dL. This prevents the development of hypoglycemia and also reduces the likelihood of cerebral edema, which may result from a too rapid decline of blood glucose.

2. **Insulin.** Immediately after the initiation of fluid replacement, a rapid bolus of 0.15 U of regular insulin per kilogram of body weight should be given intravenously to prime the tissue insulin receptors. This inhibits both gluconeogenesis and ketogenesis while promoting utilization of glucose and ketone acids. Following the initial bolus, an insulin infusion is initiated at a rate of 0.1 U/kg/h. When a continuous infusion of insulin is used, 25 U of regular human insulin should be placed in 250 mL of isotonic saline and the first 50 mL of solution flushed through to saturate the tubing before connecting it to the intravenous line. The insulin infusion should be piggybacked into the fluid line so that the rate of fluid replacement can be changed without altering the insulin delivery rate. If the plasma glucose level fails to fall at least 10% in the first hour, a repeat loading dose is recommended. Rarely, a patient with insulin resistance is encountered; this requires doubling the insulin dose every 2 to 4 hours if severe hyperglycemia does not improve after the first two doses of insulin and fluid replacement. The insulin dose should be adjusted with the goal of lowering the glucose concentration by about 50 to 70 mg/dL/h. If clinical circumstances prevent use of insulin infusion, then the insulin can be given intramuscularly. An initial 0.15 U/kg of regular insulin is given intravenously, and at the same time, the same size dose is given intramuscularly. Subsequently, regular insulin is given intramuscularly hourly at a dose of 0.1 U/kg until the blood glucose falls to around 250 mg/dL, when the insulin can be given subcutaneously. Insulin therapy, either as a continuous infusion or as injections given every 1 to 2 hours, should be continued until arterial pH has normalized.

3. **Potassium.** Total body potassium loss from polyuria and vomiting may be as high as 200 mEq. However, because of shifts of potassium from cells into the extracellular space as a consequence of acidosis, serum potassium is usually normal to slightly elevated prior to institution of treatment. As the acidosis is corrected, potassium flows back into the cells, and hypokalemia can develop if potassium replacement is not instituted. If the patient is not uremic and has an adequate urine output, potassium chloride in doses of 10 to 30 mEq/h should be infused during the second and third hours after beginning therapy. Replacement should be started sooner, if the initial serum potassium is inappropriately normal or low, and should be delayed, if serum potassium fails to respond to initial therapy and remains above 5 mEq/L, as in cases of renal insufficiency. Cooperative patients with only mild ketoacidosis may receive part or all of their potassium replacement orally.

An electrocardiogram can be of help in monitoring the patient's potassium status: high peaked T waves are a sign of hyperkalemia, and flattened T waves with U waves are a sign of hypokalemia.

Foods high in potassium content should be prescribed when the patient has recovered sufficiently to take food orally. Tomato juice has 14 mEq of potassium per 240 mL, and a medium-sized banana has about 10 mEq.

4. **Sodium bicarbonate.** The use of sodium bicarbonate in management of diabetic ketoacidosis has been questioned because clinical benefit was not demonstrated in one prospective randomized trial and because of the following potentially harmful consequences: (1) development of hypokalemia from rapid shift of potassium into cells if the acidosis is overcorrected, (2) tissue anoxia from reduced dissociation of oxygen from hemoglobin when acidosis is rapidly reversed (leftward shift of the oxygen dissociation curve), and (3) cerebral acidosis resulting from lowering of cerebrospinal fluid pH. It must be emphasized, however, that these considerations are less important when severe acidosis exists. It is therefore recommended that bicarbonate be administered to diabetic patients in ketoacidosis if the arterial blood pH is 7.0 or less with careful monitoring to prevent overcorrection.

One to two ampules of sodium bicarbonate (one ampule contains 44 mEq/50 mL) should be added to 1 L of 0.45% saline. (Note: Addition of sodium bicarbonate to 0.9% saline would produce a markedly hypertonic solution that could aggravate the hyperosmolar state already present.) This should be administered rapidly (over the first hour). It can be repeated until the arterial pH reaches 7.1, but it should not be given if the pH is 7.1 or greater, because additional bicarbonate increases the risk of rebound metabolic alkalosis as ketones are metabolized. Alkalosis shifts potassium from serum into cells, which can precipitate a fatal cardiac arrhythmia. As noted earlier, serious consideration should be given to placement of a central venous catheter when administering fluids to severely ill patients with cardiovascular compromise.

5. **Phosphate.** Phosphate replacement is seldom required in treating diabetic ketoacidosis. However, if severe hypophosphatemia of less than 1 mg/dL (<0.35 mmol/L) develops during insulin therapy, a small amount of phosphate can be replaced per hour as the potassium salt. Correction of hypophosphatemia helps restore the buffering capacity of the plasma, thereby facilitating renal excretion of hydrogen. It also corrects the impaired oxygen dissociation from hemoglobin by regenerating 2,3-diphosphoglycerate. However, three randomized studies in which phosphate was replaced in only half of a group of patients with diabetic ketoacidosis did not show any apparent clinical benefit from phosphate administration. Moreover, attempts to use potassium phosphate as the sole means of replacing potassium have led to a number of reported cases of severe hypocalcemia with tetany. To minimize the risk
Complications and Prognosis

Low-dose insulin infusion and fluid and electrolyte replacement combined with careful monitoring of patients’ clinical and laboratory responses to therapy have dramatically reduced the mortality rates of diabetic ketoacidosis to less than 5%. However, this complication remains a significant risk in the aged who have mortality rates over 20% and in patients in profound coma in whom treatment has been delayed. Acute myocardial infarction and infarction of the bowel following prolonged hypotension worsen the outlook. Prior kidney dysfunction worsens prognosis because the kidney plays a key role in compensating for pH and electrolyte abnormalities. Symptomatic cerebral edema occurs primarily in the pediatric population. Risk factors for development include severe baseline acidosis, rapid correction of hyperglycemia, and excess volume administration in the first 4 hours. Onset of headache or deterioration in mental status during treatment should lead to consideration of this complication. Intra­venous mannitol at a dosage of 1 to 2 g/kg given over 15 minutes is the mainstay of therapy. Excess crystalloid infusion can precipitate pulmonary edema. Acute respiratory distress syndrome is a rare complication of treatment for DKA.

Disposition

After recovery and stabilization, patients should receive intensive detailed instructions about how to avoid this potentially disastrous complication of diabetes mellitus. They should be taught to recognize the early symptoms and signs of ketoacidosis.

Urine ketones or capillary blood β-hydroxybutyrate should be measured in patients with signs of infection or in those using an insulin pump when capillary blood glucose is unexpectedly and persistently high. When heavy ketonuria and glycosuria persist on several successive examinations, supplemental regular insulin should be administered, and liquid foods such as lightly salted tomato juice and broth should be ingested to replenish fluids and electrolytes. Patients should be instructed to contact the physician if ketonuria persists and, especially, if vomiting develops, or if appropriate adjustment of the infusion rate on an insulin pump does not correct the hyperglycemia and ketonuria. Table 17–21 summarizes the guidelines for patients regarding ketone testing and what to do with the results. In adolescents, recurrent episodes of severe diabetic ketoacidosis often indicate poor compliance with the insulin regimen, and these patients should receive intensive family counseling.

2. HYPERGLYCEMIC, HYPEROSMOLAR STATE

This form of hyperglycemic coma is characterized by severe hyperglycemia, hyperosmolality, and dehydration in the absence
of significant ketosis. It occurs in patients with mild or occult diabetes and patients are typically middle-aged or elderly. Lethargy and confusion develop as serum osmolality exceeds 300 mOsm/kg, and coma can occur if osmolality exceeds 330 mOsm/kg. Underlying renal insufficiency or congestive heart failure is common, and the presence of either worsens the prognosis. A precipitating event such as pneumonia, cerebrovascular accident, myocardial infarction, burns, or recent operation can often be identified. Certain drugs, such as phenytoin, diazoxide, glucocorticoids, and thiazide diuretics, have been implicated in its development, as have procedures associated with glucose loading such as peritoneal dialysis.

Pathogenesis
A partial or relative insulin deficiency may initiate the syndrome by reducing glucose utilization by muscle, fat, and liver, while promoting hyperglucagonemia and increasing hepatic glucose output. The result is hyperglycemia that leads to glycosuria and osmotic diuresis with obligatory water loss. The presence of even small amounts of insulin is believed to prevent the development of ketosis by inhibiting lipolysis in the adipose stores. Therefore, even though a low insulin-glucagon ratio promotes ketogenesis in the liver, the limited availability of precursor free fatty acids from the periphery restricts the rate at which ketones are formed. If a patient is unable to maintain adequate fluid intake because of an associated acute or chronic illness or has suffered excessive fluid loss (eg, from burns or therapy with diuretics), marked dehydration results. As plasma volume contracts, renal insufficiency develops; this, then, limits renal glucose excretion and contributes markedly to the rise in serum glucose and osmolality. As serum osmolality exceeds 320 to 330 mOsm/kg, water is drawn out of cerebral neurons, resulting in mental obtundation and coma.

Clinical Features

A. Symptoms and signs The onset of the hyperglycemic, hyperosmolar, nonketotic state may be insidious, preceded for days or weeks by symptoms of weakness, polyuria, and polydipsia. A history of reduced fluid intake is common, whether due to inappropriate absence of thirst, gastrointestinal upset, or, in the case of elderly or bedridden patients, lack of access to water. A history of ingestion of large quantities of glucose-containing fluids, such as soft drinks or orange juice, can occasionally be obtained; these patients are usually less hyperosmolar than those in whom fluid intake was restricted. The absence of toxic features of ketoacidosis may retard recognition of the syndrome and thus delay institution of therapy until dehydration is profound. Because of this delay in diagnosis, the hyperglycemia, hyperosmolality, and dehydration in hyperglycemic, hyperosmolar, nonketotic coma is often more severe than in diabetic ketoacidosis.

Physical examination reveals the presence of profound dehydration (orthostatic fall in blood pressure and rise in pulse, supine tachycardia, or even frank shock, dry mucous membranes, decreased skin turgor). The patient may be lethargic, confused, or comatose. Kussmaul respirations are absent unless the precipitating event for the hyperosmolar state has also led to the development of metabolic acidosis (eg, sepsis or myocardial infarction with shock).

B. Laboratory findings Severe hyperglycemia is present, with blood glucose values ranging from 800 to as high as 2400 mg/dL (44.4-133.2 mmol/L). In mild cases, where dehydration is less severe, dilutional hyponatremia as well as urinary sodium losses may reduce serum sodium to about 120 to 125 mEq/L—this protects, to some extent, against extreme hyperosmolality. Once dehydration progresses further, however, serum sodium can exceed 140 mEq/L, producing serum osmolalities of 330 to 440 mOsm/kg (normal, 280 to 295 mOsm/kg; see the section Diabetic Ketoacidosis for a convenient method for estimating serum osmolality). Ketosis is usually absent or mild; however, a small degree of ketonuria may be present if the patient has not been eating because of illness. Acidosis is not a part of the hyperglycemic, hyperosmolar state, but it may be present (often lactic acidosis) because of other acute underlying conditions (eg, sepsis, acute renal failure, myocardial infarction). Prerenal azotemia is the rule with blood urea nitrogen frequently over 100 mg/dL.

The physician must initiate a careful search for the event that precipitated the episode of hyperglycemic, hyperosmolar state if it is not obvious after the initial history and physical examination. Chest x-rays and cultures of blood, urine, and other body fluids should be obtained to look for occult sources of sepsis. Cardiac enzymes and serial electrocardiograms can be ordered to look for evidence of silent myocardial infarction.

Treatment

There are some differences in fluid, insulin, and electrolyte replacement in this disorder, as compared with diabetic ketoacidosis. However, in common with the treatment of ketoacidotic patients, careful monitoring of the patient’s clinical and laboratory response to therapy is essential.

1. Fluid replacement. The fluid deficit may be as much as 100 to 200 mL/kg or about 9 L. If circulatory collapse is present, fluid therapy should be initiated with isotonic saline. In all other cases, initial replacement with hypotonic (usually 0.45%) saline is preferable, because these patients are hyperosmolar with considerable loss of body water and excess solute in the vascular compartment. As much as 4 to 6 L of fluid may be required in the first 8 to 10 hours. Careful monitoring of fluid quantity and type, urine output, blood pressure, and pulse is essential. Placement of a central venous pressure catheter should be strongly considered to guide replacement of fluid, especially if the patient is elderly or has underlying renal or cardiac disease. Because insulin therapy decreases plasma glucose and therefore serum osmolality, a change to isotonic saline may be necessary at some time during treatment. Once blood glucose reaches 250 mg/dL, 5% dextrose in 0.45% or 0.9% saline solution should be substituted for the sugar-free fluids. When consciousness returns, oral fluids should be encouraged.

2. Electrolyte replacement. Hyperkalemia is less marked, and much less potassium is lost in the urine during the osmotic diuresis of hyperglycemic, hyperosmolar, nonketotic coma than in diabetic ketoacidosis. There is, therefore, less severe total potassium depletion, and less potassium replacement is
Complications and Prognosis

The severe dehydration and low output state may predispose the patient to complications such as myocardial infarction, stroke, pulmonary embolism, mesenteric vein thrombosis, and disseminated intravascular coagulation. Fluid resuscitation remains the primary approach to the prevention of these complications. Low-dose heparin prophylaxis is reasonable but benefits of routine anticoagulation remain doubtful. Rhabdomyolysis is a recognized complication of the hyperosmolar state, and it should be looked for and treated.

The overall mortality rate of hyperglycemic, hyperosmolar, nonketotic coma is over 10 times that of diabetic ketoacidosis, chiefly because of its higher incidence in older patients, who may have compromised cardiovascular systems or associated major illnesses. When patients are matched for age, the prognoses of these two forms of hyperosmolar coma are reasonably comparable.

Disposition

After the patient is stabilized, the appropriate form of long-term management of the diabetes must be determined. Insulin treatment should be continued for a few weeks, but the patients usually recover sufficient endogenous insulin secretion to make a trial of diet or diet plus oral agents worthwhile. When the episode occurs in a patient who has known diabetes, then education of the patient and caregivers should be instituted. They should be taught how to recognize situations (gastrointestinal upset, infection) that predispose to recurrence of hyperglycemic, hyperosmolar state as well as detailed information on how to prevent the escalating dehydration (small sips of sugar-free liquids, increase in usual hypoglycemic therapy, or early contact with the physician) that culminates in hyperosmolar coma.

3. LACTIC ACIDOSIS

When severely ill diabetic patients present with profound acidosis and an anion gap over 15 mEq/L but relatively low or undetectable levels of keto acids in plasma, the presence of excessive plasma lactate (>5 mmol/L) should be considered, especially if other causes of acidosis such as uremia are not present.

Pathogenesis

Lactic acid is the end product of the anaerobic metabolism of glucose. Normally, the principal sources of this acid are the erythrocytes (which lack the enzymes for aerobic oxidation), skeletal muscle, skin, and brain. The chief pathway for removal of lactic acid is by hepatic (and to some degree renal) uptake for conversion first to pyruvate and eventually back to glucose, a process that requires oxygen. Lactic acidosis occurs when excess lactic acid accumulates in the blood. This can be the result of overproduction (tissue hypoxia), deficient removal (hepatic failure), or both (circulatory collapse). Lactic acidosis is not uncommon in any severely ill patient suffering from cardiac decompensation, respiratory or hepatic failure, septicemia, or infarction of the bowel or extremities. Type A lactic acidosis is associated with tissue hypoxia from hypovolemia or endotoxic shock and need not be associated with hyperglycemia. Type B lactic acidosis is defined as that which occurs in the absence of clinical evidence for tissue hypoxia and is associated with diabetes per se or with biguanide therapy.

With the discontinuance of phenformin therapy in the United States, lactic acidosis in patients with diabetes mellitus has become uncommon, but it still must be considered in the acidotic diabetic patient if the patient is seriously ill, and especially if the patient is receiving metformin therapy as well. Most cases of metformin-associated lactic acidosis occur in patients in whom there were contraindications to the use of metformin, in particular renal failure.

Clinical Features

A. Symptoms and signs

The main clinical features of lactic acidosis are marked hyperventilation and mental confusion, which may progress to stupor or coma. When lactic acidosis is secondary to tissue hypoxia or vascular collapse, the clinical presentation is variable, reflecting that of the prevailing catastrophic illness. In the rare instance of idiopathic or spontaneous lactic acidosis, the onset is rapid (usually over a few hours), the cardiopulmonary status is stable, and mentation may be relatively normal.

B. Laboratory findings

Plasma glucose can be low, normal, or high in diabetic patients with lactic acidosis, but usually it is moderately elevated. Plasma bicarbonate and arterial pH are quite low. An anion gap is present (calculated by subtracting the sum of the plasma bicarbonate and chloride from the plasma sodium; normal is 12-15 mEq/L). Ketones are usually absent from plasma, but small amounts may be present in urine if the patient has not been eating recently. Other causes of anion gap metabolic acidosis should be excluded—for example, uremia, diabetic or alcoholic ketoacidosis, and salicylate, methanol, ethylene glycol, or paraaldehyde intoxication. In the absence of azotemia, hyperphosphatemia may be a clue to the presence of lactic acidosis.
The diagnosis is confirmed by demonstrating, in a sample of blood that is promptly chilled and separated, a plasma lactate concentration of 6 mmol/L or higher (normal is ~1 mmol/L). Failure to rapidly chill the sample and separate the plasma can lead to falsely high plasma lactate values as a result of continued glycolysis by the red blood cells. Frozen plasma remains stable for subsequent assay.

**Treatment**

The cornerstone of therapy is aggressive treatment of the precipitating cause. An adequate airway and good oxygenation should be ensured. If hypotension is present, fluids and, if appropriate, pressor agents must be given to restore tissue perfusion. Appropriate cultures and empiric antibiotic coverage should be instituted in any seriously ill patient with lactic acidosis in whom the cause is not immediately apparent. Alkalization with intravenous sodium bicarbonate to keep the pH above 7.2 has been recommended in the emergency treatment of severe lactic acidosis. However, there is no evidence that the mortality rate is favorably affected by administering bicarbonate, and the matter is at present controversial, particularly because of the hazards associated with bicarbonate therapy. Hemodialysis may be useful in those cases associated with metformin toxicity. Dichloroacetate, an anion that facilitates pyruvate removal by activating pyruvate dehydrogenase, reverses certain types of lactic acidosis in animals, but in a prospective controlled clinical trial involving 252 patients with lactic acidosis, dichloroacetate failed to alter either hemodynamics or survival.

**CHRONIC COMPLICATIONS OF DIABETES MELLITUS (TABLE 17–22)**

In most patients with diabetes, a number of pathologic changes occur at variable intervals during the course of the disease. These changes involve the vascular system for the most part; however, they also occur in the nerves, the skin, and the lens. In addition to these complications, patients with diabetes have an increased incidence of certain types of infections and may handle their infections less well than the general population.

**Classifications of Diabetic Vascular Disease**

Diabetic vascular disease is conveniently divided into two main categories: microvascular disease and macrovascular disease.

**A. Microvascular disease** Disease of the smallest blood vessels, the capillary and the precapillary arterioles, is manifested mainly by thickening of the capillary basement membrane. Microvascular disease involving the retina leads to diabetic retinopathy, and disease involving the kidney causes diabetic nephropathy. Small vessel disease may also involve the heart, and cardiomegaly with heart failure has been described in diabetic patients with patent coronary arteries.

---
B. Macrovascular disease  Large vessel disease in diabetes is essentially an accelerated form of atherosclerosis. It accounts for the increased incidence of myocardial infarction, stroke, and peripheral gangrene in diabetic patients. Just as in the case of atherosclerosis in the general population, the exact cause of accelerated atherosclerosis in the diabetic population remains unclear. Abnormalities in vessel walls, platelets and other components of the clotting system, red blood cells, and lipid metabolism have all been postulated to play a role. In addition, there is evidence that coexistent risk factors such as cigarette smoking and hypertension may be important in determining the course of the disease.

Prevalence of Chronic Complications by Type of Diabetes

Although all of the known complications of diabetes can be found in both types of the disease, some are more common in one type than in the other. In type 1 diabetes, end-stage renal disease develops in up to 40% of patients, compared with less than 20% of patients with type 2 diabetes. Although blindness occurs in both types, it occurs more commonly as a result of severe proliferative retinopathy, vitreous hemorrhages, and retinal detachment in type 1 disease, whereas macular edema and ischemia are the usual cause in type 2. Similarly, although diabetic neuropathy is common in both type 1 and type 2 diabetes, severe autonomic neuropathy with gastroparesis, diabetic diarrhea, resting tachycardia, and postural hypotension is much more common in type 1.

In patients with type 1 diabetes, complications from end-stage renal disease are a major cause of death, whereas patients with type 2 diabetes are more likely to have macrovascular diseases leading to myocardial infarction and stroke as the main causes of death. Cigarette use adds significantly to the risk of both microvascular and macrovascular complications in diabetic patients.

Molecular Mechanisms by Which Hyperglycemia Causes Microvascular and Macrovascular Damage

Epidemiological data and prospective intervention studies such as the DCCT have confirmed the central role of glucose in the development of chronic diabetic complications.

Four molecular mechanisms of glucose-induced damage have been proposed: (1) increased polyol pathway flux; (2) increased intracellular advanced glycation end product (AGE) formation; (3) activation of protein kinase C; and (4) increased hexosamine pathway flux.

Increase flux through the polyol pathway consumes NADPH. Because this cofactor is needed to regenerate reduced glutathione, NADPH depletion is predicted to exacerbate intracellular oxidative stress and cause cellular injury. Inhibitors of aldose reductase, the first enzyme in the polyol pathway have been shown to improve diabetic neuropathy.

Intracellular autooxidation of glucose results in production of intracellular dicarbonyls (glyoxal, 3-deoxyglucose, methylglyoxal), also referred to as AGE precursors. These precursors damage target tissues by modifying intracellular and extracellular proteins and matrix components. Intracellular protein modifications may alter cellular functions. Modifications of extracellular matrix proteins result in abnormal interactions with other matrix proteins and integrins. The modified plasma proteins bind to receptors on endothelial cells, mesangial cells, and macrophages causing expression of cytokines and growth factors including interleukin 1, IGF-1, TNF-α, transforming growth factor-β (TGF-β), macrophage colony stimulating factor, granulocyte-macrophage stimulating factor, platelet-derived growth factor, thrombomodulin, tissue factor, vascular cell adhesion molecule 1 (VCAM 1), and vascular endothelial growth factor (VEGF). Induction of VEGF has been implicated in the vascular hyperpermeability associated with diabetes.

Protein kinase C isoforms β and δ are activated by diacylglycerol whose levels are increased by elevated intracellular glucose. Activation of these isoforms leads to alterations in expression of endothelial nitric oxide synthase, endothelin 1, VEGF, TGF-β, PAI-1, and activation of nuclear factor κB and NADPH oxidases. Inhibitors of the protein kinase β isoform improve retinopathy and nephropathy in experimental models.

Hyperglycemia increases hexosamine pathway flux by providing more fructose-6-phosphate for the rate-limiting enzyme of the pathway glutamine:fructose-6-phosphate amidotransferase. Activity of this pathway leads to increased donation of N-acetylglucosamine moieties to serine and threonine moieties of complication-promoting factors such as PAI-1 or TGF-β.

It has been proposed that all four of these pathways are associated with overproduction of superoxide by mitochondria. High ambient glucose leads to increased substrate flux through glycolysis and the tricarboxylic acid cycle. This leads to increased potential difference across the inner mitochondrial membrane and generation of superoxide by the electron transport chain. The increased production of superoxide reduces glyceraldehyde-3-phosphate dehydrogenase (GAPDH) activity, which in turn leads to upstream increase in intracellular glucose and accumulation of glycolytic intermediates such as glyceraldehyde 3-phosphate and fructose 6-phosphate. The increased intracellular glucose leads to increased flux through the polyol pathway and also is the primary initiating event in the formation of both intracellular and extracellular AGEs. The glycolytic intermediates are important initiators of the hexosamine pathway (fructose 6-phosphate) or the protein kinase C pathway (glyceraldehyde-3-phosphate).

Genetic Factors in Susceptibility to Development of Chronic Complications of Diabetes

Although no genetic susceptibility genes have been identified as yet, two unrelated observations indicate that approximately 40% of people with diabetes may be unusually susceptible to the ravages of hyperglycemia or other metabolic sequelae of an inadequate insulin effect.

1. In one retrospective study of 164 juvenile-onset diabetic patients with a median age at onset of 9 years, 40% were incapacitated or dead from end-stage renal disease with
proliferative retinopathy after a 25-year follow-up, whereas the remaining subjects were either mildly affected (40%) or had no clinically detected microvascular disease (20%). This study was completed long before the availability of glycemic self-monitoring methodology, so it is unlikely that any of these patients were near optimal glycemic control.

(2) Data from renal transplantation indicate that only about 40% of normal kidneys developed evidence of moderate to severe diabetic nephropathy within 6 to 14 years of being transplanted into diabetic subjects with end-stage renal failure, whereas as many as 60% were only minimally affected. These observations support the hypothesis that although approximately 60% of people suffer only minimal consequences from hyperglycemia and other metabolic hazards of insulin insufficiency, 40% or so suffer severe, potentially catastrophic microvascular complications if the disease is poorly controlled. The genetic mechanisms for this increased susceptibility are as yet unknown but could be related to one or more of the molecular mechanisms outlined above. Identification of the genetic mechanism(s) would be very helpful in justifying more intensive insulin therapy in the group susceptible to complications in an effort to achieve near-normalization of blood glucose. The remaining 60% of less susceptible individuals might then be spared the inconveniences of strict glycemic control as well as the risks of hypoglycemia inherent in present methods of intensive insulin therapy.

SPECIFIC CHRONIC COMPLICATIONS OF DIABETES MELLITUS (TABLE 17–22)

1. OPHTHALMOLOGIC COMPLICATIONS

Diabetic Retinopathy

For early detection of diabetic retinopathy, adolescent or adult patients who have had type 1 diabetes for more than 5 years and all patients with type 2 diabetes should be referred to an ophthalmologist for examination and follow-up. In patients with type 1 diabetes, after 10 to 15 years, 25% to 50% of patients show some signs of retinopathy. This prevalence increases to 75% to 95% after 15 years and approaches 100% after 30 years of diabetes. In patients with type 2 diabetes, 60% have nonproliferative retinopathy after 16 years. When hypertension is present in a patient with diabetes, it should be treated vigorously because hypertension is associated with an increased incidence and accelerated progression of diabetic retinopathy.

A. Pathogenesis and clinical features Two main categories of diabetic retinopathy exist: nonproliferative and proliferative. Diabetic macular edema can occur at any stage. Nonproliferative (background) retinopathy represents the earliest stage of retinal involvement by diabetes and is characterized by such changes as microaneurysms, dot hemorrhages, exudates, and retinal edema. During this stage, the retinal capillaries leak proteins, lipids, or red cells into the retina. When this process occurs in the macula (clinically significant macular edema), the area of greatest concentration of visual cells, there is interference with visual acuity; this is the most common cause of visual impairment in type 2 diabetes.

Proliferative retinopathy involves the growth of new capillaries and fibrous tissue within the retina and into the vitreous chamber. It is a consequence of small vessel occlusion, which causes retinal hypoxia; this in turn stimulates new vessel growth. New vessel formation may occur at the optic disc or elsewhere on the retina. Proliferative retinopathy can occur in both types of diabetes but is more common in type 1, developing about 7 to 10 years after onset of symptoms, with a prevalence of 25% after 15 years’ duration. Prior to proliferation of new capillaries, a preproliferative phase often occurs in which arteriolar ischemia is manifested as cotton-wool spots (small infarcted areas of retina). Vision is usually normal until vitreous hemorrhage or retinal detachment occurs. Proliferative retinopathy is a leading cause of blindness in the United States, particularly because it increases the risk of retinal detachment.

B. Treatment Extensive scatter xenon or argon photocoagulation and focal treatment of new vessels reduce severe visual loss in those cases in which proliferative retinopathy is associated with recent vitreous hemorrhages or in which extensive new vessels are located on or near the optic disk. Macular edema, which is more common than proliferative retinopathy in patients with type 2 diabetes (up to 20% prevalence), has a guarded prognosis, but it has also responded to scatter therapy with improvement in visual acuity if detected early. Injection of bevacizumab (Avastin), an antivascular endothelial growth factor (anti-VEGF), into the eye has been shown to stop the growth of the new blood vessels in diabetic eye disease. Avoiding tobacco use and correction of associated hypertension are important therapeutic measures in the management of diabetic retinopathy. There is no contraindication to using aspirin in patients with proliferative retinopathy.

Cataracts

Two types of cataracts occur in diabetic patients: subcapsular and senile. Subcapsular cataract occurs predominantly in patients with type 1 diabetes, may come on fairly rapidly, and has a significant correlation with the hyperglycemia of uncontrolled diabetes. This type of cataract has a flocculent or snowflake appearance and develops just below the lens capsule.

Senile cataract represents a sclerotic change of the lens nucleus. It is by far the most common type of cataract found in either diabetic or nondiabetic adults and tends to occur at a younger age in diabetic patients, particularly when glycemic control is poor.

Two separate abnormalities found in diabetic patients, both of which are related to elevated blood glucose levels, may contribute to the formation of cataracts: (1) glycosylation of the lens protein, and (2) an excess of sorbitol, which is formed from the increased quantities of glucose found in the insulin-independent lens. Accumulation of sorbitol leads to osmotic changes in the lens that ultimately result in fibrosis and cataract formation.

Glucoma

Glucoma occurs in approximately 6% of persons with diabetes. It is generally responsive to the usual therapy for open-angle disease.
Closed-angle glaucoma can result from neovascularization of the iris in diabetic persons, but this is relatively uncommon except after cataract extraction when accelerated new vessel growth involving the angle of the iris obstructs outflow.

2. RENAL COMPLICATIONS

Diabetic Nephropathy

A. Pathogenesis and clinical findings  About 4000 cases of end-stage renal disease due to diabetic nephropathy occur annually among diabetic patients in the United States. This represents about one-third of all patients being treated for renal failure. The cumulative incidence of nephropathy differs between the two major types of diabetes. Patients with type 1 diabetes, who have not received intensive insulin therapy and have had only fair to poor glycemic control, have a 30% to 40% chance of having nephropathy after 20 years—in contrast to the much lower frequency in patients with type 2 diabetes, who are not receiving intensive therapy, in whom only about 15% to 20% develop clinical renal disease. However, because so many more individuals are affected with type 2 diabetes, end-stage renal disease is much more prevalent in people with type 2 diabetes in the United States and especially throughout the rest of the world. There is no question that improved glycemic control and more effective therapeutic measures to control hypertension can reduce the incidence of end-stage renal disease in both types of diabetes in the future.

Diabetic nephropathy is initially manifested by proteinuria; subsequently, as kidney function declines, urea and creatinine accumulate in the blood. Thickening of capillary basement membranes and of the mesangium of renal glomeruli produces varying degrees of glomerulosclerosis and renal insufficiency. Diffuse glomerulosclerosis is more common than nodular intercapillary glomerulosclerosis (Kimmelstiel-Wilson lesions); both produce heavy proteinuria.

Sensitive radioimmunoassay methods have permitted detection of microgram concentrations of urinary albumin. Conventional 24-hour urine collections, in addition to being inconvenient for patients, also show wide variability of albumin excretion, since several factors such as sustained erect posture, dietary protein, and exercise tend to increase albumin excretion rates. For these reasons, an albumin-creatinine ratio in an early morning spot urine collected upon awakening is preferable. In the early morning spot urine, a ratio of albumin (µg/L) to creatinine (mg/L) of <30 µg/mg creatinine is normal, and a ratio of 30 to 300 µg/mg creatinine suggests abnormal microalbuminuria. At least two of early morning spot urine collections over a 3- to 6-month period should be abnormal before a diagnosis of microalbuminuria is justified.

Subsequent renal failure can be predicted by persistent urinary albumin excretion rates exceeding 30 µg/min. Glycemic control as well as a low-protein diet (0.8 g/kg/d) may reduce both the hyperfiltration and the elevated microalbuminuria in patients in the early stages of diabetes and those with incipient diabetic nephropathy. Increased microalbuminuria correlates with increased levels of blood pressure and antihypertensive therapy decreases microalbuminuria. Evidence from some studies—but not the UKPDS—supports a specific role for ACE inhibitors in reducing intraglomerular pressure in addition to lowering systemic blood pressure. An ACE inhibitor (captopril, 50 mg twice daily) in normotensive diabetics impedes progression to proteinuria and prevents the increase in albumin excretion rate. Since microalbuminuria has been shown to correlate with elevated nocturnal systolic blood pressure, it is possible that normotensive diabetic patients with microalbuminuria have slightly elevated systolic blood pressure during sleep, which is lowered during antihypertensive therapy. This action may contribute to the reported efficacy of ACE inhibitors in reducing microalbuminuria in normotensive patients.

If treatment is inadequate, then the disease progresses with proteinuria of varying severity, occasionally leading to nephrotic syndrome with hyperalbuninemia, edema, and an increase in circulating LDL cholesterol as well as progressive azotemia. In contrast to all other renal disorders, the proteinuria associated with diabetic nephropathy does not diminish with progressive renal failure (patients continue to excrete 10 to 11 g daily as creatinine clearance diminishes). As renal failure progresses, there is an elevation in the renal threshold at which glycosuria appears.

Patients with diabetic nephropathy should be evaluated and followed by a nephrologist.

B. Treatment  Hemodialysis has been of limited success in the treatment of renal failure due to diabetic nephropathy, primarily because of progression of large vessel disease with resultant death and disability from stroke and myocardial infarction. Growing experience with chronic ambulatory peritoneal dialysis suggests that it may be a more convenient method of providing adequate dialysis with a lower incidence of complications.

Renal transplantation, especially from related donors, is often successful. For patients with compatible donors and no contraindications (such as severe cardiovascular disease), it is the treatment of choice.

Necrotizing Papillitis

This unusual complication of pyelonephritis occurs primarily in diabetic patients. It is characterized by fever, flank pain, pyuria, and sloughing of renal papillae in the urine. It is treated by intravenous administration of appropriate antibiotics.

Renal Decompensation After Radiographic Dyes

The use of radiographic contrast agents in diabetic patients with reduced creatinine clearance has been associated with the development of acute renal failure. Contrast-induced nephropathy is defined as an increase in serum creatinine of at least 0.5 mg/dL or 25% compared with baseline after exposure to intravenous contrast. The increase in serum creatinine occurs shortly after the procedure and peaks 3 to 5 days later before improving over the next 1 to 3 weeks. Although frequently transient, it can cause permanent impairment of renal function. Diabetic patients with normal renal function do not appear to be at increased risk for
contrast nephropathy. If a contrast study is considered essential, patients with a serum creatinine of 1.5 to 2.5 mg/dL should be adequately hydrated before the procedure. Hydration with saline has been the cornerstone of contrast nephropathy prevention: intravenous saline 1 mL/kg/h is started 12 hours before the procedure and continued for 12 hours afterward. Some studies suggest that sodium bicarbonate infusions are more effective, and an alternate option is to infuse sodium bicarbonate: 150 mL of sodium bicarbonate (1 mEq/mL) is added to 1 L of 5% dextrose and infused at 3.5 mL/kg/h for 1 hour before the procedure; 1.2 mg/kg/h during the procedure and for 6 hours afterward. N-acetylcysteine has also been shown in some trials to decrease the incidence of contrast nephropathy. One regimen consists of using oral N-acetylcysteine 600 mg twice a day starting the day before the procedure for a total of four doses. A combination of N-acetylcysteine and intravenous saline or intravenous sodium bicarbonate may be more beneficial. Radiographic contrast material should not be given to a patient with a serum creatinine greater than 3 mg/dL unless the potential benefit outweighs the high risk of acute renal failure.

3. NEUROLOGIC COMPLICATIONS (DIABETIC NEUROPATHY)

Peripheral and autonomic neuropathy are the two most common complications of both types of diabetes. Up to 50% of patients with type 2 diabetes are affected. The pathogenesis of both types of neuropathy is poorly understood. Some lesions, such as the acute cranial nerve palsies and diabetic amyotrophy, have been attributed to ischemic infarction of the involved peripheral nerve. The much more common symmetric sensory and motor peripheral neuropathies and autonomic neuropathy are felt to be due to metabolic complications.

Unfortunately, there is no consistently effective treatment for any of the neuropathies. However, several long-term clinical trials have definitively shown that normalization of blood glucose levels can prevent development and progression of this devastating complication.

Peripheral Neuropathy

A. Distal symmetric polyneuropathy This is the most common form of diabetic peripheral neuropathy in which loss of function appears in a stocking-glove pattern and is due to an axonal neuropathic process. Longer nerves are especially vulnerable—hence the impact on the foot. Both motor and sensory nerve conduction is delayed in the peripheral nerves, and ankle jerks may be absent.

Sensory involvement usually occurs first and is generally bilateral, symmetric, and associated with dulled perception of vibration, and temperature. Pain, when present, can range from mild discomfort to severe incapacitating symptoms (see later). The sensory deficit may eventually be of sufficient degree to prevent patients from feeling pain. Patients with symptoms of sensory neuropathy should be examined with a 5.07 Semmes-Weinstein filament. Those who cannot feel the filament must be considered at risk for unperceived neuropathic injury.

The denervation of the small muscles of the foot results in clawing of the toes and displacement of the submetatarsal fat pads anteriorly. These changes, together with the joint and connective tissue changes, alter the biomechanics of the foot, increasing plantar pressures. This combination of decreased pain threshold, abnormally high foot pressures, and repetitive stress (eg, walking) can lead to calluses and ulcerations in the high-pressure areas such as over the metatarsal heads. Peripheral neuropathy also predisposes to the development of Charcot arthropathy. Other predisposing factors for this condition include autonomic neuropathy and trauma. The acute Charcot foot presents with pain and swelling, and if the condition is untreated, it leads to a rocker bottom deformity and ulceration. The early radiologic changes are of joint subluxation and periarticular fractures. As the process progresses, there is frank osteoclastic destruction leading to deranged and unstable joints particularly in the midfoot.

Not surprisingly, the key issue for healing of neuropathic ulcers in a foot with good vascular status is mechanical unloading. Additionally, any infection should be treated with debridement and appropriate antibiotics. Healing times of 8 to 10 weeks are typical. In the occasional patient, where healing appears refractory, platelet-derived growth factor (becaplermin) should be considered for local application. A postmarket epidemiologic study showed increased cancer deaths in patients who had used three or more tubes of becaplermin on their leg or feet ulcers, and there is now a boxed warning in the drug label. Once ulcers are healed, therapeutic footwear is key to preventing recurrences. Custom-molded shoes are reserved for patients with significant foot deformities. Other patients with neuropathy may require accommodative insoles that distribute the load over as wide an area as possible. Patients with foot deformities and loss of protective threshold should seek regular care from a podiatrist. They should be educated about appropriate footwear, and those patients with loss of protective threshold should be instructed to inspect their feet daily for reddened areas, blisters, abrasions, or lacerations.

B. Isolated peripheral neuropathy Involvement of the distribution of only one nerve (mononeuropathy) or of several nerves (mononeuropathy multiplex) is characterized by sudden onset with subsequent recovery of all or most of the function. This neuropathy has been attributed to vascular ischemia or traumatic damage. Cranial and femoral nerves are commonly involved, and motor abnormalities predominate. The patient with cranial nerve involvement usually presents with diplopia. Clinical examination reveals signs of single third, fourth, or sixth nerve weakness, and the pupil is spared. A full recovery of function occurs in 6 to 12 weeks. Diabetic amyotrophy presents with onset of severe pain in the front of the thigh. Within a few days or weeks of the onset of pain, the patient develops weakness and wasting of the quadriceps. Usually as the weakness appears, the pain tends to improve. Management includes analgesia and improved diabetic control. The symptoms improve over 6 to 18 months.

C. Painful diabetic neuropathy Hypersensitivity to light touch and occasionally severe burning pain, particularly at night,
can become physically and emotionally disabling. Amitriptyline, 25 to 75 mg at bedtime, has been recommended for pain associated with diabetic neuropathy. Dramatic relief has often resulted within 48 to 72 hours. This rapid response is in contrast to the 2 or 3 weeks required for an antidepressant effect. Patients often attribute benefit to having a full night’s sleep after amitriptyline, compared to many previously sleepless nights occasioned by neuropathic pain. Mild to moderate morning drowsiness is a side effect that generally improves with time or can be lessened by giving the medication several hours before bedtime. This drug should not be continued if improvement has not occurred after 5 days of therapy. If amitriptyline’s anticholinergic effects are too troublesome, then nortriptyline can be used. Desipramine in doses of 25 to 150 mg/d seems to have the same efficacy as amitriptyline. Tricyclic antidepressants in combination with phenothiazine or fluphenazine have been shown in two studies to be efficacious in painful neuropathy, with benefits unrelated to relief of depression. Gabapentin (900-1800 mg/d in three divided doses) has also been shown to be effective in the treatment of painful neuropathy and should be tried if the tricyclic drugs prove ineffective. Pregabalin, a congener of gabapentin, has been shown in an 8-week study to be more effective than placebo in treating painful diabetic peripheral neuropathy. However, this drug was not compared with an active control. Also, because of its abuse potential, it has been categorized as a Schedule V controlled substance. Duloxetine, a serotonin and norepinephrine reuptake inhibitor, has been approved for the treatment of painful diabetic neuropathy. In clinical trials, this drug reduced the pain sensitivity score by 40% to 50%. Capsaicin, a topical irritant, has been found to be effective in reducing local nerve pain; it is dispensed as a cream (Zostrix 0.025%, Zostrix-HP 0.075%) to be rubbed into the skin over the painful region two to four times daily. Gloves should be used for application, because hand contamination could result in discomfort if the cream comes in contact with eyes or sensitive areas such as the genitalia. Five percent lidocaine patch applied over an area of maximal pain has been reported to be of benefit and this therapy is currently in clinical trials.

Diabetic neuropathic cachexia is a syndrome characterized by a symmetric peripheral neuropathy associated with profound weight loss (up to 60% of total body weight) and painful dysesthesias affecting the proximal lower limbs, the hands, or the lower trunk. Treatment is usually with insulin and analgesics. The prognosis is usually good, and patients typically recover their baseline weight with resolution of the painful sensory symptoms within 1 year.

**Autonomic Neuropathy**

Neuropathy of the autonomic nervous system is common in patients with diabetes of long duration and can be a very disconcerting clinical problem. It can affect many diverse visceral functions including blood pressure and pulse, gastrointestinal activity, bladder function, and erectile function. Treatment is directed specifically at each abnormality.

Involvement of the gastrointestinal system may be manifested by nausea, vomiting, and postprandial fullness (from gastric atony); symptoms of reflux or dysphagia (from esophageal involvement); constipation and recurrent diarrhea, especially at night (from involvement of the small bowel and colon); and fecal incontinence (from anal sphincter dysfunction). Gallbladder function is altered, and this enhances stone formation.

Gastroparesis should be considered in type 1 diabetic patients in whom unexpected fluctuations and variability in their blood glucose levels develops after meals. Radiographic studies of the stomach and radioisotopic examination of gastric emptying after liquid and solid meals are of diagnostic value in these patients. Metoclopramide has been of some help in treating diabetic gastroparesis. It is a dopamine antagonist that has central antiemetic effects as well as a cholinergic action to facilitate gastric emptying. It is given in a dose of 10 mg orally three or four times a day, 30 minutes before meals and at bedtime. Drowsiness, restlessness, fatigue, and lassitude are common adverse effects. Tardive dyskinesia and extrapyramidal effects can occur especially when the drug is used for longer than 3 months and the FDA has cautioned against its chronic use. Erythromycin appears to bind to motilin receptors in the stomach and has been found to improve gastric emptying in doses of 250 mg three times daily over the short term, but its effectiveness seems to diminish over time. Tegaserod (Zelnorm), the partial 5-HT4 agonist, has been withdrawn from the US market by the FDA, so it is no longer used for this indication. In selected patients, injections of botulinum toxin into the pylorus can reduce sphincter resistance and enhance gastric emptying. Gastric electrical stimulation has been reported to improve symptoms and quality of life indices in patients with gastroparesis refractory to pharmacologic therapy.

Diarrhea associated with autonomic neuropathy has occasionally responded to broad-spectrum antibiotic therapy, although it often undergoes spontaneous remission. Refractory diabetic diarrhea is often associated with impaired sphincter control and fecal incontinence. Therapy with loperamide, 4 to 8 mg daily, or diphenoxylate with atropine, two tablets up to four times a day, may provide relief. In more severe cases, tincture of paregoric or codeine (60-mg tablets) may be required to reduce the frequency of diarrhea and improve the consistency of the stools. Clonidine has been reported to lessen diabetic diarrhea; however, its usefulness is limited by its tendency to cause orthostatic hypotension in these patients who already have autonomic neuropathy. Constipation usually responds to stimulant laxatives such as senna. Metamucil and other bulk-providing agents may relieve either the diarrhea or the constipation phases, which often alternate.

Inability to completely empty the bladder can sometimes occur. Bethanechol in doses of 10 to 50 mg three times a day has occasionally improved emptying of the atonic urinary bladder. Cather decompression of the distended bladder has been reported to improve its function, and considerable benefit has been reported after surgical severing of the internal vesicle sphincter.

Use of Jobst fitted stockings, tilting the head of the bed, and arising slowly from the supine position are useful in minimizing symptoms of orthostatic hypotension. Some patients may require the addition of a mineralocorticoid such as fludrocortisone acetate (0.1-0.2 mg twice daily). Fludrocortisone therapy, however, can...
result in supine hypertension and hypokalemia. Midodrine (10 mg three times a day), an alpha adrenergic agonist, can be tried if Jobst stockings and sleeping upright prove ineffective in providing symptomatic relief.

**Erectile dysfunction** due to neuropathy differs from the psychogenic variety in that the latter may be intermittent (erections occur under special circumstances), whereas diabetic erectile dysfunction is usually persistent. To distinguish neuropathic or psychogenic erectile dysfunction from the erectile dysfunction caused by aortoiliac occlusive disease or vasculopathy, papaverine is injected into the corpus cavernosum of the penis. If the blood supply is competent, a penile erection occurs (Chapter 12). Urinary incontinence, with large volumes of residual urine, and retrograde ejaculation can also result from pelvic neuropathy.

There are medical, mechanical, and surgical approaches available for treatment of erectile dysfunction. Penile erection depends on relaxation of the smooth muscle in the arteries of the corpus cavernosum, and this is mediated by nitric oxide-induced cyclic 3',5'-guanosine monophosphate (cGMP) formation. cGMP-specific phosphodiesterase type 5 (PDE5) inhibitors impair the breakdown of cGMP and improve the ability to attain and maintain an erection. Sildenafil (Viagra), vardenafil (Levitra), and tadalafil (Cialis) have been shown in placebo-controlled clinical trials to improve erections in response to sexual stimulation. The recommended dose of sildenafil for most patients is one 50-mg tablet taken approximately 1 hour before sexual activity. The peak effect is at 1.5 to 2 hours, with some effect persisting for 4 hours. Patients with diabetes mellitus using sildenafil reported 50% to 60% improvement in erectile function. The maximum recommended dose is 100 mg. The recommended dose of both vardenafil and tadalafil is 10 mg. The doses may be increased to 20 mg or decreased to 5 mg based on efficacy and side effects. Tadalafil has been shown to improve erectile function for up to 36 hours after dosing. In clinical trials, only a few adverse effects have been reported—transient mild headache, flushing, dyspepsia, and in some altered color vision. Priapism can occur with these drugs and patients should be advised to seek immediate medical attention if an erection persists for longer than 4 hours. The PDE5 inhibitors potentiate the hypotensive effects of nitrates, and their use is contraindicated in patients who are concurrently using organic nitrates in any form. Caution is advised for men who have suffered a heart attack, stroke, or life-threatening arrhythmia within the previous 6 months; men who have resting hypotension or hypertension, and men who have a history of cardiac failure or have unstable angina. Rarely, a decrease in vision or permanent visual loss has been reported after PDE5 inhibitor use.

Intracorporeal injection of vasoactive drugs causes penile engorgement and erection. Drugs most commonly used include papaverine alone, papaverine with phentolamine, and alprostadil (prostaglandin E₁). Alprostadil injections are relatively painless, but careful instruction is essential to prevent local trauma, priapism, and fibrosis. Intracystal pellets of alprostadil avoid the problem of injection of the drug.

External vacuum therapy (Erec-Aid System) is a nonsurgical treatment consisting of a suction chamber operated by a hand pump that creates a vacuum around the penis. This draws blood into the penis to produce an erection that is maintained by a specially designed tension ring inserted around the base of the penis and which can be kept in place for up to 20 to 30 minutes. Although this method is generally effective, its cumbersome nature limits its appeal.

In view of the recent development of nonsurgical approaches to therapy of erectile dysfunction, resort to surgical implants of penile prostheses is becoming less common.

### 4. CARDIOVASCULAR COMPLICATIONS

#### Heart Disease

Microangiopathy occurs in the heart and may explain the existence of congestive cardiomyopathies found in diabetic patients without demonstrable coronary artery disease. Much more commonly, however, heart failure in patients with diabetes is a consequence of coronary atherosclerosis. Myocardial infarction is three to five times more common in diabetic patients than in age-matched controls and is the leading cause of death in patients with type 2 diabetes. Cardiovascular disease risk is increased in patients with type 1 diabetes as well, although the absolute risk is lower than in patients with type 2 diabetes. Women with diabetes lose the protection against myocardial infarction that is usually present during the childbearing years. The increased risk of atherosclerosis in people with diabetes may reflect the combination of hyperlipidemia, abnormalities of platelet adhesiveness, coagulation factors, hypertension, and oxidative stress and inflammation.

Large intervention studies of risk factor reduction in diabetes are lacking, but it is reasonable to assume that reducing these risk factors would have beneficial effects. Lowering LDL cholesterol reduces first events in patients without known coronary disease and secondary events in patients with known coronary disease. These intervention studies included some patients with diabetes, and the benefits of lowering LDL cholesterol were apparent in this group. The National Cholesterol Education Program clinical practice guidelines have designated diabetes as a coronary risk equivalent and have recommended that patients with diabetes should have an LDL cholesterol goal of <100 mg/dL. Lowering LDL cholesterol to 70 mg/dL may have additional benefit and is a reasonable target for most patients with type 2 diabetes who have multiple risk factors for cardiovascular disease.

The ADA also recommends lowering blood pressure to 130/80 mm Hg or less. The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT) randomized 33,357 subjects (age 55 years or older) with hypertension and at least one other coronary artery disease risk factor to receive treatment with chlorthalidone, amlodipine, or lisinopril. Chlorthalidone appeared to be superior to amlodipine and lisinopril in lowering blood pressure, in reducing the incidence of cardiovascular events, in tolerability, and in cost. The study included 12,063 individuals with type 2 diabetes. The Heart Outcomes Prevention Evaluation (HOPE) study randomized 9297 high-risk patients who had evidence of vascular disease or diabetes plus one other cardiovascular risk factor to receive ramipril or placebo for a mean period of 5 years. Treatment with ramipril resulted in a 25% reduction of the risk of myocardial
infarction, stroke, or death from cardiovascular disease. The mean difference in blood pressure between the placebo and ramipril groups was 2.2 mm Hg systolic and 1.4 mm Hg diastolic, and the reduction in cardiovascular event rate remained significant after adjustment for this small difference in blood pressure. The mechanism underlying this protective effect of ramipril is unknown. Patients with type 2 diabetes who already have cardiovascular disease or microalbuminuria should therefore be considered for treatment with an ACE inhibitor. More clinical studies are needed to address the question of whether patients with type 2 diabetes, who do not have cardiovascular disease or microalbuminuria, would specifically benefit from ACE inhibitor treatment.

Aspirin (81-325 mg daily) inhibits thromboxane synthesis by platelets and is effective in reducing cardiovascular morbidity and mortality in patients who have a history of myocardial infarction or stroke (secondary prevention). It is unclear if aspirin prevents primary cardiovascular events in people with diabetes. The current recommendation is to give aspirin to those people with diabetes who are at increased risk for cardiovascular events (greater than 10% 10 year risk of cardiovascular events). Typically this includes most 50-year-old men and 60-year-old women with one or more additional risk factors (smoking, hypertension, dyslipidemia, family history of premature cardiovascular disease, and albuminuria). Contraindications for aspirin therapy include age less than 21 years (because of risk of Reye syndrome), aspirin allergy, bleeding tendency (eg, anticoagulant therapy), recent gastrointestinal bleeding, or active hepatic disease. The Early Treatment Diabetic Retinopathy Study (ETDRS) showed that aspirin does not influence the course of proliferative retinopathy. There was no statistically significant difference in the severity of vitreous/preretinal hemorrhages or their rate of resolution between the aspirin and placebo groups. Thus, it appears that there is no contraindication to aspirin use to achieve cardiovascular benefit in diabetic patients who have proliferative retinopathy.

**Peripheral Vascular Disease**

Atherosclerosis is markedly accelerated in the larger arteries. It is often diffuse, with localized enhancement in certain areas of turbulent blood flow, such as at the bifurcation of the aorta or other large vessels. Clinical manifestations of peripheral vascular disease include ischemia of the lower extremities, impotence, and intestinal angina.

The incidence of gangrene of the feet in people with diabetes is 30 times that in age-matched controls. The factors responsible for the development of this condition, in addition to peripheral vascular disease, are small vessel disease, peripheral neuropathy with loss of both pain sensation and neurogenic inflammatory responses, and secondary infection. In two-thirds of patients with ischemic gangrene, pedal pulses are not palpable. In the remaining one-third who has palpable pulses, reduced blood flow through these vessels can be demonstrated by plethysmographic or Doppler ultrasound examination. Prevention of foot injury is imperative. Agents that reduce peripheral blood flow such as tobacco and propranolol should be avoided. Control of other risk factors such as hypertension is essential. Cholesterol-lowering agents are useful as adjunctive therapy when early ischemic signs are detected and when dyslipidemia is present. Patients should be advised to seek immediate medical care if a diabetic foot ulcer develops. Improvement in peripheral blood flow with endarterectomy and bypass operations is possible in certain patients.

**5. SKIN AND MUCOUS MEMBRANE COMPLICATIONS**

Chronic pyogenic infections of the skin may occur, especially in poorly controlled diabetic patients. Eruptive xanthomas can result from hypertriglyceridemia, associated with poor glycemic control. Candidal infection can produce erythema and edema of intertriginous areas below the breasts, in the axillas, and between the fingers. It causes vulvovaginitis in most chronically uncontrolled diabetic women with persistent glucosuria and is a frequent cause of pruritus. While antifungal creams containing miconazole or clotrimazole offer immediate relief of vulvovaginitis, recurrence is frequent unless glucosuria is reduced.

Necrobiosis lipoidica diabetorum are oval or irregular shaped plaques with reddish demarcated borders and a glistening yellowish surface usually located over the anterior surfaces of the legs or the dorsal surfaces of the ankles. Rarely, lesions can occur on the hands, fingers, forearms, face, and scalp. The necrobiosis lesion usually starts out as an oval violaceous patch that slowly expands. The advancing border is red and the central area turns yellow-brown. The thinning of the dermis in the center of the lesion leads to the shiny surface and prominent telangiectasia. It also allows the subcutaneous fat to become more visible hence the yellowish appearance. Pathologically, the lesions show degeneration of collagen, granulomatous inflammation of subcutaneous tissues and blood vessels, capillary basement membrane thickening, and obliteration of vessel lumina. The condition is associated with type 1 diabetes, although it can occur in patients with type 2 diabetes and also in people without diabetes. It occurs in about 0.3% of patients with diabetes, usually in patients in their 30s and 40s, and is about three times more common in women than in men. In some studies an association with microalbuminuria and retinopathy has been reported. Improving glycemic control may help the condition. The first-line treatment includes topical and subcutaneous corticosteroids. Second-line treatments include systemic steroids, cyclosporine, ticlopidine, nicotinamide, clofazimine, fumarate esters, intraleisional etanercept, and topical psoralen with ultraviolet A. Pulsed dye lasers can improve the appearance of telangiectasias. Flare-ups are frequent. No treatment is completely effective.

**Shin spots** are uncommon in adult diabetics. They are brownish, rounded, painless atrophic lesions of the skin in the pretibial area.

**6. BONE AND JOINT COMPLICATIONS**

Bone and joint complications are generally attributed to metabolic or vascular sequelae of long-standing diabetes.

**Diabetic chorioarthropathy** is a syndrome of chronic progressive stiffness of the hand secondary to contracture and tightening of the skin over the joints. It is characterized by inability to flatten the palms against a flat surface (prayer sign). It is believed to be
due to glycosylation of collagen and perhaps other proteins in connective tissue. It is associated with poor glycemic control and with longer duration of diabetes.

Dupuytren contractures consist of nodular thickening and contracture of the palmar fascia of the hand, producing flexure contractures of the fingers. It can occur in the absence of diabetes, but is more common in people with diabetes. The etiology is unclear but there may be an inflammatory component. Glucocorticoid injection into discrete nodules can sometimes help but the standard treatment is surgical fasciectomy.

Carpal tunnel syndrome occurs when the median nerve is compressed within the carpal tunnel. It is more common in people with diabetes, especially those who also have diabetic chiroarthropathy. It is presumably due to glycosylation of collagen and other proteins in the connective tissue.

Patients with adhesive capsulitis of the shoulder (frozen shoulder) complain primarily of stiffness and loss of range of motion. They may also have shoulder pain. It occurs more frequently in people with long-standing diabetes—the incidence being two to four times higher than in the general population. The patients may also have diabetic chiroarthropathy or Dupuytren contractures. In most cases it is a limited condition that responds to physical therapy. Patients should be warned that recovery may take 6 to 18 months. For a few patients surgery may be necessary. Adhesive capsulitis of the hip has also been described.

Data on bone mineral density and fracture risk in people with diabetes are contradictory. Bone mineral density has been reported to be low, normal, or high in type 2 diabetes patients. Type 2 diabetes patients do appear to be at increased risk for nonvertebral fractures. Women with type 1 diabetes have an increased risk of fracture when compared to women without diabetes. It is likely that other factors such as duration of diabetes and diabetes complications such as neuropathy and renal disease affect both the bone mineral density and fracture risk.

Diffuse idiopathic skeletal hyperostosis (DISH) is a skeletal disease characterized by ossification of the anterior longitudinal ligament of the spine and various extraspinal ligaments. It causes stiffness and decreased range of spinal motion. The peripheral joints most commonly affected are the metacarpophalangeal joints, elbows, and shoulders. Diabetes, obesity, hypertension, and dyslipidemia are risk factors for this condition.

Hyperuricemia and gout are disorders associated with the metabolic syndrome. Thus, it is not surprising that type 2 diabetes patients are at increased risk for acute gout as well as chronic tophaceous gout.

Bursitis, particularly of the shoulders and hips, occurs more frequently than expected in patients with diabetes.

7. INFECTION

There are also several unusual infections that occur almost exclusively in diabetic patients (eg, emphysematous cholecystitis, mucormycosis, malignant otitis externa, and necrotizing papillitis). As noted earlier, atherosclerosis with peripheral vascular disease is very common in the diabetic population, and the resultant ischemia undoubtedly plays a role in the frequent and severe lower extremity infections seen in these patients.

MANAGEMENT OF DIABETES IN THE HOSPITALIZED PATIENT

A number of studies have observed that hospitalized patients with diabetes and those with new-onset hyperglycemia (ie, those without a prediagnosis of diabetes) have higher inpatient morbidity and mortality. The morbidity and mortality in diabetics is twice that of nondiabetics. Those with new-onset hyperglycemia have even a higher mortality—almost eightfold greater in one study. These observations have led to increased interest in improving glucose control in the hospitalized diabetic patient.

Most patients with diabetes are hospitalized for reasons other than their diabetes. Up to 10% to 15% of all hospitalized patients have diabetes. Audits suggest that as many as a 30% of hospitalized diabetic patients have inappropriate management of their diabetes such as being given metformin where contraindicated; failure to act on high blood glucose levels; omission of diabetes medication; no record of diabetes complications; inappropriate insulin management; or blood glucose monitoring. Use of outpatient oral therapies or insulin regimens in the hospital is challenging. Patients are not eating according to their normal schedule and are often fasting for procedures. It is, therefore, usual to use insulin, subcutaneous or intravenous, in the hospitalized patient. Insulin is safe to use in patients with cardiac, renal, and liver disease and its dosing can be adjusted to match changing inpatient needs.

Surgery represents a stressful situation during which most of the insulin antagonists (catecholamines, GH, corticosteroids) are mobilized. In the patient with diabetes, this can lead to a worsening of hyperglycemia and perhaps even ketoacidosis. The aim of medical management of people with diabetes during the perioperative period is to minimize the stress-induced changes. Recommendations for management depend both on the patient’s usual diabetic regimen and on the type of surgery (major or minor) to be done.

For people with diabetes controlled with diet alone, no special precautions are necessary unless diabetic control is markedly disturbed by the procedure. If this occurs, small amounts of short-acting insulin, as needed, will correct the hyperglycemia. Patients on oral agents should not take them on the day of surgery. If there is significant hyperglycemia, short-acting insulin can be given as needed. If this approach does not provide adequate control, an insulin infusion should be started in the manner indicated below. The oral agents can be restarted once the patient is eating normally after the operation. It is important to order a postoperative serum creatinine level to ensure normal renal function prior to restarting metformin therapy.

Patients taking insulin represent the only serious challenge to management of diabetes when surgery is necessary. The insulin regimen used to control the glucose depends on the kind of diabetes (type 1 or type 2); whether it is minor surgery (<2 hour and patient eating afterward) or major surgery (longer than 2 hours, invasion of body...
cavity, not eating afterward); and the preoperative insulin regimen (basal bolus or premixed insulin twice a day or premeal bolus only or regular before meals and NPH at bedtime). Type 1 patients have to be on some insulin to prevent the development of diabetic ketoacidosis. Many type 2 patients on insulin are fine without insulin for a few hours. Ideally patients with diabetes should undergo surgery early in the morning. Table 17-23 summarizes the approach for these various kinds of patients. One insulin infusion method adds 10 U of regular insulin to 1 L of 5% dextrose in half-normal saline, and this is infused intravenously at a rate of 100 to 180 mL/h. This gives the patient 1 to 1.8 U of insulin per hour, which, except in the most severe cases, generally keeps the blood glucose within the range of 100 to 250 mg/dL (5.5-13.9 mmol/L). The infusion may be continued for several days if necessary. Plasma glucose or blood glucose should be determined every 2 to 4 hours to be sure metabolic control is adequate. If it is not, adjustments in the ratio of insulin to dextrose in the intravenous solution can be made.

An alternative method, which is gaining increasing popularity, consists of separate infusions of insulin and glucose delivered by pumps to permit independent adjustments of each infusion rate, depending on hourly variation of blood glucose values. There are a number of different algorithms available for insulin infusions. Table 17-24 provides guidelines for management with an insulin infusion and an algorithm designed to achieve glycemic control in the range of 120 to 180 mg/dL blood glucose.

After surgery, when the patient has resumed an adequate oral intake, intravenous administration of insulin and dextrose can be stopped half an hour after the first subcutaneous insulin injection. Insulin needs may vary in the first several days after surgery because of continuing postoperative stresses and because of variable caloric intake. In this situation, multiple doses of regular insulin, guided by blood glucose determinations, can keep the patient in acceptable metabolic control.

In the intensive care units, glucose levels are controlled most frequently using insulin infusions. Patients on total parental nutrition (TPN) can have insulin added to the bag. Standard TPN contains 25% dextrose, so 50-mL/h infusion delivers 12.5 g of dextrose per hour.

On the general surgical and medical wards, most patients are managed on subcutaneous insulin regimens. Limited cross-sectional and prospective studies suggest that the best glucose control is achieved on a combination of basal and bolus regimen with 50% of daily insulin needs provided by intermediate or long-acting insulins. Standardized order sets prompt medical personnel to write more physiological insulin orders, reduce errors, and include algorithms for recognition and treatment of hypoglycemia. Table 17-25 is an example of one such order set for a subcutaneous insulin regimen.

### Table 17-23 Recommendations for management of insulin-treated diabetes during surgery.

### Targets for Glucose Control in the Hospitalized Patient

A number of studies have observed that hospitalized patients with diabetes and those with new-onset hyperglycemia (ie, those without a preadmission diagnosis of diabetes) have higher inpatient morbidity and mortality. Also, poor glucose control in diabetics at admission is associated with increased size of myocardial infarction and in some studies increased nosocomial infections after surgery. These observations have led to the question of whether lowering glucose levels close to normal in the hospital improves outcomes.

A prospective trial in surgical ICU patients (Leuven 1 study) reported that aggressive treatment of hyperglycemia (blood glucose <110 mg/dL) reduced mortality (35 deaths vs 63, p <0.04) and morbidity. Only a small number of persons in this study (204 of 1548) had a diagnosis of diabetes preoperatively, and so this study suggests that controlling hyperglycemia per se (independent of a diagnosis of diabetes) was beneficial. The benefits, however, were principally seen in patients who were in the ICU for longer than 5 days, and it was unclear whether the benefits would also apply to most surgical patients who stay in the ICU for only 1 to 2 days.

The same investigators performed a similar prospective trial among 1200 medical ICU patients (Leuven 2 study) and reported that aggressive treatment of hyperglycemia reduced morbidity (reduction in acquired renal injury and increased early weaning from mechanical ventilation) but not mortality. Again, as in the surgical ICU study, only a small number of persons (16.9%) had a diagnosis of diabetes at admission.

The findings of the Leuven studies however have not been confirmed in other prospective studies. Two other ICU-based studies (Glucotrol and VISEP) that attempted to confirm the
TABLE 17–24 Guideline for perioperative diabetes management with an intravenous insulin infusion.

| 2. Regular insulin infusion 100 U regular insulin in 100 mL NS (1 U = 1 mL) |
| A. Flush first 20 mL of infusion through tubing before connecting to patient. |
| B. Before beginning infusion, check blood glucose (BG) with glucose meter. |

| 3. Start insulin infusion rate as follows (when BG ≥100 mg/dL) |
| □ 0.3 U/h taking <30 U insulin daily (recommended for type 1; Pancreatectomy) |
| □ 1 U/h for patients previously diet controlled, taking oral hypoglycemic agent, or <30 U insulin daily |
| □ 1.5 U/h for patients taking >30 U insulin daily |
| □ Other ______ U/h |

| 4. Adjust insulin infusion rate as follows: |
| □ Standard adjustment |
| BG <80 mg/dL; stop infusion and call MD; see instruction # 5 below |
| Do not restart insulin infusion until BG >100 mg/dL © |
| BG 80-120; decrease drip by 0.5 U/h |
| BG 121-180; no change in drip rate |
| BG 181-250; increase drip by 0.5 U/h |
| BG >250 bolus 5 U regular insulin IV and increase drip by 0.5 U/h |

| □ Sensitive Adjustment (for Type 1; Pancreatectomy) |
| BG <80 mg/dL; stop infusion and call MD; see instruction # 5 below |
| Do not restart insulin infusion until BG >100 mg/dL © |
| BG 80-120; decrease drip by 0.2 U/h |
| BG 121-180; no change in drip rate |
| BG 181-250; increase drip by 0.2 U/h |
| BG >250 bolus 2 U regular insulin IV and increase drip by 0.2 U/h |

5. For a BG <80 mg/dL or >400 mg/dL on insulin infusion, call MD. |
- BG <80 mg/dL but >60 mg/dL; stop insulin infusion; check BG every 15 min. |
- BG >400 mg/dL; call MD to reassess insulin infusion rate. |
- If TPN or tube feeds are interrupted for longer than 30 min, start D10W at 50 mL/h. Notify MD about change and future action. |

6. When converting to subcutaneous (SQ) insulin, give prescribed SQ dose 30 min prior to discontinuing insulin infusion. Use Adult SQ Insulin Order Sheet. |

7. If patient eating meals give ______ U aspart SQ after patient eats carbohydrates and continue insulin infusion. |

8. Discontinue insulin infusion maintenance IV fluids when insulin infusion discontinued. |

©Check BG every hour with glucose meter until stable (range 100-180 mg/dL) for two consecutive readings and then every 2 hours. |

findings were unable to do so. These two studies, however, were stopped prematurely for the following reasons: an interim analysis (falsely) suggested increased mortality in the test group in the Glucose control study, and hypoglycemic events increased sevenfold in the intensive treatment group in the VISEP study. A large multicenter, multinational study (NICE-SUGAR) recruited 6104 surgical and medical ICU patients with hyperglycemia (20% had diabetes) and randomized them to tight control (81-108 mg/dL) or less tight control (<180 mg/dL). The tight group achieved blood glucose levels of 115 ± 18 and the conventional group 144 ± 23. There were more deaths (829 vs 751) in the tight glucose control group compared to the less tight glucose control group (p = 0.02). The intensively treated group also had more cases of severe hypoglycemia (206 vs 15 cases), and the excess deaths in the intensive group were due to cardiovascular events. |

A study on tight intraoperative glycemic control during cardiac surgery also failed to show any benefit; if anything, the intensively treated group had more events. The United Kingdom Glucose Insulin in Stroke Trial (GIST-UK) failed to show beneficial effect of tight glycemic control in stroke patients; however, the investigators acknowledged that, because of slow recruitment, the study was underpowered. Based on the evidence available so far, ICU patients with blood glucose levels above 180 mg/dL (diabetes and new-onset hyperglycemia) should be treated aiming for target glucose levels between 140 and 180 mg/dL. Targeting blood glucose control in the intensive care unit close to 100 mg/dL is not beneficial and may even be harmful. When patients leave the ICU, target glucose values between 100 mg/dL and 180 mg/dL may be appropriate, although this view is based on clinical observations rather than conclusive evidence. |

DIABETES MELLITUS AND PREGNANCY

Hormone and Fuel Balance During Pregnancy

During pregnancy, the rapidly growing fetus impacts metabolism in the mother and causes profound hormonal and metabolic changes. These changes significantly affect the management of
TABLE 17-25 Example of a standardized subcutaneous insulin order set for inpatient use.

1. Check blood glucose and give insulin before meals, bedtime, and 2 AM.
2. Discontinue previous SQ insulin order.
3. If patient becomes NPO for procedure/stop eating:
   - **HOLD** nutritional dose of rapid-acting analog.
   - Give correctional dose of rapid-acting analog if BG > 130 mg/dl.
   - Give glargine dose. If BG has been < 70 mg/dl in last 24 h, call MD to consider adjusting glargine dose.
   - Call MD for NPO orders if patient on 70/30, NPH insulin or has been NPO > 12 h.

4. Call MD for BG < 70 mg/dL or > 400 mg/dL.

5. For BG < 70 mg/dL, use Hypoglycemia Protocol below. These hypoglycemia orders remain active for duration of SQ insulin administration. For patient taking PO, give 20 g of oral fast-acting carbohydrate per patient preference:

   - ✕ Give 4 glucose tablets (5 g glucose/tablet). Repeat Q 15 min until BG ≥ 100 mg/dL.
   - or
   - ✕ Give 6 oz fruit juice. Repeat Q 15 min until BG ≥ 100 mg/dL.
   - ✕ Give 25-mL D50W IV push if patient cannot take PO. Repeat Q 15 min until BG ≥ 100 mg/dL.
   - ✕ Check fingerstick glucose every 15 min and repeat treatment until BG is ≥ 100 mg/dL.

6. Discontinue above monitoring and intervention orders when SQ insulin is discontinued.

Note: Glargine (Lantus) cannot be mixed with any other insulin. Give glargine as a separate injection.
Pregnancy in Women with Preexisting Diabetes

A. Prevalence

The prevalence of gestational diabetes in pregnant women is increasing. A study from Southern California showed that between 1999 and 2005, the prevalence of preexisting diabetes, age and race/ethnicity adjusted, increased from 0.81/100 in 1999 to 1.82/100 in 2005 (p for trend <0.001). Significant increases were observed in all age groups and all racial/ethnic groups. The incidence of type 2 diabetes increasing and in some countries, pregnant women with type 2 diabetes now outnumber those with type 1 diabetes.

In 1988 0.5% of all pregnancies in the United States were complicated by gestational diabetes and this type accounted for 65% of the complicated pregnancies compared with 26% in 1980.

B. Maternal, fetal, and neonatal consequences of presence of diabetes during pregnancy

If diabetes is poorly controlled in the first weeks of pregnancy, the risks of spontaneous abortion and congenital malformation of the infant are increased. Poor glycemic control later in pregnancy is associated with still births, fetal macrosomia, polyhydramnios, and neonatal hypoglycemia. Preexisting diabetes-related complications, particularly gastroenteropathy, retinopathy, and nephropathy can impact both the pregnant woman and the fetus.

Congenital abnormalities. Poorly controlled diabetes in the first weeks of pregnancy raises the risks of spontaneous abortion and congenital anomalies of the infant. The commonest abnormalities are cardiac, neural tube defects, and genitourinary abnormalities. Their incidence compared to the normal population and their presumed time of occurrence during embryonic development are listed in Table 17–26. The rate of anomalies is higher in diabetic women with poor preconception control. Observational studies demonstrate a linear relationship between glycated hemoglobin levels and malformation rates. From a systematic review of several observational studies, it was estimated that the relative risk reduction of congenital anomalies for each 1% decrease in HbA1c ranged from 0.39 to 0.59. Attending preconception clinics with intensive diabetic management instituted prior to conception and continued through early pregnancy, results in significant reduction in the frequency of anomalies—to rates near the population norms.

Polyhydramnios. Later in pregnancy, polyhydramnios, a common complication in women with poorly controlled diabetes, may lead to preterm delivery. Polyhydramnios also increases the risk for placenta abruptio and postpartum uterine atony.

Polyhydramnios is an excess volume of amniotic fluid (>1000 mL, often >3000 mL). It is most often associated with fetal macrosomia. The excess volume of amniotic fluid is not related simply to the concentration of glucose or other solutes in amniotic fluid or to excess fetal urine output as measured by change in bladder size on ultrasonography. Other possible factors include decreased fetal swallowing, decidual and amniotic fluid prolactin, and as yet unknown determinants of the complicated multicompartamental intrauterine transfer of water. Polyhydramnios is rare in women with well-controlled diabetes.

**Fetal macrosomia.** Many fetuses of poorly controlled diabetic mothers are macrosomic (birth weight >90th percentile for gestational age), with increased fat stores, increased length, and increased abdomen-to-head or thorax-to-head ratios. The hypothesis that fetal macrosomia results from the causal chain of maternal hyperglycemia → fetal hyperglycemia → fetal hyperinsulinemia → fetal macrosomia has been confirmed by clinical and experimental studies. Macroinfants of diabetic mothers have significantly higher concentrations of C peptide (representing endogenous insulin secretion) in their cord sera or amniotic fluid than in those with birth weights appropriate for gestational age. Monkey fetuses with insulin-releasing pellets implanted in utero become macrosomic. Other metabolic substrates that cross the placenta, such as branched-chain amino acids may also play a role in fetal macrosomia, and transplacental lipids could contribute to fat deposition.

Prevention of maternal hyperglycemia throughout pregnancy can reduce the incidence of macrosomia. The glycemic threshold for fetal macrosomia seems to be postprandial peak values above 130 mg/dL (7.2 mmol/L). On the other hand, excessively tight glycemic control (average peak postprandial blood glucose levels <110 mg/dL [6.1 mmol/L]) can be associated with insufficient fetal growth and small-for-date infants.

Complications of macrosomia include fetopelvic disproportion leading to shoulder dystocia and its attendant risk for brachial plexus injury and humeral and clavicle fractures. The neonate with macrosomia is also at increased risk for hypoglycemia, hyperbilirubinemia, hypocalcemia, respiratory distress syndrome, and polycythemia.

Adverse maternal outcomes of difficult vaginal delivery include severe perineal lacerations and subsequent urinary and/or fecal incontinence.

**Intrauterine growth retardation.** The fetus of a woman with diabetes of long duration and vascular disease may suffer intrauterine fetal growth restriction related to inadequate uteroplacental perfusion. All body diameters may be below normal on ultrasonographic measurements, but the abdominal circumference is especially affected, and oligohydramnios and abnormal Doppler flow measurements of the umbilical cord are common. In these patients provision of adequate rest, meticulous control of hypertension (target <135/85 mm Hg), maintenance of normal blood glucose levels, and intensive fetal surveillance are all essential for success.

**Intrauterine death.** Prior to the 1970s, the incidence of apparently sudden intrauterine fetal demise in the third trimester of diabetic pregnancies was at least 5%. Except for congenital malformations, the cause of stillbirth is often not obvious. The risk is greater with poor diabetic control, and the incidence of fetal death exceeds 50%, if ketoacidosis develops in the mother. Some instances of fetal demise are associated with preeclampsia-eclampsia, which is more common in pregnancies complicated by diabetes. Fetal death has also been associated with pyelonephritis—this is now largely prevented by screening for and treating asymptomatic bacteriuria. Other than these known risk factors, one can presume (based on experimental studies) that the combination of fetal hyperglycemia and hypoxia leads to acidosis and myocardial dysfunction. Good glycemic control in diabetic women greatly reduces the risk of stillbirth.

**Neonatal hypoglycemia.** Hypoglycemia is common in the first 48 hours after delivery from previously hyperglycemic mothers and is defined as blood glucose below 36 mg/dL (2.0 mmol/L) regardless of gestational age. The risk is as high for infants of mothers with type 2 diabetes as type 1 diabetes. Neonatal hypoglycemia is most closely linked to poor maternal glucose control and elevated fetal insulin levels during labor and delivery, although data from amniotic fluid insulin studies suggest that the more hyperinsulinemic the fetus in the late third trimester, the higher the risk of neonatal hypoglycemia. Infants of diabetic mothers may also have deficient catecholamine and glucagon secretion, and the hypoglycemia may be related to diminished hepatic glucose production and oxidation of free fatty acids. The symptomatic infant may be lethargic with associated apnea, tachypnea, cyanosis, or seizures. Early feeding with 10% dextrose in water by bottle or gavage by 1 hour of age should be instituted in the at-risk neonate. If this is not successful, treatment with intravenous dextrose solutions is indicated. There are usually no long-term sequelae of episodes of neonatal hypoglycemia. Keeping maternal blood glucose levels below 144 mg/dL and tight glycemic control during labor can reduce the frequency of neonatal hypoglycemia.

**Diabetic gastroenteropathy.** In early gestation, diabetic gastroparesis can severely exacerbate the nausea and vomiting of pregnancy (hyperemesis gravidarum), which sometimes continues into the third trimester. Drugs stimulating gastric motility such as erythromycin may be useful, but many patients with this complication require hyperalimentation to achieve nutritional intake adequate for fetal development.

**Diabetic retinopathy.** Background diabetic retinopathy may develop or progress during pregnancy, but it usually regresses postpartum. If background retinopathy is already present in early pregnancy, the rate of progression to neovascularization over the course of the pregnancy (proliferative diabetic retinopathy) is 6% if the background retinopathy is mild; 18% if it is moderate; and 38% if severe preproliferative changes are present. The risk factors for progression to proliferative retinopathy include poor glycemic control before and during early pregnancy, rapid improvement in glycemic control during pregnancy, hypertension, and perhaps the many growth factors derived from placental tissue. These risks are an important reason to institute intensified preconception management of diabetes. During pregnancy, sequential ophthalmologic examinations are essential in women with type 1 or type 2 diabetes, and laser photocoagulation treatment of the retina may be necessary.

**Diabetic nephropathy.** The risk of worsening of diabetic nephropathy during pregnancy depends on baseline renal function and the degree of hypertension. Total urinary albumin excretion does not increase substantially in normal pregnancy, but total urinary protein collections, which obstetricians have used to define preeclampsia, may show a twofold increase in uncomplicated gestation. Diabetic women with microalbuminuria (30-299 mg/24 h) may have worsening of the albuminuria during pregnancy and 15% to 45% develop the preeclamptic syndrome. Albuminuria usually regresses
Management

Pregnant women with preexisting diabetes should ideally receive care in a multidisciplinary clinic staffed by obstetricians, endocrinologists, diabetes nurse specialists, dietitians, and specialist midwives. There is substantial evidence that this improves the outcomes in women with pregestational diabetes.

Preconception counseling. All diabetic women of reproductive age should be counseled to use adequate birth control and plan their pregnancies. Before any planned pregnancy, the couple should be referred for preconception assessment and counseling. There should be assessment and discussion regarding management of diabetic complications. Baseline measurements should include thyroid function tests including autoantibodies; early morning spot urine albumin/creatinine ratio; urinalysis to rule out asymptomatic bacteriuria; retinal examination; and cardiovascular assessment in high-risk patients such as those with evidence of microvascular disease. ACE inhibitors and ARBs cannot be used during pregnancy. If necessary, alternative antihypertensive agents that are safe for use in pregnancy (methyldopa, nifedipine, amlodipine, labetolol) should be prescribed. Lipid-lowering therapies are also contraindicated, and lipid abnormalities must be managed by dietary measures. There should be discussion of risks and expected management strategies in the pregnancy. The patient should be given glycemic goals with the aim of achieving control as close to normal as possible before conception.

Glucose and insulin management. Women are seen every 2 to 4 weeks in the first and second trimester and then every 1 to 2 weeks until 36 weeks and then weekly to term. The goal of glucose management during pregnancy is to prevent both preprandial and postprandial hyperglycemia. Patients with type 2 diabetes on oral agents are usually switched to insulin treatment during pregnancy. There are small nonrandomized studies suggesting that metformin use is safe in the first trimester. The drug does cross the placenta, but it has not been associated with teratogenesis. Glyburide does not significantly cross the placenta, and studies in gestational diabetes suggest that it may be relatively safe late in pregnancy. Exposure to glyburide early in pregnancy does not appear to be associated with any harm but data are limited. Until randomized control studies of metformin and glyburide at conception and early pregnancy are available, caution should be exercised regarding their use early in pregnancy.

Perinatal outcome is optimal if patients aim for fasting plasma glucose levels below 100 mg/dL (5.6 mmol/L) and postprandial levels below 130 mg/dL (7.2 mmol/L). For patients with a history of recurrent severe hypoglycemic reactions, somewhat higher blood glucose targets should be selected. Self-monitoring of capillary blood glucose should be performed eight or more times a day. Occasional monitoring in the middle of the night is recommended to monitor for nocturnal hypoglycemia. There is evidence that continuous glucose monitoring systems may be helpful in reducing both hyperglycemia and hypoglycemic excursions. These systems do not replace self-monitoring of blood glucose but allow for fine-tuning of glycemic control and alert the patient to rapid changes in glucose levels. One randomized study showed that pregnancies using continuous glucose monitoring had better glycemic control in the third trimester and lower risk of macrosomia. Clinical trials using continuous glucose monitors during pregnancy are currently underway. Confirmation of long-term control is provided by sequential measurement of glycosylated hemoglobin and fructosamine every 4 to 6 weeks.

Patients should see the nutritionist to assess caloric needs and get instructed on carbohydrate counting. The caloric intake is based on ideal body weight and it is approximated 30 to 35 kcal/kg for normal-weight women; about 24 kcal/kg current weight for overweight women; and 10 to 15 kcal/kg current weight for obese women. All patients should learn how to self-adjust their doses of short-acting insulin based on planned carbohydrate load or premeal blood glucose levels.

Type 1 patients are typically on a basal bolus insulin regimen (see Table 17-16). Currently, NPH is the only intermediate insulin available for basal coverage during pregnancy. Typically a type 1 patient might require up to three small injections of NPH to provide adequate basal coverage using short-acting insulin analogs to control the glucose rise with meals. Studies on insulin glargine use during pregnancy are limited. Retrospective case control studies have not shown any adverse effects of glargine use at the time of conception and during pregnancy. Many type 1 patients elect to use insulin pumps during pregnancy. Since the risk of diabetic ketoacidosis is increased with pump use, it is especially critical that patients have adequate instruction on the use of insulin pumps and can troubleshoot any problems that may arise.

Women with type 2 diabetes can be managed with regular insulin or short-acting insulin analogs before meals and NPH insulin at bedtime. Sometimes NPH insulin is also required in the morning.

Total insulin requirements vary during gestation. There is usually an increase in insulin dose between weeks 3 and 7, then a slight decrease between weeks 7 and 15 followed by a gradual increase until about week 35. The insulin requirements in type 1 diabetes at around 35 weeks (1.0 U/kg/24 h) are almost double the prepregnancy requirements. Women with type 2 diabetes usually start out with higher doses and may eventually require as much as 1.5 to 2 U/kg/24 h. Exercise can improve insulin sensitivity and should be encouraged in type 2 patients. The benefits of exercise are less obvious in women with type 1 diabetes, and there is always a concern about exercise-induced hypoglycemia.
Hypoglycemic reactions are more frequent and sometimes more severe in early gestation but are a risk at any time during pregnancy. Therefore, insulin-treated patients should take snacks between meals and at bedtime to prevent hypoglycemia. Family members should be instructed in the use of glucagon. Hypoglycemic reactions have not been associated with fetal death or congenital anomalies, but they pose a risk to maternal health.

**Fetal monitoring (Table 17–27).** First-trimester ultrasound is often obtained to document viability, as the rate of miscarriage is higher in women with diabetes, and to estimate gestational age. A second-trimester, detailed ultrasound examination of fetal anatomy is performed at approximately 18 weeks for detection of congenital anomalies. Ultrasound examination in the third trimester (at 28–32 weeks and 38 weeks) is performed to assess fetal growth.

Antepartum fetal testing is recommended using fetal movement counting, biophysical profile, nonstress test (NST), and/or contraction stress test (CST) initiated at 32 to 34 weeks of gestation. Most simply, the infrequency of fetal movement as noted in regular fetal kick counts (fewer than four per hour) may indicate fetal jeopardy. The fetal biophysical profile is a rigorous analysis of fetal activity patterns using ultrasound to assess gross body movements, the tone of the limbs, and chest wall motions as well as reactivity of the fetal heart rate (FHR) and the volume of amniotic fluid. The presence of FHR accelerations and long-range variability on the NST and the absence of late decelerations (lower FHR persisting after the contraction subsides) on the CST indicate that the fetus is well oxygenated. Generally, the NST and CST are sensitive screening tests, and abnormal results of FHR monitoring in these tests overestimate the diagnosis of fetal distress. Therefore, it is wise to obtain additional evidence of fetal jeopardy (by biophysical ultrasonographic assessment) before cesarean delivery is recommended in preterm pregnancies. In term gestation with abnormal fetal testing, there is little to be gained by continuing the pregnancy. In complicated patients with intrauterine growth retardation, oligohydramnios, preeclampsia, or poor blood glucose control, testing may start as early as 26 weeks and is performed more frequently.

**Timing of delivery.** Unless maternal or fetal complications arise, the goal for delivery in diabetic women should be 38 to 41 weeks in order to reduce neonatal morbidity from preterm deliveries. On the other hand, the obstetrician may wish to induce labor before 39 weeks, if there is concern about increasing fetal weight. Before a preterm delivery decision (<37 weeks) is made or delivery is considered in women with poor glycemic control at 37 to 38 weeks of gestation, fetal pulmonary maturity should be determined. Tests for maturity using amniocentesis assess risk of neonatal respiratory distress syndrome and include the lecithin–sphingomyelin (L/S) ratio, phosphatidylglycerol, and other biochemical or physical assays of surfactant activity. In pregnancies complicated by hyperglycemia, fetal hyperinsulinemia can lead to low pulmonary surfactant apoprotein production. The lowest risk of respiratory distress syndrome is attained by delaying delivery (if possible) until 38 to 41 weeks and minimizing the need for cesarean sections.

**Route of delivery.** Once fetal lung maturity is likely, the route of delivery must be selected based on the usual obstetric indications. If the fetus seems large (>4200 g) on clinical and ultrasonographic examination of diabetic women, cesarean section probably should be performed because of the possibility of shoulder dystocia and birth trauma. Otherwise, induction of labor is reasonable, because maternal and peripartum risks are fewer following vaginal delivery. Once labor is underway, continuous FHR monitoring is essential. Maternal blood glucose levels greater than 150 mg/dL (8.3 mmol/L) can be associated with intrapartum fetal hypoxia.

**Insulin and glucose management during labor and delivery.** It is important to avoid maternal hyperglycemia during labor because it increases the risk for fetal acidemia and neonatal hypoglycemia. The goal is to maintain glucose levels between 70 and 110 mg/dL (3.9–6.1 mmol/L). Maternal glucose levels above 180 mg/dL (10 mmol/L) are consistently associated with neonatal hypoglycemia. During the latent phase of labor, maternal metabolic demands are fairly stable but there is significant energy expenditure during active labor and delivery and insulin needs are minimal. Glucose control is typically managed using intravenous dextrose (at 100–125 mL/h) and insulin infusions (Table 17–28).

After delivery of the placenta, the insulin-resistant state rapidly disappears, and insulin requirements are close to prepregnancy levels. Type 1 or type 2 patients who were previously on insulin can go back to their usual prepregnancy insulin regimens and doses once they start eating. Type 2 patients who were on oral agents prepregnancy frequently do not require any medication during the first 24 to 48 hours postpartum. They can stay on insulin while breastfeeding or go on metformin or glyburide which are safe while breastfeeding.

**Neonatal management.** Planning for the care of the infant should be started prior to delivery, with participation by the pediatrician or neonatologist in decisions about timing and management of delivery. In complicated cases, the pediatrician must
be in attendance to learn about antenatal problems, to assess the need for resuscitation, to identify major congenital anomalies, and to plan initial therapy for the sick infant if required. Infants of diabetic mothers have an increased risk of respiratory distress syndrome. Possible reasons include abnormal production of pulmonary surfactant or connective tissue changes leading to decreased pulmonary compliance. However, in recent years, the incidence of respiratory distress syndrome in these pregnancies has declined from 24% to 5%, probably related to better maternal glycemic control, selected use of amniotic fluid tests, and diagnosis of diabetes at the first prenatal visit. Those women at high risk should undergo OGTT testing as soon as feasible. If the test is negative, then they should be retested at 24 to 28 weeks of gestation. A fasting plasma glucose of ≥126 mg/dL or random glucose of ≥200 mg/dL confirmed on repeat testing is diagnostic of diabetes and negates the need to perform a glucose challenge test. Lower risk women are screened for GDM using a two-step protocol performed at 24 to 28 weeks. First, a glucose challenge test is performed at 24 to 28 weeks. First, a glucose challenge test is performed using a 50 g glucose load. The patient does not have to be fasting. A 1-hour plasma glucose value of 140 mg/dL (7.8 mmol/L) or greater identifies approximately 80% of women with GDM; decreasing the cutoff value to 130 mg/dL (7.2 mmol/L)

*Protocol useful also for diabetic pregnant women who are “NPO” or being treated with beta-adrenergic tocolysis or corticosteroids. The scale dosages may need to be doubled for the latter. Boluses of short-acting insulin must be used to cover meals.

Gestational Diabetes

Gestational diabetes (GDM) is defined as glucose intolerance that develops or is first recognized during pregnancy. As insulin resistance increases during pregnancy, euglycemia depends on a compensatory increase in insulin secretion. Failure to compensate with increased insulin secretion leads to gestational diabetes. As the increase in insulin resistance is greatest in the third trimester, GDM usually develops going into this period. The prevalence of GDM in a population is reflective of the prevalence of type 2 diabetes in that population. In low-risk populations, such as those found in Sweden, the prevalence in population-based studies is lower than 2% even when universal testing is offered, while studies in high-risk populations, such as the Native American Cree, Northern Californian Hispanics, and Northern Californian Asians, reported prevalence rates ranging from 4.9% to 12.8%. Other risk factors include a history of macrosomia (birth weight >4000 g), polycystic ovarian syndrome, essential hypertension or pregnancy-related hypertension, history of spontaneous abortions and unexplained still births, family history of diabetes, obesity, age older than 25 years, and history of gestational diabetes (Table 17–29).

Women with GDM are at increased risk for urinary tract infections, pyelonephritis, asymptomatic bacteriuria, and preeclampsia. There is a 10% risk of polyhydramnios. Fetal risks of poor glucose control include stillbirths and macrosomia. There is no increase in risk for congenital anomalies since the glucose intolerance develops later in pregnancy.

Strategies for diagnosis are outlined in Table 17–30. Currently, international consensus is lacking regarding the diagnostic criteria for GDM. The 100 g 3-hour OGTT test is commonly used in the United States and the 75 g 2-hour WHO test is used in many other countries. The risk assessment for GDM (see Table 17–29) should be performed at the first prenatal visit. Those women at high risk should undergo OGTT testing as soon as feasible. If the test is negative, then they should be retested at 24 to 28 weeks of gestation. A fasting plasma glucose of ≥126 mg/dL or random glucose of ≥200 mg/dL confirmed on repeat testing is diagnostic of diabetes and negates the need to perform a glucose challenge test. Lower risk women are screened for GDM using a two-step protocol performed at 24 to 28 weeks. First, a glucose challenge test is performed using a 50 g glucose load. The patient does not have to be fasting. A 1-hour plasma glucose value of 140 mg/dL (7.8 mmol/L) or greater identifies approximately 80% of women with GDM; decreasing the cutoff value to 130 mg/dL (7.2 mmol/L).
These women do not need retesting for GDM. The Australian Carbohydrate Intolerance Study in Pregnant Women (ACCHOIS) trial found that intervention to lower glucose levels to less than 100 mg/dL before meals and less than 126 mg/dL 2 hours after meals reduced the rate of serious perinatal outcomes (defined as death, shoulder dystocia, bone fracture, and nerve palsy) from 4% to 1%. After diagnosis, the patient should be placed on a diabetic meal plan modified for pregnancy. The caloric intake is based on ideal body weight—25 to −35 kcal/kg ideal weight, 40% to 55% carbohydrate, 20% protein, and 25% to 40% fat. Calories are distributed over three meals and three snacks (see Table 17–25). Most patients can be taught to count their carbohydrates and to read food labels. This caloric distribution will help 75% to 80% of patients to become normoglycemic. Patients should also be encouraged to participate in moderate aerobic exercise such as walking or antenatal exercise classes, of at least 15 to 30-minutes duration, three or more times a week. In normal pregnancy, expected weight gain varies according to the prepregnancy weight. The Fifth International Workshop-Conference on Gestational Diabetes Mellitus recommends a relatively small gain during pregnancy of 7 kg (15 lb) for obese women (BMI ≥30 kg/m²) and a proportionally greater weight gain (up to 18 kg or 40 lb) for underweight women (BMI <18.5 kg/m²) at the onset of pregnancy. However, there are no data on optimal weight gain for women with GDM.

The goal of therapy is prevention of fasting and postprandial hyperglycemia. The Australian Carbohydrate Intolerance Study in Pregnant Women (ACCHOIS) trial found that intervention to lower glucose levels to less than 100 mg/dL before meals and less than 126 mg/dL 2 hours after meals reduced the rate of serious perinatal outcomes (defined as death, shoulder dystocia, bone fracture, and nerve palsy) from 4% to 1%. After diagnosis, the patient should be placed on a diabetic meal plan modified for pregnancy. However, there are no data on optimal weight gain for women with GDM.

If fasting capillary blood glucose levels exceed 90 to 100 mg/dL (5-5.6 mmol/L) or if 1-hour or 2-hour postprandial glucose values are consistently greater, respectively, than 130 or 105 mg/dL (7.2 or 5.8 mmol/L), therapy is begun with insulin. The total insulin dose varies from 0.7 to 2 U/kg. NPH is the preferred long-acting insulin. Insulin glargine and insulin detemir have not been well studied. Insulin aspart or lispro and regular insulin can be used. Hypoglycemia is a risk factor with aggressive management of glucose levels with insulin. Patients and family members should be instructed on monitoring for and treating hypoglycemia.

Metformin and glyburide can be considered as alternative options to insulin therapy. Metformin does cross the placenta but has not been associated with teratogenesis. The advantage of this drug is that it does not result in hypoglycemia. An open label study (the MiG trial) of 751 women with GDM at 20 to 33 weeks' gestation randomized to either metformin or insulin did not show a difference in primary composite outcome of neonatal complications. Forty-six percent of the subjects on insulin and 82% on glyburide. There was significant difference in fetal outcomes in the two groups—large for gestational infants, macrosomia, neonatal ICU admission, or fetal abnormalities. Target glycemic control was achieved in 88% of patients on insulin and 82% on glyburide. There was significant reduction in maternal hypoglycemic episodes in the glyburide group compared to the insulin group (2% vs 20%). There were some differences in neonatal outcomes such as more neonatal hypoglycemia in the glyburide arm. The study was not adequately

The test is positive if two of the following glucose levels are found.

- Fasting: ≥95 mg/dL (≥5.3 mmol/L)
- 1 h: ≥180 mg/dL (≥10 mmol/L)
- 2 h: ≥155 mg/dL (≥8.6 mmol/L)
- 3 h: ≥140 mg/dL (≥7.8 mmol/L)

If one value is abnormal, repeat test in 4 wk

One-step protocol:

Perform diagnostic 100 g OGTT testing as soon as feasible. If negative, repeat at 24-28 wk.

powered, however, to determine the statistical significance of these differences.

Patients are usually scheduled for follow-up visits every 1 to 2 weeks. A 24-hour urine collection may be performed to establish baseline level of proteinuria and creatinine clearance due to the higher likelihood of preclampsia. It is not necessary to routinely perform ophthalmic examinations in these patients unless there is a strong suspicion of preexisting type 2 diabetes mellitus. Fetal monitoring is warranted in those patients who are not well controlled, requiring insulin therapy, or who have other complications of pregnancy. The most commonly used test is a twice-weekly nonstress test.

If blood glucose levels are close to normal and there are no other complications, the delivery can go to term. It is generally recommended that the pregnancy does not go beyond term. Most patients do not require insulin during delivery. Blood glucose levels should be monitored the following day to ensure that the patient has reverted to normoglycemia. About 95% of patients return to normal glucose status.

Progression to type 2 diabetes later in life occurs in 5% to 50% of women with gestational diabetes. The wide range in incidence is influenced by body weight, family history, glucose levels, and the need for insulin treatment during pregnancy—and the choice of contraception and lifestyle after pregnancy. All patients with gestational diabetes should undergo a 75 g 2-hour glucose tolerance test at 6 to 10 weeks after delivery to guide future medical management. Follow-up protocols after pregnancy and criteria for the diagnosis of diabetes mellitus in the nonpregnant state are presented in Table 17–11.

Circulating plasma glucose concentrations are kept within a relatively narrow range by a complex system of interrelated neural, humoral, and cellular controls. Under the usual metabolic conditions, the central nervous system is wholly dependent on plasma glucose and counteracts declining blood glucose concentrations with a carefully programmed response. This is often associated with a sensation of hunger and, as the brain receives insufficient glucose to meet its metabolic needs (neuroglycopenia), an autonomic response is triggered to mobilize storage depots of glycogen and fat. In the postabsorptive state, hepatic glycogen reserves and gluconeogenesis from the liver and kidney directly supply the central nervous system with glucose, which is carried across the blood-brain barrier by a specific glucose transport system, while the mobilization of fatty acids from triglyceride depots provides energy for the large mass of skeletal and cardiac muscle, renal cortex, liver, and other tissues that utilize fatty acids as their basic fuel, thus sparing glucose for use by the tissues of the central nervous system.

The normal lower limit of fasting plasma glucose is typically 70 mg/dL (3.9 mmol/L). Lower values may occur during prolonged fasting, strenuous exercise, or pregnancy or may occur as a laboratory artifact. In normal men, plasma glucose does not fall below 55 mg/dL (3 mmol/L) during a 72-hour fast. However, for reasons that are not clear, normal women may experience a fall to levels as low as 30 mg/dL (1.7 mmol/L) despite a marked suppression of circulating insulin to less than 5 μU/mL. They remain asymptomatic in spite of this degree of hypoglycemia, presumably because ketogenesis is able to satisfy the energy needs of the central nervous system. Basal plasma glucose declines progressively during normal pregnancy, and hypoglycemic levels may be reached during prolonged fasting. This may be a consequence of a continuous fetal consumption of glucose and diminished availability of the gluconeogenic substrate alanine. The cause of these diminished alanine levels in pregnancy is unclear. The greatly increased glucose consumption by skeletal muscle that occurs during prolonged strenuous exercise may lead to hypoglycemia (blood glucose <45 mg/dL) despite increases in hepatic glucose production. Whether the hypoglycemia in this circumstance contributes to fatigue or other symptoms in distance runners is unknown.

In vitro consumption of glucose by blood cell elements may give rise to laboratory values in the hypoglycemic range. This can be avoided by adding a small amount of the metabolic inhibitor sodium fluoride to collection tubes used for specimens containing increased numbers of blood cells (as in leukemia, leukemoid reactions, or polycythemia) and keep samples on ice until separated.
PATHOPHYSIOLOGY OF THE COUNTERREGULATORY RESPONSE TO NEUROGLYCOPENIA

The plasma concentration of glucose that signals the need by the central nervous system to mobilize energy reserves depends on a number of factors, such as the status of blood flow to the brain, the integrity of cerebral tissue, the prevailing arterial level of plasma glucose, the rapidity with which plasma glucose concentration falls, and the availability of alternative metabolic fuels.

A hierarchy of responses has been shown to occur as plasma glucose falls in healthy young volunteers, with hormonal counterregulatory responses being triggered at glucose levels slightly higher (~67 mg/dL [3.7 mmol/L]) than those that induce symptoms of hypoglycemia (Figure 18–1). The first symptoms to appear in healthy people are mediated by autonomic neurotransmitters and occur at plasma glucose levels below 60 mg/dL (3.3 mmol/L). The symptoms consist of tremor, anxiety, palpitations, and sweating, which result from sympathetic discharge; and hunger, which is a consequence of parasympathetic vagal response. Ganglionic blockade and cervical cord section or sympathectomy—but not adrenalectomy—ameliorates these symptoms, indicating that they are due to the release of autonomic neurotransmitters and not dependent on adrenal hormones. As plasma glucose falls below 50 mg/dL (2.8 mmol/L), cerebral neuroglycopenia ensues, consisting of impaired cognition, along with weakness, lethargy, confusion, incoordination, and blurred vision. If counterregulatory responses are inadequate to reverse this degree of profound hypoglycemia, convulsions or coma may occur. This can result in brain damage or death, particularly in those who have not adapted to repeated episodes of hypoglycemia.

In elderly people, however, with compromised cerebral blood supply, neuroglycopenic manifestations may be provoked at slightly higher plasma glucose levels. Patients with chronic hyperglycemia (eg, those with poorly controlled, insulin-treated diabetes mellitus) may experience symptoms of neuroglycopenia at considerably higher plasma glucose concentrations than persons without diabetes. This has been attributed to a downregulated glucose transport system across the blood–brain barrier. Conversely, in patients exposed to chronic hypoglycemia (eg, those with an insulin-secreting tumor or those with diabetes who are receiving excessively tight glycemic control with an insulin pump), adaptation to recurrent hypoglycemia occurs by upregulation of the glucose transporters, which results in hypoglycemic unawareness, whereby they show greater tolerance to hypoglycemia without manifesting symptoms. Restoring and maintaining an adequate supply of glucose for cerebral function proceeds by a series of neurogenic events that act directly to raise the plasma glucose concentration and to stimulate hormonal responses that augment the adrenergic mobilization of energy stores (Table 18–1).

Counterregulatory Response to Hypoglycemia

**Insulin:** Endogenous insulin secretion is lowered both by reduced glucose stimulation to the pancreatic β cell and by sympathetic nervous system inhibition from a combination of α-adrenergic neural effects and increased circulating catecholamine levels. This reactive insulinopenia appears to be essential for glucose recovery, because it facilitates the mobilization of energy from existing energy stores (glycogenolysis and lipolysis); increases hepatic enzymes involved in gluconeogenesis and ketogenesis; increases enzymes of the renal cortex, promoting gluconeogenesis; and at the same time prevents muscle tissue from consuming the blood glucose being released from the liver (Chapter 17).

**Catecholamines:** Circulating catecholamines—and norepinephrine produced at sympathetic nerve endings—provide muscle tissue with alternative sources of fuel by activating beta-adrenergic receptors, resulting in mobilization of muscle glycogen, and by providing increased plasma-free fatty acids from lipolysis of adipocyte triglyceride. Metabolism of these free fatty acids provides energy to promote gluconeogenesis in the liver and kidney, thereby adding to plasma glucose levels already raised by the glycogenolytic effect of catecholamines on the liver. Their cardiovascular and other side effects provide a signal that diabetic patients learn to recognize as a warning of their need to rapidly ingest absorbable carbohydrate.

**Glucagon:** Plasma glucagon is released by the beta-adrenergic effects of both sympathetic innervation and circulating catecholamines on pancreatic α cells as well as by the direct stimulation of α cells by the low plasma glucose concentration itself. Data are available suggesting that a falling-off of intra-islet insulin concentration in subjects with functioning pancreatic β cells can release pancreatic α cells from insulin inhibition and thus augment glucagon release during hypoglycemia. This glucagon release increases hepatic output of glucose by direct glycogenolysis as well as by facilitating the activity of gluconeogenic enzymes in the liver but not in the kidney. As shown in Figure 18–2, plasma glucagon

![FIGURE 18–2](image-url)
appears to be the key counterregulatory hormone affecting recovery from acute hypoglycemia in nondiabetic humans, with the adrenergic-catecholamine response representing a major backup system. However, in most clinical situations, where hypoglycemia develops more gradually, as with inappropriate dosage of insulin or sulfonylureas, or in cases of insulinoma, the role of glucagon may be less influential. When normal volunteers received a prolonged low-dose insulin infusion to produce a gradual decline in plasma glucose levels without waning of insulin levels, the rise of endogenous glucagon contributed much less to counterregulation than after acute hypoglycemia induced by intravenous insulin, which is followed by rapid waning of insulin levels. This finding suggests that glucagon's role in glucose recovery occurs primarily when the level of insulin wanes.

**Cortisol:** Pituitary corticotrophin (ACTH) is released in association with the sympathetic nervous system stimulation by neuroglycopenia. This results in elevation of plasma cortisol levels, which in turn permissively facilitates lipolysis and actively promotes protein catabolism and conversion of amino acids to glucose by the liver and kidney.

**Growth hormone:** Pituitary growth hormone is also released in response to falling plasma glucose levels. Its role in counteracting hypoglycemia is less well defined, but it is known to antagonize the action of insulin on glucose utilization in muscle cells and to directly activate lipolysis by adipocytes. This increased lipolysis provides fatty acid substrate to the liver and renal cortex which facilitates gluconeogenesis.

**Cholinergic neurotransmitters:** Acetylcholine is released at parasympathetic nerve endings, and its vagal effects induce the sensation of hunger that signals the need for food to counteract the hypoglycemia. In addition, postsynaptic fibers of the sympathetic nervous system that innervate the sweat glands to signal hypoglycemia also release acetylcholine—in contrast to all other sympathetic postsynaptic fibers, which without exception release norepinephrine.

### Maintenance of Euglycemia in the Postabsorptive State

Glucose absorption from the gastrointestinal tract ceases by 4 to 6 hours after a meal. During the postabsorptive state which immediately follows, glucose must be produced endogenously from previously stored nutrients to meet the requirements of the central nervous system and other glucose-dependent tissues. These include 125 mg/min of glucose required by the brain and spinal cord as well as an additional 25 mg/min by red blood cells and the renal medulla. It was previously thought that the liver is the only organ involved in glucose production during an overnight fast, but recent data indicate that the renal cortex also has the requisite enzymes for production and release of glucose.

**Liver:** The liver initially provides glucose by the breakdown of stored hepatic glycogen. However, because these reserves are limited to 80 to 100 g, they begin to be depleted several hours into the postabsorptive state. Thereafter, hepatic glucose production is augmented by gluconeogenesis—the formation of glucose from amino acids, lactate, and glycerol. These substrates are delivered to the liver and kidney from peripheral stores. Muscle and other structural tissues supply amino acids, mainly alanine; blood cell elements supply lactate, the end product of glycolytic metabolism; and adipose tissue supplies glycerol from lipolysis of triglyceride. In addition, oxidation of the fatty acids released from adipose cells during lipolysis supplies the energy required for gluconeogenesis and provides ketone bodies, acetoacetate, and β-hydroxybutyrate, which can serve as alternative metabolic fuels for the central nervous system during periods of prolonged fasting. Studies have shown that an insulin infusion does not reduce hepatic glucose production if elevated levels of fatty acids are maintained by intravenous administration of a fat emulsion and heparin, suggesting that fatty acids may be the major mediator of gluconeogenesis.

The principal mechanisms regulating hepatic glucose output are the availability of gluconeogenic substrates and the regulation of transcription of key regulatory enzymes such as phosphoenolpyruvate carboxykinase (PEPCK) and glucose-6-phosphatase (G-6-Pase). Glucagon and glucocorticoids through signaling intermediates induce the expression of PEPCK and G-6-Pase. Insulin on the other hand suppresses the expression of these enzymes.

**Kidney:** Although it is generally acknowledged that after fasting for 60 hours the kidney contributes up to 20% to 25% of endogenous glucose production, its role after an overnight fast remains controversial. One group has found that it produces as much as 25% of the postabsorptive glucose requirement, yet a second group using different methodology found a contribution of no more than 5% in the postabsorptive state. Despite these conflicting findings, it is clear that because the renal medulla removes almost as much glucose as the renal cortex produces, the net renal contribution is minimal in the short-term postabsorptive state as compared to the liver.

The kidney does not have glycogen stores and is dependent on gluconeogenesis as its only source of glucose production. Glutamine—rather than alanine—is the predominant amino acid substrate for renal gluconeogenesis. In addition to its contribution to glucose homeostasis after an overnight fast, the kidney also has been shown to be an important contributor to glucose counterregulation in the event of hypoglycemia. Although glucagon does not affect the kidney, the counterregulatory rise in catecholamines has been shown to stimulate gluconeogenesis in the renal cortex. As with the liver, insulin inhibits renal gluconeogenesis and glucose release. Hormonal changes that begin early in the postabsorptive state regulate the enzymatic steps necessary for hepatic glycogenolysis and hepatic and renal gluconeogenesis and ensure the delivery of the necessary substrate (Table 18-2). An appropriate fall in circulating insulin levels with a corresponding rise in glucagon is most important; elevations in the counterregulatory hormones, namely cortisol and growth hormone, contribute to it but are less critical. Thus, numerous endocrine and metabolic events interact to provide a continuous source of fuel for proper functioning of the central nervous system. Malfuction of any of these mechanisms can lead to symptomatic hypoglycemia.
A clinical classification of the more common causes of symptomatic hypoglycemia in adults is presented in Table 18–3. This classification is useful in directing diagnostic considerations. Symptomatic fasting hypoglycemia is a serious and potentially life-threatening problem warranting thorough evaluation. Conditions that produce inappropriate fasting hyperinsulinism are the most common cause of fasting hypoglycemia in otherwise healthy adults. These include insulin-secreting pancreatic β cell tumors and iatrogenic or surreptitious administration of insulin or sulfonylureas. In patients with illnesses that produce symptomatic fasting hypoglycemia despite appropriately suppressed insulin levels, the clinical picture is generally dominated by the signs and symptoms of the primary disease, with hypoglycemia often only a late or associated manifestation. Hypoglycemia, sometimes severe, can also occur postprandially. In patients with gastric surgery, overrapid gastric emptying and accelerated glucose absorption may result in excess insulin secretion, rapid disposal of glucose, and hypoglycemia. An uncommon condition of islet hyperplasia or adult neisidioblastosis called noninsulinoma pancreatogenous hypoglycemia syndrome can result in hypoglycemia 4 to 6 hours after meals.

### SPECIFIC HYPOGLYCEMIC DISORDERS

1. **DIABETES (SEE ALSO CHAPTER 17)**

Iatrogenic hypoglycemia is common in type 1 patients and also in insulin treated type 2 patients. Most type 1 patients aiming for HbA1c levels below 7% have on average one to two symptomatic hypoglycemic episodes per year. Severe hypoglycemia is defined as an episode requiring assistance, and in one study, incidence rates were about 12 per 100 patient years for both type 1 and insulin-treated type 2 patients. Sulfonylureas, repaglinide, and nateglinide can also cause hypoglycemia. Increased risk factors include age (70 years and older), renal failure, hepatic failure, and use of the long-acting sulfonylureas. A number of other drug-drug interactions (clarithromycin, salicylates, sulfonamides) can also potentiate the hypoglycemic effects of sulfonylureas. The annual incidence of sulfonylurea-induced hypoglycemia is approximately 0.2 per 1000 patient years.

As β cell failure progresses (early in type 1 and late in type 2 diabetes), patients lose their glucagon response to hypoglycemia. This combination of insulin deficiency and impaired glucagon response makes it harder for patients to achieve HbA1c levels below 7% without occasional hypoglycemia. These hypoglycemic episodes attenuate the sympathoadrenal response to hypoglycemia, with decreased epinephrine release from the adrenal and decreased sympathetic neural responses (hypoglycemic unawareness). The hypoglycemia unawareness in turn increases the risk for recurrent hypoglycemia. About 20% to 25% of type 1 patients have hypoglycemic unawareness. Other factors that increase the risk for hypoglycemia include poor self-management skills. Patients may take too much insulin for the carbohydrates or take the wrong insulin or do not appropriately time insulin administration with food ingestion. They also may not adjust the insulin for acute exercise or take extra carbohydrates for unexpected exercise or reduce insulin doses for improved insulin sensitivity with exercise training. Alcohol can decrease endogenous glucose production and can cause hypoglycemia, especially if it is consumed on an empty stomach. Diabetes complications—gastroparesis, autonomic neuropathy, and renal failure also increase the risk for hypoglycemia.

There are other consequences of hypoglycemia apart from the autonomic and neurogenic symptoms of acute hypoglycemia. In severe cases, hypoglycemia can cause convulsions and coma. Permanent neurological damage is rare. Although cross-sectional studies and case reports have reported intellectual decline with recurrent hypoglycemia, longitudinal studies have not shown...
significant cognitive dysfunction in adults. In the Diabetes Control and Complications Trial, there was no evidence for cognitive decline related to hypoglycemia in 18 years of follow-up. Young children however may be more vulnerable to the effects of hypoglycemia on the brain. Hypoglycemia via its autonomic stimulation and catecholamine release increases cardiac output. In patients with cardiac disease it can also precipitate cardiac arrhythmias, angina, myocardial infarction, and congestive heart failure.

Hypoglycemia can also exert a psychological toll. Acute hypoglycemia induces mood changes including fatigue, pessimism, anger, and behavior changes. Nocturnal hypoglycemia can lead to fatigue and decreased sense of well being the following day. Patients who have had severe hypoglycemia may develop a phobia about hypoglycemia and keep their sugars unreasonably high. Some patients develop an anxiety syndrome. Hypoglycemia can also impact personal relationships, occupation, driving, and leisure activities. Surveys show that type 1 patients have increased risk of driving mishaps (crashes, moving violations) when compared to nondiabetic spouses; and that these are related to hypoglycemia.

The goal of therapy is to restore levels of plasma glucose to normal as rapidly as possible. If the patient is conscious and able to swallow, glucose-containing foods such as candy, orange juice with added sugar, and cookies should be quickly ingested. Fructose, found in many nutrient low-calorie sweeteners for diabetics, should not be used. While it can be metabolized by neurons, fructose is not transported across the blood–brain barrier.

If the patient is unconscious, rapid restoration of plasma glucose must be accomplished by giving 20 to 50 mL of 50% dextrose intravenously over 1 to 3 minutes (the treatment of choice) or, when intravenous glucose is not available, 1 mg of glucagon intramuscularly or intravenously. Families or friends of insulin-treated diabetics should be instructed in the administration of glucagon intramuscularly for emergency treatment at home. Glucagon should not be given if the hypoglycemia is due to sulfonylurea use. Under these circumstances, glucagon can stimulate insulin secretion and worsen the hypoglycemia. Attempts to feed the patient or to apply glucose-containing jelly to the oral mucosa should be avoided because of the danger of aspiration. When consciousness is restored, oral feedings should be started immediately. In patients who have taken massive overdoses of sulfonylureas, the response to intravenous dextrose may be poor. For these patients, intravenous boluses of diazoxide (150-300 mg) may be tried but can result in hypotension. Intravenous octreotide (100 µg) has also been reported to be of benefit.

Patients on insulin or sulfonylureas should be instructed on how to recognize and treat hypoglycemia and what measures they can take to prevent such episodes. Type 1 patients and insulin-treated type 2 patients should monitor their blood glucose frequently. Hypoglycemia not infrequently occurs at night and patients should avoid taking large doses of short-acting insulin just before going to bed. Patients should from time to time also monitor blood glucose levels in the middle of the night. Hypoglycemia can also occur many hours after strenuous exercise, and patients should be advised to monitor at these times and cut back their insulin doses and/or eat more carbohydrate. Continuous glucose monitoring systems are increasingly used by type 1 patients to alert them to falling glucose levels and prevent hypoglycemia. Finally, it is important to individualize glycemic goals. Early in the course of both type 1 and type 2 diabetes when there is still some endogenous β cell function, it is easier to achieve HbA1c levels close to normal with low risk of hypoglycemia. As β cell failure progresses, however, aiming for normality may lead to unacceptably high rates of hypoglycemia. Patients who have had frequent hypoglycemia and have hypoglycemia unawareness should be encouraged to temporarily raise their glycemic targets—as little as 2 to 3 weeks of scrupulous avoidance of hypoglycemia reverses hypoglycemia unawareness and improves the attenuated epinephrine response. Diabetes complications, previous incidence of hypoglycemia, and life expectancy should all be considered in the establishment of glycemic goals.

2. FACTITIOUS HYPOGLYCEMIA

Factitious hypoglycemia should be suspected in any patient with access to insulin or sulfonylurea drugs. It is most commonly seen in health professionals and diabetic patients or their relatives. The reasons for self-induced hypoglycemia vary, with many patients having severe psychiatric disturbances or a pathological need for attention. Inadvertent ingestion of sulfonylureas resulting in clinical hypoglycemia has also been reported, due either to patient error or to a prescription mishap on the part of a pharmacist. Patients with diabetes and factitious hypoglycemia have a presentation similar to brittle diabetes.

When insulin is used to induce hypoglycemia, an elevated serum insulin level often raises suspicion of an insulin-producing pancreatic β cell tumor. It may be difficult to prove that the insulin is of exogenous origin. The combination of hypoglycemia, high immunoreactive insulin levels, suppressed plasma C peptide, and suppressed proinsulin level is pathognomonic of exogenous insulin administration in nondiabetic patients. Patients with renal failure may have normal or even high plasma C-peptide levels, but plasma proinsulin levels are suppressed.

When sulfonylurea abuse is suspected, plasma or urine should be screened for its presence. Hypoglycemia with inappropriately elevated levels of serum insulin and C peptide along with detectable sulfonylureas in blood or urine is diagnostic of inadvertent or factitious sulfonylurea overdose. It is important to use assays which measure not only all the sulfonylurals but also repaglinide and nateglinide.

Treatment of factitious hypoglycemia involves psychiatric therapy and social counseling.

3. DRUGS

Numerous pharmacologic agents may potentiate the effects of insulin and predispose to hypoglycemia. Common offenders include fluoroquinolones such as gatifloxacin and levofloxacin, pentamidine, quinine, angiotensin-converting enzyme (ACE) inhibitors, ethanol, salicylates, and beta-adrenergic-blocking drugs. The fluoroquinolones, especially gatifloxacin, have been
associated with both hypoglycemia and hyperglycemia. Hypoglycemia is an early event; hyperglycemia occurs after several days into therapy. It is thought that the drugs act on ATP-sensitive potassium channels in the β cell. Intravenous pentamidine is cytotoxic to pancreatic β cells, resulting in acute insulin release and hypoglycemia. This occurs in about 10% to 20% of patients receiving the drug and may be followed later by persistent insulinopenia and hyperglycemia. Fasting patients taking noncardioselective beta blockade can have an exaggerated hypoglycemic response to starvation. Beta blockade inhibits fatty acid and gluconeogenic substrate release and reduces plasma glucagon levels resulting in hypoglycemia. Also the symptomatic response to hypoglycemia is altered—tachycardia is blocked while hazardous elevations of blood pressure may result during hypoglycemia in response to the unopposed alpha-adrenergic stimulation from circulating catecholamines and neurogenic sympathetic discharge. However, symptoms of sweating, hunger, and uneasiness are not masked by beta-blocking drugs and remain indicators of hypoglycemia in the aware patient.

Therapy with ACE inhibitors increases the risk of hypoglycemia in diabetic patients who are taking insulin or sulfonylureas, presumably because these drugs increase sensitivity to circulating insulin by increasing blood flow to muscle.

Ethanol-associated hypoglycemia has been proposed to occur as a consequence of hepatic alcohol dehydrogenase activity depleting NADH. The resultant change in the redox state (NADH-to-NAD⁺ ratio) limits the conversion of lactate to pyruvate, the main substrate for hepatic gluconeogenesis. In the patient who is imbibing ethanol but not eating, fasting hypoglycemia may occur after hepatic glycogen stores have been depleted (within 8–12 hours of a fast). No correlation exists between the blood ethanol levels and the degree of hypoglycemia, which may occur while blood ethanol levels are declining. It should be noted that ethanol-induced fasting hypoglycemia may occur at ethanol levels as low as 45 mg/dL (10 mmol/L)—considerably below most states’ legal standards (80 mg/dL [17.4 mmol/L]) for being under the influence. Most patients present with neuropsychiatric symptoms, which may be difficult to differentiate from the neurotoxic effects of the alcohol. These symptoms in a patient whose breath smells of alcohol may be mistaken for alcoholic stupor. Intravenous dextrose should be administered promptly to all such stuporous or comatose patients. Because hepatic glycogen stores have been depleted by the time hypoglycemia occurs, parenteral glucagon is not effective. Adequate food intake during alcohol ingestion prevents this type of hypoglycemia.

4. AUTOIMMUNE HYPOGLYCEMIA

In recent years, a rare autoimmune disorder has been reported in which patients have circulating insulin antibodies and the paradoxical feature of hypoglycemia. More than 200 cases of insulin-antibody-associated hypoglycemia have been reported since 1970, with 90% of cases reported in Japanese patients. HLA class II alleles (DRB1*0406, DQA1*0301, and DQB1*0302) are associated with this syndrome, and these alleles are 10 to 30 times more prevalent in Japanese and Koreans, which may explain the higher prevalence of this syndrome in these populations. Hypoglycemia generally occurs 3 to 4 hours after a meal and follows an early postprandial hyperglycemia. It is attributed to a dissociation of insulin-antibody immune complexes, releasing free insulin. This autoimmune hypoglycemia, which is due to accumulation of high titers of antibodies capable of reacting with endogenous insulin, has been most commonly reported in methimazole-treated patients with Graves disease from Japan as well as in patients with various other sulfhydryl-containing medications (captopril, penicillamine) and other drugs such as hydralazine, isoniazid, and procainamide. In addition, it has been reported in patients with autoimmune disorders such as rheumatoid arthritis, systemic lupus erythematosus, and polymyositis, as well as in multiple myeloma and other plasma cell dyscrasias where paraproteins or antibodies cross-react with insulin.

High titers of insulin autoantibodies, usually IgG class, can be detected. Insulin, proinsulin, and C-peptide levels may be elevated but the results may be erroneous because of the interference of the insulin antibodies with the immunoassays for these peptides.

In most cases the hypoglycemia is transient and usually resolves spontaneously within 3 to 6 months of diagnosis, particularly when the offending medications are stopped. The most consistent therapeutic benefit in management of this syndrome has been achieved by dietary treatment with frequent, low-carbohydrate, small meals. Prednisone therapy (30–60 mg/d) has been used to lower the titer of insulin antibodies.

Hypoglycemia due to insulin receptor autoantibodies is also an extremely rare syndrome; most cases have occurred in women often with a history of autoimmune disease. Almost all of these patients have also had episodes of insulin-resistant diabetes and acanthosis nigricans. Their hypoglycemia may be either fasting or postprandial and is often severe and is attributed to an agonistic action of the antibody on the insulin receptor. Balance between the antagonistic and agonistic effects of the antibodies determines whether insulin-resistant diabetes or hypoglycemia occurs. Hypoglycemia was found to respond to glucocorticoid therapy but not to plasmapheresis or immunosuppression.

5. PANCREATIC β CELL TUMORS

Spontaneous fasting hypoglycemia in an otherwise healthy adult is most commonly due to insulinoma, an insulin-secreting tumor of the islets of Langerhans. Eighty percent of these tumors are single and benign; 10% are malignant (if metastases are identified); and the remainder are multiple, with scattered micro- or macroadenomas interspersed within normal islet tissue. (As with some other endocrine tumors, histologic differentiation between benign and malignant cells is difficult, and close follow-up is necessary to ensure the absence of metastases.) These adenomas may be familial and have been found in conjunction with tumors of the parathyroid glands and the pituitary (multiple endocrine neoplasia type I; see Chapter 22). Over 99% of them are located within the pancreas and less than 1% in ectopic pancreatic tissue.
These tumors may appear at any age, although they are most common in the fourth to sixth decades. A slight predominance in women has been reported in some studies. However, others suggest that there is no gender predilection.

Clinical Findings

The signs and symptoms are chiefly those of subacute or chronic neuroglycopenia rather than adrenergic discharge. The typical picture is that of recurrent central nervous system dysfunction at times of exercise or fasting. Symptoms include episodic disorientation, somnolence, personality changes, amnesia, and loss of consciousness. The preponderance of neuroglycopenic symptoms, rather than those more commonly associated with hypoglycemia (adrenergic symptoms), often leads to delayed diagnosis following prolonged psychiatric care, or treatment for seizure disorders or transient ischemic attacks. Some patients learn to relieve or prevent their symptoms by taking frequent feedings. Obesity may be the result; however, obesity is seen in less than 30% of patients with insulin-secreting tumors.

Diagnosis of Insulinoma

Experts in this field emphasize that the most important prerequisite to diagnosing an insulinoma is simply to consider it, particularly when facing a clinical presentation of fasting hypoglycemia with symptoms of central nervous system dysfunction such as confusion or abnormal behavior. Whipple triad consists of history of symptoms consistent with hypoglycemia, associated low plasma glucose and relief of symptoms upon raising the plasma glucose. β cell tumors do not demonstrate suppression of insulin secretion in the presence of hypoglycemia, and a serum insulin level of 6 μU/mL or more with concomitant plasma glucose values below 45 mg/dL (2.5 mmol/L) suggests an insulinoma. Other causes of hyperinsulinemic hypoglycemia must be considered, however, such as surreptitious administration of insulin or sulfonylureas.

One of the most important steps is to carefully review the patient’s history. Attention should be paid to the nature of the symptoms and factors that precipitate and resolve the symptoms. Patients typically complain of feeling tired, experiencing blurred vision, and not thinking clearly. Eating or drinking readily absorbable carbohydrates improves the symptoms within approximately 15 minutes. Timing of the symptoms in relation to meals and exercise should be noted. In insulinoma patients, the symptoms are most likely to occur early in the morning before breakfast or if a meal is missed during the day. Patients occasionally present when they attempt to go on a diet to lose weight. Exercise may precipitate hypoglycemia.

With the ready availability of home blood glucose-monitoring systems, patients sometimes present with documented fingerstick blood glucose levels in 40s and 50s at time of symptoms. Access to diabetic medications (sulfonylureas or insulin) should be explored—does a family member have diabetes or does the patient or family member work in the medical field? Medication-dispensing errors should be excluded—has the patient’s prescription medication changed in shape or color? Other illnesses that cause hypoglycemia such as renal failure, hepatic failure, Addison disease, or nonislet tumor should be considered. Patients with insulinoma or factitious hypoglycemia usually have a normal physical examination.

An overnight fast and observed in the office. Activity such as walking should be encouraged and fingerstick blood glucose measured repeatedly during observation. If symptoms occur or fingerstick blood glucose is below 50 then samples for plasma glucose, insulin, C peptide, proinsulin, sulfonylurea screen, serum ketones, and antibodies to insulin should be sent. If outpatient observation does not result in symptoms or hypoglycemia and if the clinical suspicion remains high, then the patient should undergo an inpatient, supervised, 72-hour fast.

A suggested protocol for the supervised fast is set forth in Table 18–4. In normal men, the blood glucose value does not fall below 55 mg/dL (3.1 mmol/L) during a 72-hour fast, whereas insulin levels fall below 10 μU/mL; in some normal women, however, plasma glucose may fall below 30 mg/dL (1.7 mmol/L) (lower limits have not been established), but serum insulin levels also fall appropriately to less than 5 μU/mL. These women remain asymptomatic despite this degree of hypoglycemia, presumably because ketogenesis is able to provide sufficient fuel for maintenance of central nervous system function. The fast is timed from the last intake of calories. The term 72-hour fast is actually a misnomer in most cases, because the fast should be immediately terminated as soon as symptoms and laboratory confirmation of hypoglycemia are evident. About 43% of patients with insulinomas are symptomatic within the first 12 hours, 67% by 24 hours and 93% to 95% by 48 hours. Since a minority of patients (~5%-7%) may not demonstrate hypoglycemia after 48 hours of fasting, it is preferable to continue the fast for up to 72 hours. Patients can drink water and decaffeinated, noncaloric drinks. It is important that patients are active (walking) during the fast since exercise may help precipitate hypoglycemia. An intravenous cannula
TABLE 18–4 Suggested hospital protocol for supervised rapid diagnosis of insulinoma.

1. Obtain baseline serum glucose, insulin, proinsulin, and C-peptide measurements at onset of fast and place intravenous cannula.
2. Permit only calorie-free and caffeine-free fluids and encourage supervised activity (such as walking).
3. Measure urine for ketones at the beginning and every 12 hours and at end of fast.
4. Obtain capillary glucose measurements with a reflectance meter every 4 hours until values <60 mg/dL are obtained. Then increase the frequency of fingersticks to each hour, and when capillary glucose value is <49 mg/dL, send a venous blood sample to the laboratory for serum glucose, insulin, proinsulin, and C-peptide measurements. Check frequently for manifestations of neuroglycopenia.
5. If symptoms of hypoglycemia occur or if a laboratory value of serum glucose is <45 mg/dL or if 72 hours have elapsed, then conclude the fast with a final blood sample for serum glucose, insulin, proinsulin, C-peptide, β-hydroxybutyrate or acetone, and sulfonylurea measurements. Then give oral fast-acting carbohydrate followed by a meal. If the patient is confused or unable to take oral agents, administer 50 mL of 50% dextrose intravenously over 3–5 minutes. Do not conclude a fast based simply on basis of a capillary blood glucose measurement—wait for the laboratory glucose value unless the patient is symptomatic and it would be dangerous to wait.

have a lower increment. Intravenous glucagon can also cause an exaggerated release of insulin from insulinomas. Patients are tested after an overnight fast, and serum insulin levels measured every 5 minutes for 15 minutes after 1 mg IV glucagon. An increase in insulin level exceeding 130 μU/mL (twice upper limit of normal) suggests an insulin-secreting tumor. However, only about half of patients with insulinomas have insulin levels above 130 μU/mL and so the test is not so helpful. Also, in some patients the exaggerated insulin secretion can lead to severe hypoglycemia. Nausea is an unpleasant side effect, often occurring several minutes after administration of intravenous glucagon.

The oral glucose tolerance test is of no value in the diagnosis of insulin-secreting tumors. A common misconception is that patients with insulinomas have flat glucose tolerance curves because the tumors discharge insulin in response to oral glucose. In fact, most insulinomas respond poorly, and curves typical of diabetes are more common. In those rare tumors that do release insulin in response to glucose, a flat curve may result; however, this also can be seen occasionally in normal subjects.

Low HbA1c values have been reported in patients with insulinoma, reflecting the presence of chronic hypoglycemia. There is however considerable overlap with normal patients and no HbA1c value is diagnostic.

**Tumor localization studies** After the diagnosis of insulinoma has been unequivocally made by clinical and laboratory findings, studies to localize the tumor should be initiated. The focus of attention should be directed at the pancreas only, because virtually all insulinomas originate from this tissue; ectopic cancers secreting insulin are unknown to all major centers, with only one published report describing an atypical insulin-producing tumor believed to have originated from a small cell carcinoma of the cervix.

Because of the small size of these tumors (average diameter of 1.5 cm in one large series), imaging studies do not necessarily identify all tumors. A pancreatic dual phase, thin section, helical CT scan can identify 82% to 94% of the lesions. MRI scans with gadolinium can be helpful in detecting a tumor in 85% of cases. One case report suggests that diffusion-weighted MRI can be useful for detecting and localizing small insulinomas, especially those with no hypervascular pattern. The imaging study used will depend upon local availability and local radiologic skill. If the imaging study is negative, then an endoscopic ultrasound should be performed. In experienced hands, about 80% to 90% of tumors can be detected. Finally, needle aspiration of the identified lesion can be attempted to confirm the presence of a neuroendocrine tumor. If the tumor is not identified or imaging results are equivocal, then the patient should undergo selective calcium-stimulated angiography which has been reported to localize the tumor to particular regions of the pancreas approximately 90% of the time. In this test, angiography is combined with injections of calcium gluconate into the gastroduodenal, splenic, and superior mesenteric arteries and insulin levels are measured in the hepatic vein effluent. The procedure is performed after an overnight fast. Ten percent of calcium gluconate, diluted to a volume of 5 mL normal saline, is bolused into selected arteries at a dose of 0.0125 mmol Ca²⁺/kg (0.005 mmol/kg for obese patients). Five milliliter blood samples are taken from the hepatic effluent at times 0, 30, 60, 90, 120, and 180 seconds after calcium injection. Fingerstick blood glucose levels are measured at intervals and a dextrose infusion is maintained throughout the procedure. Calcium stimulates insulin release from insulinomas but not normal islets. A step-up in insulin levels at 30 or 60 seconds (twofold or greater) regionalizes the source of the hyperinsulinism to the head of the pancreas for the gastroduodenal artery, the uncinate process for the superior mesenteric artery, and the body and tail of the pancreas for the splenic artery. A less than twofold elevation of insulin in the 120 second sample may represent effects of recirculating calcium and is not considered a positive localization. In a single insulinoma, the response is in one artery alone (Figure 18–3) unless the

**FIGURE 18–3** Responses of serum insulin to selective intra-arterial calcium stimulation in a patient with biochemical confirmation of inappropriate hyperinsulinism. An islet cell tumor was removed from the tail of the pancreas.
tumor resides in an area fed by two arteries or if there are multiple insulinas as in multiple endocrine neoplasia, type 1. Patients who have diffuse islet hyperplasia (the noninsulinoma pancreatogenous hypoglycemia syndrome [NIPHS]) will have positive responses in multiple arteries. Because diazoxide may interfere with this test, it should be discontinued for at least 48 to 72 hours before sampling. Patients should be closely monitored during the procedure to avoid hypoglycemia (as well as hyperglycemia), which could affect insulin gradients. These studies combined with careful intraoperative ultrasonography and palpation by a surgeon experienced in insulinoma surgery correctly identify up to 98% of tumors.

### Treatment of Insulinoma

The treatment of choice for insulin-secreting tumors is surgical resection. While waiting for surgery, patients should be given diazoxide, a potent inhibitor of insulin secretion. It acts by opening the ATP-sensitive potassium channel of the pancreatic β cell and hyperpolarizing the cell membrane. This reduces calcium influx through the voltage-gated calcium channel, thereby reducing insulin release. Divided doses of 300 to 400 mg/d usually suffice, but occasionally a patient may require up to 800 mg/d. A liquid preparation of diazoxide (50 mg/mL) is available in the United States. Side effects include edema due to sodium retention (which generally necessitates concomitant thiazide administration), gastric irritation, and mild hirsutism.

Tumor resection should be performed only by surgeons with extensive experience with removal of islet cell tumors, because these tumors may be small and difficult to recognize. The tumors are enucleated whenever possible unless they have malignant features (e.g., hardness or an appearance of infiltration). Preoperative imaging studies, including endoscopic ultrason, can identify tumors amenable to laparoscopic surgery. Laparoscopic surgery is associated with faster postoperative recovery. Laparoscopic intraoperative ultrasound should be used to confirm the location and depth of the tumor within the gland and also note its relationship to the pancreatic duct and splenic vessels. Open surgery is still necessary for some tumors such as those in the head of the pancreas close to the main pancreatic duct. In the very occasional case where the tumor cannot be found at operation despite the use of intraoperative ultrasound, it is no longer advisable to blindly resect the body and tail of the pancreas since a non palpable tumor, missed by ultrasound, is most likely embedded within the fleshy head of the pancreas that is left behind with subtotal resections. Most surgeons prefer to close the incision and treat the patient medically and/or repeat the localization studies.

Diazoxide should be administered on the day of surgery in patients who are responsive to it, because the drug greatly reduces the need for glucose supplements and the risk of hypoglycemia during surgery. Typically, it does not mask the glycemic rise indicative of surgical cure. Blood glucose levels should be monitored frequently during the operation and a 5% or 10% dextrose infusion should be used to maintain euglycemia. Hyperglycemia occurs for a few days postoperatively most likely due to edema and inflammation of the pancreas secondary to its mobilization and manipulation during surgical resection of the insulinoma. However, other possible contributing factors include high levels of counterregulatory hormones induced by the procedure, chronic downregulation of insulin receptors by the previously high circulating insulin levels from the tumor, and, perhaps, suppression of normal pancreatic β cells by long-standing hypoglycemia. Small subcutaneous doses of regular insulin may be prescribed every 4 to 6 hours if plasma glucose exceeds 300 mg/dL (16.7 mmol/L), but in most cases pancreatic insulin secretion recovers after 48 to 72 hours, and very little insulin replacement is required.

Diazoxide therapy is the treatment of choice in patients with inoperable functioning islet cell carcinomas and in those who are poor candidates for operation. A few patients have been maintained on long-term (>10 years) diazoxide therapy with no apparent ill effects. Hydrochlorothiazide, 25 to 50 mg daily, should also be prescribed to counteract the edema and hyperkalemia secondary to diazoxide therapy as well as to potentiate its hyperglycemic effect. Frequent carbohydrate feedings (every 2-3 hours) can also be helpful in maintaining euglycemia, although obesity may become a problem.

When patients are unable to tolerate diazoxide because of side effects such as gastrointestinal upset, hirsutism, or edema, a calcium channel blocker such as verapamil (80 mg given orally every 8 hours) may be tried. This is based, in part, on verapamil's inhibitory effect on insulin release from insulinoma cells in vitro.

A potent long-acting synthetic octapeptide analog of somatostatin (octreotide) has been used to inhibit release of hormones from a number of endocrine tumors, including inoperable insulinas, but it has had limited success with the latter. Of the five somatostatin receptors (SSTRs) that have been identified in humans, SSTR2, which predominates in the anterior pituitary, has a much greater affinity for octreotide than SSTR5, which predominates in the pancreas. This explains why octreotide is much more effective in treating acromegaly than in treating insulinoma, except in the occasional cases where insulinoma cells happen also to express SSTR2. When hypoglycemia persists after attempted surgical removal of the insulinoma and if diazoxide or verapamil is poorly tolerated or ineffective, a trial of 50 μg of octreotide injected subcutaneously twice daily may control the hypoglycemic episodes in conjunction with multiple small carbohydrate feedings.

Streptozocin has proved to be beneficial in patients with islet cell carcinomas. With selective arterial administration, effective cytotoxic doses have been achieved without the undue renal toxicity that characterized early experience. Benign tumors appear to respond poorly, if at all.

### 6. NONISLET CELL TUMOR

#### HYPOGLYCEMIA (NICTH)

A variety of nonislet cell tumors have been found to cause fasting hypoglycemia. Most are large and mesenchymal in origin, retroperitoneal fibrosarcoma being the classic prototype. However, hepatocellular carcinomas, adrenocortical carcinomas, renal cell carcinomas, gastrointestinal tumors, lymphomas, leukemias, and a variety of other tumors have also been reported.
Laboratory diagnosis depends on fasting hypoglycemia associated with serum insulin levels below 5 μU/mL. In many cases, the hypoglycemia is due to the expression and release of an incompletely processed insulin-like growth factor II (IGF-II) by the tumor (see also Chapter 21). The primary IGF-II translation product is pre-pro-IGF-II consisting of N-terminal signal peptide of 24 amino acids, 67 amino acid mature IGF-II, and an 89 amino acid extension (E-domain) at the C-terminus. Posttranslational processing of pre-pro-IGF-II involves removal of the N-signal sequence; O-glycosylation of one or more threonine residues of the E-domain and sequential proteolysis of the E-domain. During this process an IGF-II protein with a 21 amino acid extension of the E-domain (pro-IGF-II[68-88]) is relatively stable intermediate that may be secreted from the cell. Most of the mature IGF-II released from the liver is complexed with IGF-binding protein-3 (IGFBP3) and acid-labile subunit (ALS). This ternary protein complex is generally inactive in adults because it is unable to bind properly to tissue receptors. It is only the free IGF-II (1% of total IGF-II) and that bound in binary complexes (predominantly IGFBP2 and IGFBP3) that is accessible to tissue compartment and available to bind the IGF and insulin receptors. However, in patients with nonpancreatic tumors associated with hypoglycemia, incompletely processed mainly nonglycosylated forms of IGF-II are released—in particular pro-IGF-IIE (68-88) form. These incompletely processed molecules are heterogeneous in size and are also referred to as big IGF-II and have molecular mass of 10 to 17 kDa in contrast to mature IGF-II at 7.5 kDa. Pro-IGF-II can form binary complexes with IGFBP3 but have reduced affinity for forming a tertiary complex with ALS. As a consequence, more of the pro-IGF-II is available for binding to the insulin receptors in the muscle to promote glucose transport and to insulin receptors in liver and kidney to reduce glucose output. The increased production of pro-IGF-II by the tumor may also displace processed IGF-II from IGFBPs, increasing free, unbound IGF-II. The IGF-II may bind to receptors for IGF-I in the pancreatic β cell to inhibit insulin secretion and in the pituitary to suppress growth hormone release. With the reduction of growth hormone, there is a consequent lowering of IGF-I levels as well as IGFBP-3 and ALS.

Size exclusion acid chromatography has been the standard method for detection of Pro-IGF-II in NICTH but the process is time consuming. Immunoblot analysis after separating the proteins on 16.5% tricine-sodium dodecyl sulphate-polyacrylamide gels is a more rapid and equally sensitive method. The IGF-II antibody used recognizes both mature and pro-IGF-II forms. In normal subjects, most of the IGF-II migrates at 7.5 kDa and a small amount in the 10 to 17 kDa region, whereas with NICTH most of the IGF-II migrates in the 10 to 17 kDa region and a small amount at 7 kDa.

The clinical syndrome of nonislet cell tumor hypoglycemia, therefore, is supported by laboratory documentation of serum insulin levels below 5 μU/mL with plasma glucose measurements of 45 mg/dL or lower. Values for growth hormone and IGF-I are also decreased. Levels of IGF-II may be increased but often are normal in quantity despite the presence of the immature, higher molecular weight form of IGF-II, which can only be detected by special laboratory techniques.

Not all the patients with NICTH have elevated pro-IGF-II. Ectopic insulin production has been described (bronchial carcinoid, ovarian carcinoma, and a small cell carcinoma of the cervix). Hypoglycemia due to IGF-I released from a metastatic large cell carcinoma of the lung has also been reported.

Treatment is aimed toward the primary tumor, with supportive therapy using frequent feedings. Diazoxide is ineffective in reversing the hypoglycemia caused by these tumors.

7. ALIMENTARY (REACTIVE) HYPOGLYCEMIA

Some disorders cause hypoglycemia in the postprandial state. This condition occurs in patients following gastric surgery (including Roux-en-Y gastric bypass surgery), in autoimmune hypoglycemia, in islet hyperplasia (noninsulinoma pancreaticogenous hypoglycemia syndrome), and occasionally in occult diabetes.

Late dumping syndrome: After major gastric surgery (gastrectomy, vagotomy, pyloroplasty, gastrojejunostomy, and laparoscopic Nissen fundoplication, Billroth II procedure, and Roux-en-Y gastric bypass), some patients develop hypoglycemia post meals especially when they consume foods containing high levels of carbohydrates. This is also referred to as the late dumping syndrome. Late dumping occurs 1 to 3 hours after a meal. Rapid delivery of a meal to the small intestine results in an initial high concentration of carbohydrates in the proximal small bowel and rapid absorption of glucose. This is countered by a hyperinsulinemic response. The high insulin levels are responsible for the subsequent hypoglycemia. The hypoglycemic symptoms include lightheadedness, sweating, confusion, and even loss of consciousness. Gastrointestinal hormones—glucose-dependent insulino- tropic polypeptide (GIP) and glucagon-like peptide 1 (GLP-1)—may play a role in the hyperinsulinemic response. An increased GLP-1 response has been noted in patients after total gastrectomy, esophageal resection, partial gastrectomy, and Roux-en-Y surgery. Furthermore, a positive correlation was found between the rise in plasma GLP-1 and insulin release. Decrease in requirement for gastric surgery for peptic ulcer disease and newer gastric operations such as proximal gastric vagotomy have reduced the incidence of postgastrectomy syndromes. However, as Roux-en-Y gastric bypass surgery has become a popular treatment for morbid obesity, there have been a number of reports of severe postprandial neuroglycopenia. The prevalence of the syndrome after Roux-en-Y procedure is not known. The University of Minnesota surgery group identified 14 cases of postprandial hypoglycemia in 3082 procedures (0.4%), but it is unclear how many patients may have eluded detection or failed to maintain follow-up.

Patients typically complain of the symptoms more severe after consumption of large amounts or readily absorbable carbohydrates. The mixed meal test can be used to precipitate the symptoms. The composition of the mixed meal has not been standardized, and it is reasonable to request the patient to consume a meal that leads to symptoms during everyday life. The University of Minnesota

After overnight fast (≥8 hours) give high carbohydrate meal on day 1 and low carbohydrate meal on day 2. Measure plasma glucose and serum insulin levels before (fasting) and 30, 60, 90, 120, 150, and 180 minutes after the meal.

Investigators formalized a high carbohydrate and a low carbohydrate test meal (Table 18–6) and showed that in patients with postgastric bypass hypoglycemia, the high carbohydrate meal resulted in hyperglycemia and concomitant hyperinsulinemia at about 30 minutes after a meal. Glucose levels then fell to a nadir (range 28-62 mg/dL) at 90 to 120 minutes. Eating the low carbohydrate meal, however, resulted in very little change in plasma glucose levels and only a modest increase in plasma insulin. The prolonged (5 hour) oral glucose tolerance test is not recommended for evaluation because a large number of healthy subjects will have a false-positive result. There have been case reports of insulinoma and noninsulinoma pancreaticogenous hypoglycemia syndrome occurring in patients who present with hypoglycemia post-Roux-en-Y surgery. It is unclear how often this occurs. A careful history may identify those patients who have history of hypoglycemia with exercise or when meals are missed, and these individuals may require a formal 72-hour fast to rule out an insulinoma. Those patients with well-documented postprandial hyperinsulinemic hypoglycemia, which does not respond to medical treatment, may need to have selective calcium-stimulated angiography to identify diffuse islet cell hyperplasia (nesidioblastosis).

Several different treatments can be tried for the late dumping syndrome. Dietary modification is the best option but may be difficult to sustain for some patients. More frequent meals with smaller portions of less rapidly assimilated carbohydrate and more slowly absorbed fat or protein can be tried. Alpha glucosidase inhibitors (acarbose and miglitol) can be a useful adjunct to a low carbohydrate diet in some patients. Octreotide 50 μg administered subcutaneously two or three times a day 30 minutes prior to each meal has been reported to improve symptoms in patients with severe dumping refractory to other forms of medical interventions. Information regarding long-term octreotide use is however limited. Various surgical procedures to slow down gastric emptying have been reported to improve symptoms, but long-term efficacy studies are lacking. Recently it has been reported that endoscopic gastrojejunal anastomotic reduction to induce delay in gastric pouch emptying in patients with Roux-en-Y surgery improves the dumping syndrome symptoms. Partial pancreatectomy is also an option for those postgastric bypass patients with hypoglycemia who have a positive selective arterial calcium stimulation test and in whom medical therapy has failed.

Noninsulinoma pancreaticogenous hypoglycemia syndrome (NIPHS): These are patients with hyperinsulinemic hypoglycemia due to generalized islet hyperplasia and nesidioblastosis. These patients predominantly have symptoms 2 to 4 hours after meals and only rarely while fasting. The majority of patients are male (70%), and all have neuroglycopenic symptoms including diplopia, dysarthria, confusion, disorientation, and even convulsions and coma. At the time of hypoglycemia, these patients have elevated insulin; C-peptide and proinsulin levels; and negative sulfonylurea, repaglinide, and nateglinide screens. Typically these patients have a negative 72-hour fast. Imaging studies are also negative. These patients have a positive selective arterial calcium stimulation test—usually positive for multiple arteries. NIPHS patients do not have mutations in the KIR6.2 and SUR1 genes, which have been abnormal in some cases of children with a syndrome of familial hyperinsulinemic hypoglycemia (see later) Gradient-guided partial or subtotal pancreatectomy relieves the hypoglycemic symptoms in the majority of patients.

Late hypoglycemia of occult diabetes: This condition is characterized by insulin release from pancreatic β cells, resulting in initial exaggeration of hyperglycemia during a glucose tolerance test. In response to this hyperglycemia, exaggerated delayed insulin release produces late hypoglycemia 4 to 5 hours after ingestion of glucose. These patients are often obese, frequently have a family history of diabetes mellitus and have impaired glucose tolerance. In the obese, treatment is directed at reduction to ideal weight. These patients also often respond to reduced intake of refined sugars with multiple, spaced, small feedings high in dietary fiber. They should be considered to have prediabetes or early diabetes (type 1 or 2) and advised to have periodic medical evaluations.

Postprandial syndrome (functional alimentary hypoglycemia): Patients present with symptoms suggestive of increased sympathetic activity—anxiety, weakness, tremor, sweating, or palpitations after meals. Physical examination and laboratory tests are normal. Previously many of these patients underwent a 5-hour oral glucose tolerance test and the detection of glucose levels in the 50s was determined to be responsible for the symptoms, and the recommendation was to modify the diet. It is now recognized that at least 10% of normal subjects who do not have any symptoms have nadir glucose levels less than 50 mg/dL during a 4- to 6-hour oral glucose tolerance test. In a study comparing responses to an oral glucose tolerance test with the response to a mixed meal test, none of the patients who had plasma glucose levels less than 50 mg/dL on oral glucose testing had low glucose values with the mixed meal. Thus, it is not recommended that these patients undergo either a prolonged oral glucose tolerance test or a mixed meal test. The patients should instead be given home blood glucose monitors (with memories) and instructed to monitor fingerstick glucose levels at the time of symptoms. Only patients who have symptoms when their fingerstick blood glucose is low (<50 mg/dL) and who have resolution of symptoms when the
glucose is raised by consumption of readily absorbable carbohydrate need additional evaluation. Patients who do not have evidence for low glucose levels at the time of symptoms are generally reassured by their findings. Counseling and support should be the mainstays of therapy in this group, with dietary manipulation used only as an adjunctive form of therapy.

8. DISORDERS ASSOCIATED WITH LOW HEPATIC GLUCOSE OUTPUT

Reduced hepatic gluconeogenesis can result from a direct loss of hepatic tissue (acute yellow atrophy from fulminant viral hepatitis or toxic damage), from disorders that reduce amino acid substrate for hepatic gluconeogenesis (severe muscle wasting and inanition from anorexia nervosa, chronic starvation, uremia, and glucocorticoid deficit from adrenocortical deficiency), or from inborn errors of carbohydrate metabolism affecting glycolytic or gluconeogenic enzymes.

CONGENITAL HYPERINSULINISM

Neonatal hypoglycemia is a very common problem and can be due to a variety of causes (Table 18–7). In the first day of life, normal babies do not tolerate fasting for periods of 8 hours after delivery. Hypoglycemia in this setting is attributed to impaired ketogenesis and gluconeogenesis. This developmental immaturity in the metabolic response to fasting resolves within the first 2 to 3 days of life. Hypoglycemia in the first few days of life may be directly related to maternal factors, such as maternal diabetes, intravenous glucose use during labor and delivery, and various medications. All of these factors induce a transient hyperinsulinism in the newborn. Prolonged neonatal hypoglycemia may result from perinatal stress, the Beckwith-Wiedemann syndrome, and hypopituitarism. The risk for hypoglycemia can persist for weeks to months. Persistent hypoglycemia may result from: (1) a deficiency in one or more counter-regulatory hormones; (2) defects in glycogenolysis, gluconeogenesis, or fatty acid oxidation; or (3) congenital hyperinsulinism, the various forms of which are discussed further below.

As with adults, hyperinsulinism is the most frequent cause of persistent hypoglycemia in infants and children. As compared to adults, where the most common cause of hyperinsulinism is an insulin-secreting adenoma, in infants hyperinsulinism most likely stems from an underlying genetic disorder. This condition has been referenced in various ways, including persistent hyperinsulinemic hypoglycemia of infancy or islet dysregulation syndrome, but hereafter will be referred to as congenital hyperinsulinism. Transient congenital hyperinsulinism is a common disorder in the immediate neonatal period. Persistent disorders are rarer, occurring in approximately 1 in 50,000. This problem was originally attributed to an anomaly in islet development, termed nesidioblastosis, a reference to endocrine cell budding from pancreatic ducts. However, this budding has since been noted to represent a normal developmental process during the first year of life. Recent advances in our understanding of the regulation of insulin secretion have begun to elucidate the underlying pathophysiology of this complex disease. Congenital hyperinsulinism has now been attributed to at least seven different gene defects. However, depending on the series cited, no genetic explanation is found in 50% or more of cases. Timely diagnosis and aggressive treatment are essential to prevent long-term neurologic sequelae in the affected individual.

Transient Hyperinsulinism

A. Infants of diabetic mothers The fetuses of mothers with poorly regulated diabetes are exposed to sustained hyperglycemia, leading to increased fetal insulin secretion, with resultant macrosomia. This increased insulin secretion persists postpartum and usually resolves after several days. As a result, infants of diabetic mothers are at high risk of developing hypoglycemia after birth. They can usually be managed with early, frequent feedings or intravenous glucose until insulin secretion has normalized, often 1 to 2 days after birth.

B. Small for gestational age, asphyxiation, and other conditions in newborns Various perinatal stresses are known to induce hyperinsulinism. Small-for-gestational age and asphyxiated newborns, usually from toxemic mothers, frequently experience hyperinsulinism and hypoglycemia. Hyperinsulinism is also reported in erythroblastosis fetalis, sepsis, cerebral hemorrhage, and severely stressed newborns. Hypoglycemia usually resolves within a period of several days or weeks but may persist in these settings for 6 to 12 months. Some newborns with Beckwith-Wiedemann syndrome and Soto syndrome (also known as cerebrogigantism) show β cell hyperplasia and experience transient hypoglycemia from hyperinsulinism.

Persistent Hyperinsulinism

Persistent hyperinsulinism, continuing for more than several weeks, results from a group of heterogeneous disorders, rather than a single entity, and the various subtypes are discussed below.

These forms may be classified in a variety of different ways, including usual time of presentation (shortly after birth vs after months to years of life); mode of genetic transmission (autosomal recessive vs dominant); or anatomic (focal vs diffuse). In this section, the forms are grouped into defects in the pancreatic β cell ATP-sensitive potassium channel, defects affecting intracellular metabolism, and several other miscellaneous conditions.

A. Channel defects

1. Sulfonylurea receptor and Kir6.2—The most common cause of congenital hyperinsulinism appears to be related to defects in the pancreatic β cell ATP-sensitive potassium channel. This channel consists of a multimer of two proteins, the sulfonylurea receptor (SUR), a member of the ATP-binding cassette superfamily, and Kir6.2, a member of a family of inwardly rectifying potassium channels. With increases in intracellular ATP, the channel closes, leading to depolarization and insulin secretion (see Chapter 17). Defects in either component of the channel result in channel closure, inappropriate β cell depolarization, and secretion of insulin, even in the face of low or normal glucose concentrations.

The two genes encoding the channel components are located in tandem on chromosome 11p15. Numerous mutations have now been described and appear to occur more frequently in the SUR than the Kir6.2 gene. They are usually autosomal recessive defects, but dominant defects have also been reported. Sequencing of these molecules is now available commercially and may not be merely of academic interest: patients harboring SUR or Kir6.2 mutations often do not respond well to medical therapy. Thus, knowledge of the underlying defect may influence treatment decisions for a particular patient as well as inform the family about risk to future children. Relative to other forms of congenital hyperinsulinism, patients with defects in the ATP-sensitive potassium channel often present early in life, with more marked clinical symptomatology, including macrosomia. They experience early onset and severe hypoglycemia that requires high rates of glucose infusion to normalize serum glucose concentrations and typically require pancreatectomy to restore euglycemia.

2. Focal versus diffuse disease—Two histologically distinct forms of congenital hyperinsulinism have been described, a diffuse form, mentioned above, which constitutes 35% to 70% of cases, depending on the series cited, and a focal form (focal adenomatous hyperplasia). Diagnosis of the focal form is made by pancreatic venous sampling and by percutaneous extemporaneous histologic examination. [18F]Fluorodopa positron emission tomography may also be of utility in defining focal lesions. Histologic examination of the focal form reveals focal hyperplasia, with hypertrophied β cells harboring giant nuclei, in contrast to the diffuse form, where all the islets of Langerhans are irregular in size and contain hypertrophied β cells. The molecular explanation for the focal defect is based on a two-hit model, in which the child already harbors a mutant allele from a paternally derived potassium-ATP channel defect. Subsequent somatic loss of heterozygosity for the maternal 11p chromosome is associated with focal disease and may result from a decrease in dosage of an independent growth-suppressing gene(s) in this region. The distinction between these two forms of hyperinsulinism has potentially important implications for therapy, because patients with focal disease may be cured with more limited partial pancreatectomy, whereas those with the diffuse form require more aggressive near-total resection. Such patients can only be fully evaluated and treated at centers equipped with a team of endocrinologists, interventional radiologists, pathologists, and surgeons with expertise in this disorder.

B. Metabolic defects The second most common form of congenital hyperinsulinism is the hyperinsulinism-hyperammonemia syndrome, which results from activating mutations of the glutamate dehydrogenase (GDH) gene. This condition is inherited in autosomal dominant fashion. This enzyme mediates oxidative deamination of glutamate to alpha ketoglutarate. Activating mutations impair GDH sensitivity to guanosine triphosphate, an allosteric inhibitor, and increase sensitivity to leucine, an allosteric activator. With increased GDH activity, increased production of alpha ketoglutarate with subsequent oxidation in the Krebs cycle generates increased ATP, which in turn activates the ATP-sensitive potassium channel and leads to depolarization and insulin secretion. GDH is also expressed in hepatocytes, and increased activity generates ammonia via glutamate oxidation. Thus, one hallmark of this defect is increased ammonia concentrations three to five times normal. The patients with GDH mutations usually have a milder course than those with defects in the ATP-sensitive potassium channel, often presenting outside of the neonatal period. They often have postprandial hypoglycemia, particularly in response to higher protein loads, but may also manifest fasting hypoglycemia. They usually respond well to diazoxide, and many are able to eventually discontinue treatment.

A much rarer form of autosomal dominant hyperinsulinism results from mutations in glucokinase, the first and rate-limiting step in glycolysis, and an enzyme that is considered to play an essential role in glucose sensing by the β cell. Individuals heterozygous for inactivating mutations have a form of maturity onset diabetes of the young. On the other hand, activating mutations have been described in two families that result in increased rates of glycolysis at lower glucose concentrations. The resultant increase in the intracellular ATP/ADP ratio increases insulin secretion at any given serum glucose concentration, resulting in hypoglycemia.

An entity referred to as exercise-induced hyperinsulinism has been described, in which hyperinsulinism is noted following exercise. An underlying genetic cause has not yet been proven, although it is suspected that this represents another metabolic defect. This problem appears to be milder than the others described earlier, and it neither presents in the neonatal period nor results in fasting hypoglycemia. A recent report suggested an autosomal dominant pattern of inheritance in multiple members of two families. Hyperinsulinism was induced by exercise and by pyruvate infusion, suggesting that this disorder results from abnormal transport or metabolism of pyruvate in β cells.

Another autosomal recessive form of congenital hyperinsulinism results from mutations in the gene encoding the short chain L-3-hydroxyacyl-CoA dehydratase. This enzyme mediates the penultimate step in fatty acid beta oxidation and as such represents the first link between defects in fatty acid metabolism and insulin secretion. However, it is not yet clear how this defect results in congenital hyperinsulinism.
Congenital disorders in glycosylation have also been linked with congenital hyperinsulinism. The mechanism is unclear, although hypoglycosylation of the SUR with a resultant defect in trafficking to the cell membrane has been offered as a possible explanation. Nonetheless, these patients appear to be responsive to diazoxide, suggesting that at least some functional ATP-sensitive potassium channels reach the cell surface. Affected individuals have multisystem disorders, including neurologic defects. Despite the evolving elucidation of defects known to be associated with congenital hyperinsulinism, the underlying diagnosis remains unknown in up to one-half of infants diagnosed with this condition.

**Clinical Presentation**

The cardinal symptoms of hyperinsulinism are recurrent episodes of hypoglycemia and can occur any time after birth until several years of age, or manifest even later in life, depending on the nature and severity of the defect. As in adults, the symptoms of hypoglycemia are secondary to adrenergic responses or neuroglycopenia. However, in neonates and infants, symptoms are difficult to detect and may be less specific. They may include tremors, cyanosis, hyperthermia, apnea or irregular breathing, lethargy, apathy, limpness, refusal to eat, high-pitched cries, and seizures of any type. Even if newborns appear asymptomatic, hypoglycemia can be as severe as in symptomatic neonates.

**Diagnosis**

The differential diagnosis for hypoglycemia in a neonate is quite long and includes deficiencies in counterregulatory hormones (e.g., growth hormone, ACTH, glucocorticoids); defects in gluconeogenesis, glycogen synthesis, and breakdown; and disorders in fatty acid metabolism. Hyperinsulinism is suspected in hypoglycemic newborns or infants who require unusually high glucose infusion rates (12-30 mg/kg/min) to maintain blood glucose levels in the target range. Macrosomia may be another clue to hyperinsulinism, although it is not always present. The crucial diagnostic step is to obtain a critical blood sample for glucose, insulin, growth hormone, cortisol, blood gas, lactate, free fatty acids, and ketones (β-hydroxybutyrate) during hypoglycemia. Urinary ketones should be measured in the first urine after hypoglycemia. Insulin levels must often be measured during several episodes of hypoglycemia because insulin levels at times of hypoglycemia are not always diagnostically elevated. In fact, insulin levels that are inappropriately measurable during episodes of hypoglycemia are still consistent with the diagnosis. As in adults, the hallmarks of hyperinsulinism include measurable plasma insulin in the face of hypoglycemia (glucose <40 mg/dL), low or unmeasurable ketones and free fatty acids, and hyperresponsive-ness to glucagon challenge, with the glycemic response to 0.5 to 1 mg of parenteral glucagon of more than 30 mg/dL (with glucose monitored every 15 minutes for up to 45 minutes after glucagon injection). Low IGF-binding protein (IGFBP) 1 levels also suggest this diagnosis, as insulin suppresses IGFBP1 secretion from the liver.

**Treatment**

**A. Medical therapy** Management of children with congenital hyperinsulinism remains one of the most challenging problems for pediatric endocrinologists, and affected children should be transferred to a tertiary center that has experience in managing such children. Patients may require high glucose infusion rates to maintain euglycemia, and thus a secure central line is usually necessary. They also require frequent glucose monitoring, extensive ongoing laboratory assessment to establish the underlying diagnosis, and a series of medical and/or surgical interventions to effect a cure.

Hypoglycemia in infancy has to be treated aggressively in order to prevent long-term neurologic sequelae. Relative to adults, younger children (up to age 5 to 6 years) appear to be particularly vulnerable to such damage. Those with hyperinsulinism are particularly at risk, because ketone bodies are not present as an alternative fuel source. The therapeutic goal is to achieve glucose levels above 60 mg/dL while the infant is on an appropriate feeding schedule for age. Infants receiving appropriate therapy must be able to support a fast for at least 4 to 6 hours without hypoglycemia. In selected cases in which food refusal or intercurrent illness is a problem, hypoglycemia can be prevented by placing a gastrostomy tube to administer food on a regular basis.

For acute management of hypoglycemia, stabilization of blood glucose may require infusion rates of glucose up to 20 to 30 mg/kg/min, well above the 4 to 8 mg/kg/min needed to stabilize most neonates. Some centers employ aggressive enteral feeding, using frequent feeds or continuous feeding via nasogastric or gastrostomy tube, with or without cornstarch, as a means to avoid hypoglycemia. The following drugs are also used in the medical management of hyperinsulinemic hypoglycemia.

1. **Diazoxide**—Diazoxide is the drug of choice in neonates who cannot be weaned from intravenous glucose. Diazoxide increases blood glucose by stabilizing the ATP-sensitive potassium channel in the open state, thereby inhibiting membrane depolarization and insulin secretion. Functionally intact SUR and Kir6.2 proteins are necessary for the full action of the drug, and thus, patients with channel defects often do not respond, whereas those with other forms of hyperinsulinism do exhibit salutary responses. Diazoxide also increases catecholamine release, which suppresses insulin release and inhibits insulin’s actions peripherally. The initial recommended dose is 10 to 15 mg/kg/d divided every 8 hours, up to a maximal dose of 20 mg/kg/d. Positive responses are usually seen within 48 hours if they are going to occur. Diazoxide has several important side effects that should be considered. Fluid retention can be managed by simultaneous administration of chlorothiazide. Hypertrichosis and coarse facial changes may become quite striking and can be reduced only by decreasing the dose or discontinuing the diazoxide altogether. Hyperuricemia, leukopenia, and thrombocytopenia are rare, but routine serum studies must be monitored while therapy continues. Diazoxide is also an antihypertensive drug, but these effects are rarely encountered with oral administration.

Depending on the study cited, diazoxide appears to be efficacious in only one-fourth to one-half of the patients with hyperinsulinism and appears to be less likely to work in those patients presenting in the immediate newborn period, a population that
often has more marked defects in ATP-sensitive potassium channel activity. Thus, in those patients with persistent hyperinsulinism, determining whether mutations are present in SUR or Kir6.2 genes may help anticipate the response to medical therapy and predict the need for more definitive surgical intervention.

2. Somatostatin analogs—This is usually a second-line approach, for those unresponsive to diazoxide. Somatostatin acts via a G protein–coupled receptor to lower intracellular calcium and to hyperpolarize the β cell membrane, thereby inhibiting insulin release. Somatostatin has a half-life of only 1 to 3 minutes, but the synthetic analog octreotide may be administered at intervals of up to 8 hours or via continuous subcutaneous infusion and is efficacious in some patients with congenital hyperinsulinism. A starting dose of 5 to 10 μg/kg/d, administered either as a continuous infusion or via continuous subcutaneous infusion in a pump, often produces salutary initial responses, but because of tachyphylaxis, the dose sometimes has to be increased to as much as 40 μg/kg/d. Some physicians advocate octreotide in patients who fail to respond to diazoxide therapy alone. However, optimal control of blood glucose often cannot be achieved by adding octreotide, and partial pancreatectomy is necessary. Nonetheless, the medication may help stabilize blood glucose concentrations in the preoperative period and may prove efficacious postoperatively in those patients who have persistent hyperinsulinism even with reduced β cell mass. There are some reports of long-term success (>5 years) with octreotide alone.

Short-term side effects are mostly self-limited within the first several weeks of therapy. Octreotide has nonspecific effects on the gastrointestinal tract, including decreased perfusion of the splanchnic circulation, gallbladder contractility, and bile secretion. Short-term effects may include vomiting, abdominal distension, and steatorrhea, with later risk of cholelithiasis. Possible inhibitory effects of octreotide on other hormonal axes, including effects on the pituitary somatotrope, adrenal, and thyroid, raise concerns about its long-term use, although some centers report successful and eventful use for years without significant problems.

3. Glucagon—Glucagon has a place in the management of hyperinsulinism during initial stabilization of the hypoglycemic infant in the intensive care unit or prior to surgery. This agent stimulates hepatic glycogenolysis and is very effective in these patients because their glycogen stores are replete. A variety of doses has been shown to be effective, including a bolus of 0.2 mg intravenously in cases of severe hypoglycemia followed by a continuous infusion at a dose of 2 to 10 mg/kg/h. An intramuscular glucagon injection may also be used as an emergency treatment of recurrent hypoglycemic episodes at home. Attempts have been made to administer glucagon continuously via subcutaneous infusion with limited success.

4. Calcium antagonists—Because calcium influx is required for insulin secretion, calcium antagonists could play a potential role in the treatment of hyperinsulinism. Calcium channel blockers also decrease the transcriptional response of insulin to glucose. However, only rare and limited success has been achieved with this class of drugs, perhaps because of failure to block calcium channels selectively within the β cells.

B. Surgical therapy Partial pancreatectomy is undertaken when maintenance of euglycemia cannot be achieved with medical treatment alone. The initial surgical procedure of choice has traditionally been a 95% pancreatectomy. However, such procedures are now being reconsidered, with the appreciation that some of these infants may have a focal rather than diffuse process and may require only selective resection of the affected pancreatic tissue in order to effect a cure. Unfortunately, only a limited number of medical centers around the world are now equipped to conduct the pre- and perioperative evaluation to distinguish focal from diffuse disease, which includes selective venous sampling and histological analysis.

Even with more aggressive resections, β cell mass reduction does not always lead to euglycemia, and medical therapy may have to be continued following surgery. If this fails to restore euglycemia, a second surgical intervention may be required in which near-total pancreatectomy (99%) is performed. Potential surgical complications include intraoperative injury to the common bile duct and adhesions with intestinal obstruction. Additional complications include exocrine pancreatic insufficiency, often requiring oral supplements at mealtimes, and diabetes mellitus.

Outcome

Neurologic sequelae are the major concern with severe hypoglycemia during infancy and childhood. Multiple episodes of hypoglycemia are more often associated with sequelae than one severe hypoglycemic episode with convulsions. At least one-third of patients with congenital hyperinsulinism suffer from developmental delay based on follow-up via a telephone survey.

Patients with the familial form of congenital hyperinsulinism who harbor mutations in the SUR receptor may be at additional neurologic risk. The SUR is expressed in the brain, and defects in this molecule could potentially interfere with neural development. The role of this receptor in the brain, however, has yet to be elucidated.

Affected individuals also appear to be at higher risk for later development of diabetes. This problem may be related to reduced β cell mass following pancreatectomy or from β cell apoptosis following chronic depolarization in subjects who harbor channel defects.

Disorders of Lipoprotein Metabolism

Mary J. Malloy, MD and John P. Kane, MD, PhD

The clinical importance of lipoprotein disorders derives chiefly from the role of lipoproteins in atherogenesis and its associated risk of coronary and peripheral vascular disease. The greatly increased risk of acute pancreatitis associated with severe hypertriglyceridemia is an additional indication for intervention. Disordered lipid metabolism is also a critical element in nonalcoholic fatty liver disease. Characterization of dyslipidemia is important for selection of appropriate treatment and may provide clues to underlying primary clinical disorders.

ATHEROSCLEROSIS

Atherosclerosis is the leading cause of death in the United States. Abundant epidemiologic evidence establishes its multifactorial character and indicates that the effects of the multiple risk factors are at least additive. Risk factors include hyperlipidemia, hypertension, smoking, diabetes, physical inactivity, decreased levels of high-density lipoproteins (HDL), hyperhomocysteinemia, and hypercoagulable states. Atheromas are complex lesions containing cellular elements, collagen, and lipids. The progression of the lesion is chiefly attributable to its content of unesterified cholesterol and cholesteryl esters. Cholesterol in the atheroma originates in circulating lipoproteins. Atherogenic lipoproteins include low-density (LDL), intermediate density (IDL), very low density lipoproteins (VLDL), and Lp(a) species, all of which contain the B-100 apolipoprotein (Apo B-100). Chylomicron remnants containing apoB-48 are also atherogenic. All of these are subject to oxidation by reactive oxygen species in the tissues and also by lipooxygenases secreted by macrophages in atheromas. Oxidized lipoproteins cause impairment of endothelial cell-mediated vasodilatation and stimulate endothelium to secrete monocyte chemoattractant protein-1 (MCP-1) and adhesion molecules that recruit monocytes to the lesion. Tocopherols (vitamin E) are natural antioxidants that localize in the surface monolayers of lipoproteins, exerting resistance to oxidation.
Increased oxidative stress such as that induced by smoking depletes the tocopherol content. Oxidation of lipoproteins stimulates their endocytosis via scavenger receptors on macrophages and smooth muscle cells, leading to the formation of foam cells. Recent studies strongly support a role of vitamin D in prevention of atherosclerosis, probably by influencing inflammatory activity of macrophages.

Hypertension increases access of lipoproteins to the subintima. Smoking accelerates atherogenesis by reducing HDL and increasing thrombogenesis by platelets—in addition to its pro-oxidant effect. Activated platelets release platelet-derived growth factor (PDGF), stimulating proliferation and migration of cells of smooth muscle origin into the lesion.

Activated macrophages secrete cytokines that drive an inflammatory and proliferative process. Metalloproteases secreted by macrophages weaken the atheroma so that fissuring and rupture can occur. Exposure of blood to subintimal collagen and tissue factor stimulates thrombogenesis, precipitating acute coronary events. The inverse relationship between HDL levels and atherogenesis probably reflects the role of certain species of HDL in cholesterol retrieval and in protecting lipoproteins against oxidation.

**Reversal of Atherosclerosis**

Angiographic intervention trials have shown that regression of atherosclerotic lesions can occur with lipid-lowering therapy. Large trials have demonstrated striking reductions in the incidence of new coronary events in individuals with hyperlipidemia who have had no prior clinical coronary disease (primary prevention) as well as in patients with antecedent disease (secondary prevention). Thus, timely hypolipidemic therapy appropriate to the lipid disorder decreases the incidence of coronary disease and reduces the need for angioplasty, stenting, and bypass surgery. Side-effects of treatment have been minimal in comparison with the magnitude of this benefit.

Average levels of LDL in the United States and northern Europe are higher than in many other nations, where the levels appear to approach the biologic norm. This probably accounts in part for the higher incidence of coronary disease in industrialized Western nations and suggests that dietary changes that reduce lipoprotein levels would be beneficial.

**OVERVIEW OF LIPID TRANSPORT**

**The Plasma Lipoproteins**

Because lipids are relatively insoluble in water, they are transported in association with proteins. The simplest complexes are those formed between unesterified, or free, fatty acids (FFA) and albumin, which serve to carry the FFA from peripheral adipocytes to other tissues.

The remainder of the lipids are transported in spherical lipoprotein complexes (Table 19–1), with core regions containing hydrophobic lipids. The principal core lipids are cholesteryl esters and triglycerides. Triglycerides predominate in the cores of chylomicrons, which transport newly absorbed lipids from the intestine, and in VLDL, which originate in liver. The relative content of cholesteryl ester is increased in the cores of remnants derived from these lipoproteins. Cholesteryl esters are the predominant core lipid in LDL and HDL. Surrounding the core in each lipoprotein is a monolayer containing amphiphilic phospholipids and unesterified (free) cholesterol. Apolipoproteins, noncovalently bound to the lipids, are located on this surface monolayer (Figure 19–1).

**B Apolipoproteins**

Several lipoproteins contain very high molecular weight B proteins that behave like intrinsic proteins of cell membranes. Unlike the smaller apolipoproteins, the B proteins do not migrate from one lipoprotein particle to another. VLDL contain the B-100 protein, which is retained in the formation of LDL from VLDL remnants by liver. The intestinal B protein, B-48, is found only in chylomicrons and their remnants. Apo B-100 has a ligand domain for binding to the LDL receptor that is conformed as VLDL are transformed into LDL.

**Other Apolipoproteins**

In addition to the B proteins, the following proteins are present in lipoproteins (see Table 19–1.)

*C apolipoproteins* are lower molecular weight proteins that equilibrate rapidly among the lipoproteins. There are four distinct species: C-I, C-II, C-III, and C-IV. Apo C-II is a requisite cofactor for lipoprotein lipase.

Three isoforms of Apo E—E-2, E-3, and E-4—are the products of allelic genes. Unlike Apo E-3 and Apo E-4, Apo E-2 does not contain a functional ligand for the LDL receptor. The Apo E-4 alleles are associated with early-onset Alzheimer disease and increased risk of coronary disease.

Apo A-I is the major apolipoprotein of HDL. It is also present in chylomicrons and is the most abundant of the apolipoproteins of human serum (about 125 mg/dL). It is a cofactor for lecithin-cholesterol acyltransferase (LCAT).

Apo A-II is an important constituent of HDL. It contains cysteine, which permits the formation of disulfide-bridged dimers with Apo E.

Apo A-IV is chiefly associated with chylomicrons.

Apo A-V plays a significant role in the removal of triglycerides from plasma.

The (a) protein is a glycoprotein that has a high degree of sequence homology with plasminogen, resulting in binding affinity for tissue plasminogen activator. It is found as a disulfide-bridged dimer with Apo B-100 in LDL-like species of lipoproteins (Lp[a] lipoproteins).

Absorption of Dietary Fat; Secretion of Chylomicrons

Dietary triglycerides are hydrolyzed in the intestine to β-monoglyceride and fatty acids by pancreatic lipase, which is activated by bile acids and a protein cofactor. The partial glycerides and fatty acids form micelles that are absorbed by intestinal epithelium. The fatty acids are reesterified with β-monoglycerides to form triglycerides, and free cholesterol is esterified with fatty acids by acyl-CoA:cholesterol acyltransferase-2 (ACAT-2). Droplets of triglyceride with small amounts of cholesteryl esters, associated with B-48, acquire a monolayer of phospholipid and free cholesterol. Apo A-I and Apo A-II are added, and the nascent chylomicron emerges into the extracellular lymph space (see Figure 19-1). The new chylomicron begins to exchange surface components with HDL, acquiring Apo C and Apo E and losing phospholipids. This process continues as the chylomicron is carried via the intestinal lymphatics to the thoracic duct and thence into the bloodstream.

Formation of Very Low Density Lipoproteins

The liver exports triglycerides to peripheral tissues in the cores of VLDL (Figure 19-2). These triglycerides are synthesized in liver from free fatty acids abstracted from plasma and from fatty acids synthesized de novo. Release of VLDL by liver is augmented by any condition that results in increased flux of FFA to liver in the absence of compensating ketogenesis. Obesity, increased caloric intake, ingestion of ethanol, and estrogens stimulate release of VLDL and are important factors in hypertriglyceridemia.

Metabolism of Triglyceride-Rich Lipoproteins in Plasma

A. Hydrolysis by lipoprotein lipase Fatty acids derived from the triglycerides of chylomicrons and VLDL are delivered to tissues through a common pathway involving hydrolysis by the lipoprotein lipase (LPL) system. Members of a family of fatty acid transfer proteins facilitate FFA uptake in tissues. LPL is bound to capillary endothelium in heart, skeletal muscle, adipose tissue, mammary gland, and other tissues.

B. Biologic regulation of lipoprotein lipase When glucose levels in plasma are elevated and the release of insulin is stimulated, LPL is transcriptionally upregulated in adipose tissue, and fatty acids derived from triglycerides of circulating lipoproteins are stored. During prolonged fasting, and in diabetic
ketoacidosis, LPL activity of adipose tissue falls, preventing storage of fatty acids. Heparin is a cofactor for LPL. When it is given intravenously (0.1-0.2 mg/kg), LPL activity is displaced into plasma, permitting its measurement. Apo C-II is an obligatory cofactor.

C. Formation of lipoprotein remnants Hydrolysis by LPL results in depletion of triglycerides in the cores of chylomicrons and VLDL, producing progressive decreases in particle diameter. Lipids from the surface and C proteins are transferred to HDL. The remnant lipoproteins thus formed contain their original complement of Apo B, significant amounts of Apo E, and little Apo C. They have lost about 70% of their triglycerides and are enriched in cholesteryl esters.

D. Fate of lipoprotein remnants Chylomicron remnants are removed from blood quantitatively by high-affinity, receptor-mediated endocytosis in the liver. The receptors include the LDL (B-100:E) receptors and the LDL receptor-related protein-1 (LRP-1). Endocytosis of chylomicron remnants by both requires the presence of Apo E-3 or Apo E-4. The lipids enter hepatic pools, and B-48 protein is degraded. Cholesterol derived from chylomicron remnants exerts feedback control of cholesterol biosynthesis in liver. Some VLDL remnants are removed from blood via the B-100:E receptors (see later) and are degraded. Those that escape uptake are transformed into LDL. Thus, the rate of removal of VLDL remnants is a determinant of LDL production.

Formation of LDL involves the removal of residual triglycerides by hepatic lipase, facilitated by Apo E. LDL contain cholesteryl esters in their cores and retain Apo B-100. In normal individuals, a major fraction of VLDL is converted to LDL, and all of the LDL Apo B comes from VLDL. In certain hypertriglyceridemic states, conversion of VLDL to LDL is decreased. In the absence of impaired conversion, increased secretion of VLDL results in increased production of LDL. This precursor-product relationship explains the clinical phenomenon referred to as the beta shift, an increase of LDL (beta-lipoprotein) as hypertriglyceridemia resolves. An example of this occurs temporarily following institution of insulin treatment in uncontrolled diabetes with lipemia. Insulin induces LPL activity, resulting in rapid conversion of VLDL to LDL. Because of its longer half-life, LDL accumulates in plasma. Elevated levels of LDL may persist beyond the time when levels of triglyceride-rich lipoproteins have returned to normal. A similar phenomenon may occur when patients with familial combined hyperlipidemia (FCH) are treated with fibric acid derivatives.

E. Half-lives of lipoproteins Normally, the half-life of chylomicrons is 5 to 20 minutes; that of VLDL is 0.5 to 1 hour; and that of LDL is about 2½ days. At triglyceride levels of 800 to 1000 mg/dL, LPL is at kinetic saturation. Increased input of triglycerides into plasma at those levels rapidly augments the hypertriglyceridemia.

F. Effect of dietary fat restriction Individuals consuming a typical North American diet transport 75 to 100 g or more of

triglyceride per day in chylomicrons, whereas the liver exports 10 to 30 g in VLDL. When LPL is saturated and triglycerides are measured in thousands of milligrams per deciliter, acute restriction of dietary fat produces a significant reduction in levels. This intervention is especially important in the lipemic patient with impending pancreatitis. If symptoms suggest that pancreatitis is imminent, oral intake should be eliminated, gastric acid should be suppressed with H₂ blockade, and the patient should not be fed by mouth until the symptoms subside and triglycerides decrease to less than 800 to 1000 mg/dL.

**Catabolism of Low-Density Lipoproteins**

LDL catabolism is mediated by high-affinity receptors on the cell membranes of virtually all nucleated cells but most importantly hepatocytes. Ligands for these LDL receptors exist in Apo B-100 and Apo E. After endocytosis, Apo B is degraded, and the receptor returns to the cell membrane. The cholesterol esters of LDL are hydrolyzed to free cholesterol for production of cell membrane bilayers. Free cholesterol down regulates hydroxymethylglutaryl-CoA (HMG-CoA) reductase and other rate-limiting enzymes in the biosynthetic pathway for cholesterol. Cholesterol in excess of need for membrane synthesis is esterified by ACAT-2 for storage. In addition to suppression of cholesterol biosynthesis, the entry of cholesterol via the LDL pathway leads to downregulation of LDL receptors, an effect also observed with dietary saturated fat. Further regulatory mechanisms involve shortening of the residence time of LDL receptors in cell membranes. The PCSK9 protein increases the proteolytic degradation of LDL receptors, decreasing the ability of cells to endocytose LDL. Another mechanism that leads to receptor degradation involves ubiquitination of the receptors by Idol (inducible degrader of the LDL receptor).

**Metabolism of High-Density Lipoproteins**

When isolated by ultracentrifugation, HDL appear to comprise two major classes: HDL₂ and HDL₃. Similar quantities of HDL₃ are isolated from serum of men and women, but about twice as much HDL₁ is found in premenopausal women. Immunochemical studies indicate that there are as many as 20 discrete species of HDL that are obscured by ultracentrifugation. One of these, the 67-kDa prebeta-1 HDL, is the primary acquisitor of cholesterol in the retrieval pathway from peripheral tissues.

**A. Sources of HDL**

Both liver and intestine produce HDL apolipoproteins, which organize with lipids into the native species of HDL in lymph and plasma. Excess free cholesterol and phospholipids liberated from the surface monolayers of chylomicrons and VLDL as hydrolysis of triglycerides proceeds are transferred to HDL by phospholipid transfer protein. Free cholesterol acquired by HDL is esterified by LCAT. This enzyme transfers 1 mol of fatty acid from a lecithin molecule to the hydroxyl group of unesterified cholesterol, forming cholesterol esters. LCAT is secreted by liver. In severe hepatic parenchymal disease, levels in plasma are less than 800 to 10 000 mg/dL.

**B. Metabolic roles for HDL**

HDL serve as carriers for the C apolipoproteins, transferring them to nascent VLDL and chylomicrons. HDL as well as LDL deliver cholesterol to the adrenal cortex and gonads in support of steroidogenesis. HDL play a major role in the centripetal transport of cholesterol. Unesterified cholesterol, exported by the ATP-binding cassette transporter A1 (ABCA1), is acquired from the membranes of peripheral tissues by prebeta-1 HDL and is esterified by LCAT, passing through other HDL species before the cholesteryl esters are incorporated into HDL of alpha-electrophoretic mobility. Cholesterol effluxed from macrophages by the ATP-binding cassette transporter G1 (ABCG1) is acquired by larger HDL. The cholesteryl esters are then transferred to LDL and to triglyceride-rich lipoproteins mediated by cholesteryl ester transfer protein (CETP). Remnants of chylomicrons and a significant fraction of VLDL remnants and LDL are taken up by liver. Cholesteryl esters are also transferred from HDL to hepatocytes by scavenger receptor, class B, type I (SR-BI) receptors.

**C. Catabolism of HDL**

The pathways of catabolism of HDL are not yet known. Radiochemical studies indicate that Apo A-I and Apo A-II are removed from plasma synchronously and that a portion of the degradation occurs in liver and in kidney.

**The Cholesterol Economy**

Cholesterol is an essential constituent of the plasma membranes of cells and of myelin. It is required for adrenal and gonadal steroidogenesis and for production of bile acids by liver. Cells synthesize cholesterol, commencing with acetyl-CoA. Formation of HMG-CoA is the initial step. The first committed step, mediated by HMG-CoA reductase, is the formation of mevalonic acid, which is then metabolized via a series of isoprenoid intermediaries to squalene. The latter cyclizes to form a series of sterols leading to cholesterol. A small amount of the mevalonate is converted to the isoprenoid substances ubiquinone, dolichol, and isopentenyl pyrophosphate. This pathway also yields the isoprenoid intermediaries geranyl and farnesyl pyrophosphates that are involved in prenylation of proteins. Prenylation provides an anchor so that proteins such as the low molecular weight G proteins can bind to membranes. Cholesterol synthesis is tightly regulated by cholesterol or its metabolites, which down regulate HMG-CoA reductase. Thus, cells can produce cholesterol not provided by circulating lipoproteins. Hepatocytes and intestinal epithelial cells use cholesterol for secretion of lipoproteins. In addition, cells constantly transfer cholesterol to circulating lipoproteins, chiefly HDL. Cholesterol is converted to bile acids in liver via a pathway initiated by cholesterol 7α-hydroxylase. Most of the bile acids are reabsorbed from the intestine, but the small amount that is lost in stool provides a means of elimination of cholesterol. Activity of cholesterol 7α-hydroxylase is decreased in hypothyroidism, as are the expression of LDL receptors and hepatic lipase.
At usual levels of cholesterol intake, about one-third of
the amount ingested is absorbed. Most is transported to liver in chylo-
micron remnants, suppressing hepatic cholesterogenesis. Individuals
may differ substantially in the effect of dietary choles-
terol on levels of serum lipoproteins.

DIFFERENTIATION OF DISORDERS OF
LIPOPROTEIN METABOLISM

Laboratory Analyses of Lipids and
Lipoproteins

Because chylomicrons normally may be present in plasma up to
10 hours after a meal, they contribute as much as 600 mg/dL
(6.9 mmol/L) to the triglycerides measured during that period.
This alimentary lipemia can be prolonged if alcohol is consumed
with the meal. Thus, serum lipids and lipoproteins should be
measured after a 10-hour fast. If blood glucose is not to be mea-
sured, patients may have fruit and black coffee with sugar (which
provide no triglyceride) for breakfast.

A. Inspection Much useful information is gained from inspec-
tion of the serum, especially before and after overnight refrigeration.
Opalescence is due to light scattering by large triglyceride-rich
lipoproteins. Serum begins to appear hazy when the level of triglyc-
erides reaches 200 mg/dL (2.3 mmol/L). Chylomicrons are readily
detected, because they form a white supernatant layer after refrig-
eration. Uncommon cases in which binding of immunoglobulins to
lipoproteins takes place can be detected by the formation of a curd-
lke lipoprotein aggregate or a snowy precipitate as serum cools. If
one of these disorders is suspected, blood should be kept at 37°C
during the formation of the clot and separation of the serum, because
the critical temperatures for precipitation of the cryoglobulin
complex may be higher than room temperature.

B. Laboratory techniques Several chemical techniques pro-
vide reliable measures of cholesterol and triglycerides, an essential
minimum for differentiation of disorders of lipoproteins. Unesterified and esterified cholesterol are usually measured
the reported value is the total content of choles-
terol in serum. A more complete characterization of lipoproteins
is achieved by measurement of the cholesterol and triglyceride
contents of individual lipoprotein fractions, separated by prepara-
tive ultracentrifugation, a technique usually available only in
research laboratories. An efficient quantitative method employs
vertical rotor ultracentrifugation, affording assessment of lipoprotein
concentrations and particle diameters. LDL particle size can
also be assessed by electrophoresis. The content of HDL can be
measured using a technique in which they are the only lipopro-
teins that remain in solution after treatment of the serum with
heparin and manganese. Although rapid, the results of this
technique tend to be unacceptably variable unless rigid quality
control is exercised. Prognostic implications of small changes in
HDL cholesterol make such controls necessary. An important
determinant of the content of cholesteryl esters in HDL is the
amount of triglyceride-rich lipoproteins to which the HDL are
exposed in plasma. Cholesteryl esters from HDL transfer into
triglyceride-rich lipoproteins, leading to an inverse dependence of
HDL cholesterol on plasma triglycerides. HDL cholesterol cannot
be interpreted without knowledge of the level of serum triglyc-
erides. For example, a level of HDL that would normally contain
45 mg/dL (1.17 mmol/L) of cholesterol might contain 37 mg/dL
(0.96 mmol/L) when the triglycerides were 200 mg/dL
(2.3 mmol/L) and 30 mg/dL (0.78 mmol/L) when they reach
500 mg/dL (5.7 mmol/L).

More sophisticated tests of composition of isolated lipoprotein
fractions are of use in certain instances, including the ratio of
cholesterol to triglycerides. Enrichment of VLDL by cholesteryl
esters is typical of familial dysbetalipoproteinemia that is due to
homozygosity for Apo E-2. The Apo E genotype can be deter-
minded by PCR analysis. Clinically useful immunoaassays are avail-
able for Apo B and Lp(a).

Epidemiologic evidence suggests that LDL particles of smaller
than normal diameter are associated with an increased risk of
atherosclerosis. Small, dense LDL particles are a constant finding
when triglyceride levels are elevated even marginally. Laboratory
measurement of LDL diameters is therefore unnecessary in
patients with hypertriglyceridemia.

Clinical Differentiation of Abnormal
Patterns of Plasma Lipoproteins

A. Preliminary screening Serum cholesterol and triglycer-
ide levels are continuously distributed in the population; there-
fore, some arbitrary levels must be established to define significance.
Epidemiologic studies in Europe and the United States have
shown a progressive increase in risk of coronary disease as levels of
cholesterol increase. Physicians should at least encourage patients
at risk to eat diets low in saturated fats, trans fats, and cholesterol
to minimize the burden of LDL in plasma.

The National Cholesterol Education Program has developed
guidelines for treatment of hypercholesterolemia in adults. Since
this 2001 report, the results of major clinical trials have suggested
that more aggressive lipid management is justified. For patients at
high risk (coronary heart disease [CHD] or CHD risk equivalents,
including diabetes), a suggested LDL-cholesterol goal is less than
70 mg/dL (1.8 mmol/L). Triglyceride levels above 150 mg/dL
(1.7 mmol/L) merit investigation. One abnormality commonly
associated with increased risk of coronary disease that is not detected
if screening is limited to hyperlipidemia is hyperalphalipoproteine-
mia, or deficiency of HDL. Many affected individuals have normal
levels of cholesterol and triglycerides and no clinical features to alert
the physician. HDL deficiency underscores the importance of con-
trolling other risk factors and avoiding factors that reduce HDL,
such as smoking, the use of some drugs, and obesity.

B. Identification of abnormal patterns The second step
in investigation of hyperlipidemia is determination of the species
of lipoproteins involved. In some cases, this may include multiple
species; in others, qualitative properties of the lipoproteins are
of diagnostic importance. Secondary hyperlipemias of similar
pattern may be the sole cause of the lipoprotein abnormality or may aggravate primary disorders of lipoprotein metabolism. The differentiation of specific primary disorders usually requires additional clinical and genetic information.

The following diagnostic protocol, based on initial measurement of cholesterol, triglycerides, and HDL in serum after a 10-hour fast, supplemented by observation of serum and by additional laboratory measurements where essential, serves as a guide in identifying abnormal patterns. The term \textit{hyperlipidemia} denotes high levels of any class of lipoprotein; \textit{hyperlipemia} denotes high levels of any of the triglyceride-rich lipoproteins.

**Case 1: Serum Cholesterol Levels Increased; Triglycerides Normal**

If the serum cholesterol level is modestly elevated (up to 260 mg/dL [6.72 mmol/L]), elevated levels of HDL may account for the observed increase in serum cholesterol. This is usually not associated with disease processes. The LDL cholesterol (in mg/dL) may be estimated by subtracting the HDL cholesterol and the estimated cholesterol contribution of VLDL from the total cholesterol level. The VLDL cholesterol is approximated as one-fifth of the serum triglyceride level.

$$\text{LDL cholesterol} = \text{total cholesterol} - \left( \frac{\text{TG}}{5} + \text{HDL cholesterol} \right)$$

Very high levels of HDL measured by the precipitation technique can signal the presence of the abnormal lipoprotein of cholestasis (Lp-X). This disorder is characterized by elevated alkaline phosphatase activity. Rarely, deficiency of CETP or hepatic lipase can cause high levels of HDL.

**Case 2: Predominant Increase of Triglycerides; Moderate Increase in Cholesterol May Be Present**

Here it is apparent that the primary abnormality is an increase in triglyceride-rich VLDL (hyperprebeta1lipoproteinemia) or chylomicrons (chylomicronemia), or both (mixed lipemia). Because both contain free cholesterol in their surface monolayers and a small amount of cholesteryl ester in their cores, the total cholesterol may be increased, although to a much smaller extent than triglycerides. Low levels of LDL of ten seen in hypertriglyceridemia may offset the increase in cholesterol due to the triglyceride-rich lipoproteins, especially in primary chylomicronemia. Because VLDL and chylomicrons compete as substrates in a common removal pathway, chylomicrons are nearly always present when triglyceride levels exceed 1000 mg/dL (11.5 mmol/L).

**Case 3: Cholesterol and Triglyceride Levels Both Elevated**

This pattern can be the result of either of two abnormal phenotypes. One is a combined increase of VLDL and LDL. This pattern is termed combined hyperlipidemia and is one of the three phenotypic patterns encountered in kindreds with the disorder FCH. The second phenotype is an increase of remnant lipoproteins derived from VLDL and chylomicrons. These particles have been partially depleted of triglyceride by LPL and enriched with cholesteryl esters by the LCAT system, such that the total content of cholesterol in serum is similar to that of triglycerides. This pattern is almost always an expression of familial dysbetalipoproteinemia. Diagnosis of this disorder is confirmed by a genotype demonstrating absence of the normal E-3 and E-4 alleles.

**CLINICAL DESCRIPTIONS OF PRIMARY AND SECONDARY DISORDERS OF LIPOPROTEIN METABOLISM**

**The Hypertriglyceridemias**

**Atherogenicity**

Epidemiologic evidence supports the atherogenicity of VLDL and their remnants. They have been demonstrated in atherosclerotic plaques from humans. Impaired capacity of the VLDL of some individuals to accept cholesteryl esters from the LCAT reaction may also contribute to atherogenesis by impeding centripetal transport of cholesterol.

**Cause of Pancreatitis**

Very high levels of triglycerides in plasma are associated with a risk of acute pancreatitis, probably from the local release of FFA and lyssolecithin from lipoprotein substrates in the pancreatic capillary bed. When the concentrations of these lipids exceed the binding capacity of albumin, they could lyse membranes of parenchymal cells, initiating a chemical pancreatitis. Many patients with lipemia have intermittent episodes of epigastric pain during which serum amylase does not reach levels commonly considered diagnostic for pancreatitis. This is especially true in patients who have had previous attacks. The observation that these episodes frequently evolve into classic pancreatitis suggests that they represent incipient pancreatic inflammation. The progression of pancreatitis can be prevented by rapid reduction of triglycerides, usually accomplished by restriction of all dietary fat. In some cases, parenteral feeding, excluding fat emulsions, may be required for a few days. The clinical course of pancreatitis in patients with lipemia is typical of the general experience with this disease.

**Clinical Signs (Figure 19–3)**

When triglyceride levels in serum exceed 3000 to 4000 mg/dL (34.5-46 mmol/L), light scattering by these particles in the blood lends a whitish cast to the venous vascular bed of the retina, a sign known as lipemia retinalis. Markedly elevated levels of VLDL or
chyomicrons may be associated with the appearance of eruptive cutaneous xanthomas (see Figure 19–3E). These lesions, filled with foam cells, appear as yellow morbilliform eruptions 2 to 5 mm in diameter, often with erythematous areolae. They usually occur in clusters on extensor surfaces such as the elbows, knees, and buttocks. They are transient and disappear within a few weeks after triglyceride levels are reduced.

Effects of Hypertriglyceridemia on Laboratory Measurements

Light scattering from high levels of triglyceride-rich lipoproteins can cause erroneous results in most chemical determinations involving photometric measurements. Amylase activity in serum may be inhibited; therefore, lipemic specimens should be diluted.
for measurement of this enzyme. Because the lipoproteins are not permeable to ionic or polar molecules, their core regions constitute a second phase in plasma. When the volume of this phase becomes appreciable, electrolytes and other hydrophilic species are underestimated with respect to their true concentration in the aqueous phase. A practical rule for correcting these values is as follows: For each 1000 mg/dL (11.5 mmol/L) of triglyceride, the measured concentrations of all hydrophilic molecules and ions should be adjusted upward by 1%.

**PRIMARY HYPERTRIGLYCERIDEMIA**

1. **DEFICIENCY OF LIPOPROTEIN LIPASE ACTIVITY**

**Clinical Findings**

**A. Symptoms and signs**  The activity of LPL is dependent upon the integrity of the enzyme and its cofactor, Apo C-II. In addition, defects in Apo A-V, GPIHDLBP, and LMF1 proteins can result in severe impairment of LPL activity. The LMF1 protein is essential for the secretion of both LPL and hepatic lipase in their active conformations. Because the clinical expressions of these defects are similar, they are considered together. On a typical North American diet, lipemia is usually severe (triglycerides of 2000-25,000 mg/dL) (23-287.5 mmol/L). Hepatomegaly and splenomegaly are frequently present. Foam cells laden with lipid are found in liver, spleen, and bone marrow. Splenic infarct has been described and may be a source of abdominal pain. Hypersplenism with anemia, granulocytopenia, and thrombocytopenia can occur. Recurrent epigastric pain and overt pancreatitis are frequently encountered. Eruptive xanthomas may be present. These disorders may be recognized in early infancy or may go unnoticed until an attack of acute pancreatitis occurs or lipemic serum is noted on blood sampling as late as middle age. Patients with these disorders are usually not obese and have normal carbohydrate metabolism unless pancreatitis impairs insulinogenic capacity. Estrogens intensify the lipemia by stimulating hepatic production of VLDL. Therefore, in pregnancy and lactation or during the administration of estrogenic steroids, the risk of pancreatitis increases.

**B. Laboratory findings**  There is a preponderance of chylomicrons in serum such that the infranatant layer of serum refrigerated overnight may be nearly clear with a supernatant chylomicron layer. Many patients have a moderate increase in VLDL, however, and in pregnant women or those receiving estrogens, a pattern of mixed lipemia may be present. Levels of LDL in serum are decreased, probably representing the predominant catabolism of VLDL by pathways that do not involve the production of LDL. Levels of HDL cholesterol are also decreased.

A presumptive diagnosis of these disorders can be made by restricting oral intake of fat to 10 to 15 g/d. Triglycerides drop precipitously, usually reaching 200 to 600 mg/dL (2.3-6.9 mmol/L) within 3 to 4 days. Confirmation of deficiency of LPL is obtained by measurement of the lipolytic activity of plasma 10 minutes after injection of heparin (0.2 mg/kg) intravenously. Analysis of lipolysis is done with and without 0.5 mol/L sodium chloride, which inhibits LPL but does not suppress the activity of hepatic lipase. Absence of the Apo C-II cofactor can be demonstrated most readily by electrophoresis or isoelectric focusing of the proteins of VLDL.

**Treatment**

Treatment of primary chylomicronemia is entirely dietary. Intake of fat should be reduced to 10% or less of total calories. In an adult, this represents 15 to 30 g/d. Because the defect involves lipolysis, both saturated and unsaturated fats must be curtailed. The diet should contain at least 5 g of polyunsaturated fat as a source of essential fatty acids, and fat-soluble vitamins must be provided. Administration of 500 mg daily of marine omega-3 fatty acids is also recommended. Adherence to this diet invariably maintains triglycerides below 1000 mg/dL (11.2 mmol/L) in the absence of pregnancy, lactation, or the administration of exogenous estrogens. Because this is below the level at which pancreatitis usually occurs, compliant patients are at low risk. Pregnant women with these disorders require particularly close monitoring.

2. **ENDOGENOUS AND MIXED LIPEMIAS**

**Etiology and Pathogenesis**

Endogenous lipemia (elevated VLDL) and mixed lipemia probably both result from several genetically determined disorders. Because VLDL and chylomicrons are competing substrates in the intravascular lipolytic pathway, saturating levels of VLDL impede the removal of chylomicrons. Therefore, as the severity of endogenous lipemia increases, a pattern of mixed lipemia may supervene. In other cases, the pattern of mixed lipemia appears to be present continuously. Although specific pathophysiologic mechanisms remain obscure, certain familial patterns are known. In all forms, factors that increase the rate of secretion of VLDL aggravate the hypertriglyceridemia (ie, obesity with insulin resistance, appearance of fully developed type 2 diabetes mellitus, alcohol, and exogenous estrogens). Studies of VLDL turnover indicate that either increased production or impaired removal of VLDL may be operative in different individuals. A substantial number of patients with mixed lipemia have partial defects in catabolism of triglyceride-rich lipoproteins, often due to heterozygosity for mutations in LPL. Most patients with significant endogenous or mixed lipemia have centripetal obesity.

**Clinical Findings**

Clinical features of these forms of hypertriglyceridemia depend on their severity and include eruptive xanthomas, lipemia retinalis, recurrent epigastric pain, and acute pancreatitis.

Endogenous lipemia is frequently an element in a constellation of metabolic abnormalities termed the metabolic syndrome. Insulin resistance, usually associated with central obesity, is a core...
The first element of treatment is severe restriction of total fat intake. The objective of long-term dietary management is reduction to ideal body weight. Because alcohol causes significant augmentation of VLDL production, abstinence is important. If weight loss is achieved, the triglycerides almost always show a marked response, often approaching normal values. When the fall in triglycerides is not satisfactory, a fibrate or nicotinic acid (in the absence of insulin resistance), singly or in combination, usually produces further reductions. When insulin resistance is present, metformin—with or without a thiazolidinedione—may be a useful adjunct. Pioglitazone is the drug of choice in this class because it is more effective in reducing triglycerides and, unlike rosiglitazone, it does not increase LDL cholesterol.

3. FAMILIAL COMBINED HYPERLIPIDEMIA

Etiology
This inherited disorder, which is the most common form of hyperlipidemia, occurs in 1% to 2% of the population. The underlying process involves overproduction of VLDL. Some affected individuals have increased levels of both VLDL and LDL (combined hyperlipidemia); some have predominantly increased levels of either VLDL or LDL. The level of Apo B-100 is increased. Patterns in the serum of an individual may change with time. It is known that the offspring of an individual having any one of the three phenotypic patterns and a normal individual can have one of the other patterns. Affected children often have hyperlipidemia. If the child is obese, hypertriglyceridemia is likely present, whereas a child of normal weight may have only an elevated LDL.

Clinical Findings
Neither tendinous nor cutaneous xanthomas other than xanthelasma occur. This disorder appears to be inherited as a Mendelian dominant trait involving alternative loci. Modifying genes have been published but major loci have not been identified. Factors that increase the severity of hypertriglyceridemia in other disorders aggravate the lipemia in this syndrome as well.

Treatment
The risk of coronary disease is significantly increased, and patients should be treated aggressively with diet and drugs. Because LDL levels often increase with fibrates in these patients and because resins increase triglycerides, the recommended treatment is an HMG-CoA reductase inhibitor. The addition of niacin or fenofibrate may be required if triglycerides remain elevated or if HDL deficiency is also present. Fenofibrate may be used cautiously with rosuvastatin.

4. FAMILIAL DYSBETALIPOPROTEINEMIA

(TYPE III HYPERLIPOPROTEINEMIA)

Etiology and Pathogenesis
A permissive genetic constitution for this disease (homozygosity for Apo E-2) occurs in about 2% of the US population but the expression of hyperlipidemia apparently requires environmental and possibly additional genetic determinants. The molecular basis is the presence of isoforms of Apo E that are poor ligands for high-affinity receptors. In its fully expressed form, the lipoprotein pattern is dominated by the accumulation of remnants of VLDL and chylomicrons. Two populations of VLDL are usually present: normal prebeta lipoproteins and remnants with beta-electrophoretic mobility. Remnant particles of intermediate density are also present. Levels of LDL are decreased, reflecting interruption of the transformation of VLDL remnants to LDL. The primary defect is impaired hepatic uptake of remnants of triglyceride-rich lipoproteins. The remnant particles are enriched in cholesterol esters such that the level of cholesterol in serum is often as high as that of triglycerides. Absence of the E-3 and E-4 alleles in genomic DNA confirms the diagnosis. Additional mutations of Apo E are now known to result in dysbetalipoproteinemia. Some of these cause hyperlipidemia in the heterozygous state, a disorder termed dominant dysbetalipoproteinemia.

Clinical Findings
Hyperlipidemia and clinical signs are not usually evident before age 20. In younger patients with hyperlipidemia, hypothyroidism or obesity is likely to be present. Adults frequently have tuberous or tubereroeruptive xanthomas (Figure 19-3C). Both tend to occur on extensor surfaces, especially elbows and knees. Tuberoeruptive xanthomas are pink or yellowish skin nodules 3 to 8 mm in diameter that often become confluent. Tuberous xanthomas—shiny reddish or orange nodules up to 3 cm or more in diameter—are usually moveable and nontender. Another type, planar xanthomas of the palmar creases, strongly suggests dysbetalipoproteinemia. The skin creases assume an orange color from deposition of carotenoids. They occasionally are raised above the level of adjacent skin and are not tender. (Planar xanthomas are also seen in cholestasis.) Some patients have impaired glucose tolerance, which is usually associated with higher levels of blood lipids. Obesity is commonly present and tends to aggravate the lipemia. Patients with the genetic constitution for dysbetalipoproteinemia often develop severe hyperlipidemia if they are hypothyroid. Atherosclerosis of the coronary and peripheral vessels occurs with increased frequency, and the prevalence of disease of the iliac and femoral vessels is especially high.

Treatment
Management includes a weight reduction diet providing a reduced intake of cholesterol, fat, and alcohol. When the hyperlipidemia does not respond satisfactorily to diet, a fibrate or niacin in low doses (if the patient does not have insulin resistance) is usually
effective. These agents can be used together in resistant cases. Some patients respond to the more potent reductase inhibitors alone, and the addition of niacin normalizes the lipid levels in most.

SECONDARY HYPERTRIGLYCERIDEMIA

1. DIABETES MELLITUS
In patients with diabetes, levels of VLDL in plasma are frequently elevated. The severe lipemia associated with absence or marked insufficiency of insulin is attributable to decreased transcription of the LPL gene. The administration of insulin usually restores triglyceride levels to normal within a few days. However, if massive fatty liver is present, weeks may be required for the VLDL to return to normal while the liver secretes its triglycerides. Conversion of massive amounts of VLDL to LDL as the impedance of VLDL catabolism is relieved leads to marked accumulation of LDL that may persist for weeks, leading to a spurious diagnosis of primary hypercholesterolemia.

The moderately elevated VLDL seen in type 2 diabetes under average control probably reflects chiefly an increased flux of FFA to liver that stimulates production of triglycerides and their secretion in VLDL. In addition to VLDL, LDL levels are also somewhat increased in diabetic individuals under poor control, probably accounting in part for their increased risk of CHD. Some have much higher levels of VLDL, suggesting that an additional genetic factor predisposing to lipemia is present. Still another cause of lipemic diabetes is the compromised insulinogenic capacity that can result from acute pancreatitis. The deficiency may be severe enough to require exogenous insulin, often only in small doses. In diabetic individuals who develop nephrosis, the secondary lipemia of nephrosis compounds their hypertriglyceridemia. In hyperglycemia, lipoproteins become glycosylated, leading to their uptake by macrophages.

Lipemia may be very severe, with elevated levels of both VLDL and chyomicrons when control is poor. Lipemic patients usually have ketoacidosis when they are insulin-deficient, but lipemia can occur in its absence. Patients with type 1 diabetes who have been chronically undertreated with insulin may have mobilized most of the triglyceride from peripheral adipose tissue, so that they no longer have sufficient substrate for significant ketogenesis. These emaciated individuals may have severe lipemia and striking hepatomegaly.

In type 1 diabetes, the rigid control of blood glucose levels, which can be attained with continuous subcutaneous insulin infusion, is associated with sustained normalization of levels of both LDL and VLDL. The lipemia of type 2 diabetes usually responds well to control of the underlying disorder. In obese insulin-resistant individuals, weight loss is essential. Diets containing slowly absorbed carbohydrates are well tolerated, allowing a decrease in the burden of chyomicron triglycerides in plasma (see Chapter 17).

2. UREMIA
Uremia is associated with modest isolated increases in VLDL. The most important underlying mechanisms are probably insulin resistance and impairment of catabolism of VLDL. Many uremic patients are also nephrotic. The additional effects of nephrosis on lipoprotein metabolism may produce a combined hyperlipidemia. Patients who have had renal transplants may be receiving glucocorticoids, which induce elevation of LDL.

3. HUMAN IMMUNODEFICIENCY VIRUS INFECTION
HIV infection per se is associated with hypertriglyceridemia (see Chapter 25). A syndrome of partial lipodystrophy and insulin resistance, often with marked lipemia, occurs with multidrug treatment that includes certain inhibitors of viral proteases. Acute pancreatitis can ensue. Limited clinical experience suggests that fibric acid derivatives are of some value. Alcohol must be avoided.

4. CORTICOSTEROID EXCESS
In endogenous Cushing syndrome, and with corticosteroid treatment, insulin resistance is present and levels of LDL are increased. It appears that the hyperlipidemia is primarily due to increased secretion of VLDL, which is then catabolized to LDL. More severe lipemia ensues when steroidogenic diabetes appears, reducing catabolism of triglyceride-rich lipoproteins via the LPL pathway.

5. EXOGENOUS ESTROGENS
When estrogens are administered to normal women, triglyceride levels may increase by as much as 15%, reflecting increased production of VLDL. Paradoxically, estrogens increase the efficiency of catabolism of triglyceride-rich lipoproteins. Whereas estrogens tend to induce insulin resistance, it is not clear that this is an important mechanism, because certain nortestosterone derivatives decrease plasma triglycerides despite the induction of appreciable insulin resistance.

Certain individuals, usually those with preexisting mild lipemia, develop marked hypertriglyceridemia when receiving estrogens even in relatively small doses. Thus, triglycerides should be monitored during estrogen therapy. Contraceptive combinations with predominantly gestational effects produce less hypertriglyceridemia than purely estrogenic compounds. Transdermal delivery of estrogen probably results in lesser increases in VLDL secretion because it avoids the hepatic first-pass effect.

6. ALCOHOL INGESTION
Ingestion of appreciable amounts of alcohol does not necessarily result in significantly elevated levels of triglycerides, but many alcoholics are lipemic. Alcohol profoundly increases triglycerides in patients with primary or secondary hyperlipemias. In Zieve syndrome, the alcohol-induced lipemia is associated with hemo­lytic anemia and hyperbilirubinemia. Because LCAT originates in liver, severe hepatic parenchymal dysfunction may lead to deficiency in the activity of this enzyme. A resultant accumulation of unesterified cholesterol in erythrocyte membranes may account for the hemolysis seen in Zieve syndrome.
Alcohol is converted to acetate, exerting a sparing effect on the oxidation of fatty acids that are then incorporated into triglycerides. This results in hepatomegaly due to fatty infiltration and in marked enhancement of secretion of VLDL. In many individuals, there is sufficient adaptive increase in the removal capacity for triglycerides so that plasma levels are normal.

7. NONALCOHOLIC FATTY LIVER DISEASE AND NONALCOHOLIC STEATOHEPATITIS

These conditions are characterized by hepatic steatosis and abnormalities of liver enzymes in the absence of alcohol ingestion. The cause is not yet understood, but it is likely that misdirection of fatty acids from oxidative pathways to hepatic triglyceride synthesis is involved. Five to ten percent of patients with nonalcoholic fatty liver disease (NAFLD) progress to more severe liver disease, including cirrhosis, end-stage liver disease, and hepatocellular carcinoma. In NAFLD, spontaneous improvement can occur, but liver disease is the third most common cause of death. About 80% of patients with NAFLD or nonalcoholic steatohepatitis (NASH) have features of the metabolic syndrome, including abdominal obesity, hypertension, insulin resistance/glucose intolerance, and hypertriglyceridemia. They are at increased risk for atherosclerosis. Weight reduction with exercise and diet in overweight or obese patients is a central element of treatment. Bariatric surgery has proven effective in a large percentage of morbidly obese patients with NASH. Studies to date reveal only marginal benefit attributable to metformin and thiazolidinediones, although pioglitazone shows some promise. Treatment of coexisting dyslipidemia, diabetes, and hypertension is important. Statins, fenofibrate, and marine omega-3 fatty acids do not appear to increase the risk of further hepatic injury in most patients. Mixed tocopherols are beneficial.

8. NEPHROSIS

The hyperlipidemia of nephrosis is biphasic. Before serum albumin levels fall below 2 g/dL, LDL increases selectively. The synthesis and secretion of VLDL appear to be coupled to that of albumin. The increased flux of VLDL from liver increases production of LDL. As albumin falls below 1 to 2 g/dL, lipemia ensues. Impaired hydrolysis of triglycerides by LPL is due to lack of albumin as an FFA receptor. FFA bind to lipoproteins when albumin levels are low, impairing their ability to undergo lipolysis.

Because coronary disease is prevalent in patients with long-standing nephrotic syndrome, treatment of the hyperlipidemia is indicated, although few studies of the effect of treatment have been reported. The hyperlipidemia is resistant to diet. Fibrates may precipitate myopathy even in small doses. Bile acid–binding resins, niacin, and reductase inhibitors are useful.

9. GLYCOGEN STORAGE DISEASE

In type I glycogenosis, insulin secretion is decreased, leading to increased flux of FFA to liver and increased secretion of VLDL. The low levels of insulin in plasma are the probable cause of reduced activity of LPL. The fatty liver in these patients tends to progress to cirrhosis.

Frequent small feedings help maintain blood glucose levels and ameliorate the lipemia. Nocturnal nasogastric drip feeding is of considerable benefit. Other forms of hepatic glycogen storage disease may be associated with elevated levels of VLDL and LDL in serum.

10. HYPOPIITUITARISM AND ACROMEGALY

Part of the hyperlipidemia of hypopituitarism is attributable to secondary hypothyroidism, but hypertriglyceridemia persists after thyroxine replacement. Deficiency of growth hormone is associated with elevated levels of both LDL and VLDL. Decreased insulin levels may be the major underlying defect; however, deficiency of growth hormone may impair the disposal of FFA by oxidation and ketogenesis in the liver, favoring synthesis of triglycerides. Mild hypertriglyceridemia is often associated with acromegaly, probably resulting from insulin resistance. Although growth hormone acutely stimulates lipolysis in adipose tissue, FFA levels are normal in acromegaly.

11. HYPOTHYROIDISM

Whereas significant hypothyroidism produces elevated levels of LDL in nearly all individuals, only a few develop hypertriglyceridemia. The increase in LDL results in part from decreased conversion of cholesterol to bile acids and downregulation of LDL receptors. Lipemia, when present, is usually mild, although serum triglycerides in excess of 3000 mg/dL (34.5 mmol/L) can occur in myxedema reflecting decreased activity of hepatic lipase. Increased content of cholesteryl esters and Apo E in the triglyceride-rich lipoproteins suggests accumulation of remnant particles. Hypothyroidism often causes expression of hyperlipidemia in individuals with dysbeta lipoproteinemia.

12. IMMUNOGLOBULIN-LIPOPROTEIN COMPLEX DISORDERS

Both polyclonal and monoclonal hypergammaglobulinemias may cause hypertriglyceridemia. IgG, IgM, and IgA have each been involved. Monoclonal antibodies associated with myeloma, macroglobulinemia, lymphomas, and lymphocytic leukemias have been implicated. Lupus erythematosus and other autoimmune disorders have been associated with the polyclonal type. Binding of heparin by immunoglobulin, with resulting inhibition of LPL, can cause severe mixed lipemia. More commonly, the triglyceride-rich lipoproteins have an abnormally high density, probably as a result of bound immunoglobulin, although some may be remnant-like particles. These complexes usually have gamma mobility on electrophoresis.

Xanthomatosis associated with immunoglobulin complex disease includes tuberous and eruptive xanthomas, xanthelasmas, and planar xanthomas of large areas of skin. The latter are otherwise seen only in patients with cholestasis. Deposits of lipid-rich
hyaline material can occur in the lamina propria of the intestine, causing malabsorption and protein-losing enteropathy. Circulating immunoglobulin-lipoprotein complexes can fix complement, leading to hypocomplementemia. In such patients, administration of whole blood or plasma can cause anaphylaxis. Hence, washed red cells or albumin are recommended when blood volume replacement is required.

Treatment is directed at the underlying disorder. The critical temperature of cryoprecipitation of some of these complexes is close to body temperature. Therefore, if plasmapheresis is indicated to remove offending immunoglobulins, it should be done at a temperature above the critical temperature measured in serum.

**THE PRIMARY HYPERCHOLESTEROLEMIAS**

**FAMILIAL HYPERCHOLESTEROLEMIA**

**Etiology and Pathogenesis**

Familial hypercholesterolemia (FH), which in its heterozygous form occurs in approximately 1 in 500 individuals, is a codominant trait with high penetrance. Because half of first-degree relatives are affected, all members of a family should be screened. A selective increase in LDL exists from birth and tends to increase during childhood and adolescence such that cholesterol in adult heterozygotes usually varies from about 260 to 400 mg/dL (6.7-10.4 mmol/L). Some individuals—especially those in kindreds in which hypertriglyceridemia is present—may have higher than normal levels of VLDL and IDL. In a few patients with FH, the expression is blunted by independent genetic determinants.

The underlying defect is a deficiency of normal LDL receptors on cell membranes. A number of genetic defects affecting the structure, translation, modification, or transport of the receptor protein have been identified.

Some individuals have combined heterozygosity. In cases in which a kinetic mutant is combined with an ablative mutant, the hypercholesterolemia is greater than that seen in simple heterozygosity, usually in the range of 500 to 800 mg/dL (13-20.8 mmol/L). Those patients who are homozygous for null alleles have extremely severe hypercholesterolemia (approaching 1000 mg/dL [26 mmol/L] or greater) and fulminant atherosclerosis.

Production rates for LDL are moderately increased in heterozygotes and are higher in homozygotes because of increased conversion of VLDL to LDL. In the heterozygote, a greater fraction of LDL is removed by nonreceptor-dependent mechanisms than in normal subjects. In homozygotes, all removal of LDL proceeds through such pathways.

**Clinical Findings**

Tendon xanthomas are frequently present, causing a broadening or fusiform mass in the tendon. They can occur in almost any tendon but are most readily detected in the Achilles and patellar tendons and in the extensor tendons of the hands (Figure 19–3F, 19–3G, and 19–3H). Patients who are physically active may complain of achillodynia. Arcus corneae (Figure 19–3B) may occur as early as the third decade. Xanthelasmas (Figure 19–3A) may also be present. Both arcus and xanthelasmas are seen in some individuals who do not have hyperlipidemia, however. Coronary atherosclerosis tends to occur prematurely in heterozygotes. It is particularly prominent in individuals who are relatively deficient in HDL. It is probable that this represents a coincident inheritance of both traits. Homozygous FH is catastrophic. Xanthomatosis progresses rapidly. Patients may have tuberous xanthomas (Figure 19–3C and 19–3D) and elevated plaque-like xanthomas of the extremities, buttocks, interdigital webs, and aortic valves. Coronary disease may be evident in the first decade of life.

Serum cholesterol in excess of 300 mg/dL (7.8 mmol/L) in the absence of significant hypertriglyceridemia and conditions known to cause secondary hypercholesterolemia makes the diagnosis of heterozygous FH likely. The presence of affected first-degree relatives is supportive of this diagnosis, especially if no other phenotypes of hyperlipidemia are present in the family that would suggest FCH. The finding of tendon xanthomas is nearly pathognomonic—beta-sitosterolemia, cerebrotendinous xanthomatosis (cholestanolosis), ligand-defective Apo B, and autosomal recessive hypercholesterolemia (ARH) are exceptions. Although the cholesterol content of umbilical cord blood is usually elevated, the diagnosis is most easily established by measuring serum cholesterol after the first year of life.

**Treatment**

Treatment of heterozygotes with HMG-CoA reductase inhibitors may normalize LDL levels. However, achieving optimal levels may require one of the binary or ternary combinations involving reductase inhibitors, niacin, bile acid sequestrants, or ezetimibe. Levels of LDL cholesterol less than 100 mg/dL (2.6 mmol/L) can be obtained with combinations of these drugs in most patients. Treatment of homozygotes is extremely difficult. Partial control may be achieved with LDL apheresis in conjunction with niacin, ezetimibe, and a potent statin. Striking reduction of LDL levels is observed after liver transplantation, illustrating the important role of hepatic receptors in LDL clearance.

**FAMILIAL COMBINED HYPERLIPIDEMIA**

In some individuals in kindreds with FCH (see "Primary Hypertriglyceridemia," earlier), LDL and IDL are the only lipoproteins that are elevated. This pattern may vary in an individual over time. Predominant elevation of VLDL or combined elevations of LDL and VLDL may be observed in the patient or the patient’s relatives. Some affected children express hyperlipidemia. In contrast to most cases of FH, the cholesterol level may be as low as 250 mg/dL (6.5 mmol/L) and xanthomas are absent in FCH. Studies of kindreds with the FCH phenotype suggest codominant transmission. Coronary atherosclerosis is accelerated, accounting for about 15% of all coronary events in the United States. The underlying mechanism involves increased secretion of VLDL.
Treatments of the hypercholesterolemia should begin with diet and either niacin or a reductase inhibitor. It may be necessary to use a combination of these agents, or fenofibrate with a statin, to normalize levels of LDL and triglyceride.

**Lp(a) HYPERLIPOPROTEINEMIA**

Lp(a) normally comprises a very minor fraction of circulating lipoproteins, but it may be present in high concentrations in some individuals. It contains Apo B-100 and the (a) protein, a homolog of plasminogen that can inhibit fibrinolysis. It has been demonstrated in atherosclerotic plaques, and several large studies imply that either niacin or a reductase inhibitor. It may be necessary to normalize levels of LDL and triglyceride.

**FAMILIAL LIGAND-DEFECTIVE Apo B-100**

Mutations involving the ligand domain in Apo B-100 impair the ability of LDL to bind to its receptor. Two prevalent mutations at codon 3500 or 3531 occur in about one in 500 individuals and may be found in compound states with familial hypercholesterolemia. The hypercholesterolemia with ligand defects alone is generally less severe than in FH because the removal of VLDL remnants is normal, resulting in a lower production of LDL. Patients may have tendon xanthomas and are at increased risk of coronary disease. Response to reductase inhibitors varies, but many show some resistance because upregulation of receptors cannot correct the defect completely although it can decrease LDL production because LDL particles are endocytosed by liver via interaction of the LDL receptor with Apo E.

**CHOLESTEROL 7α-HYROXYLASE DEFICIENCY**

Loss of function mutations in cholesterol 7α-hydroxylase result in diminished catabolism of cholesterol to bile acids and accumulation of cholesterol in hepatocytes. Downregulation of LDL receptors causes elevated LDL in plasma. VLDL may also be increased. Homozygous patients have early coronary disease and marked resistance to reductase inhibitors as single agents and may have premature cholesterol gallstone disease. Heterozygous patients have moderately elevated LDL. The hyperlipidemia responds well to niacin with a reductase inhibitor.

**SECONDARY HYPERCHOLESTEROLEMIA**

**HYPOTHYROIDISM**

In hypothyroidism, LDL and IDL are elevated. Some patients may have lipemia, as described in the section on secondary hyperlipemia. Hyperlipidemia may occur with no overt signs or symptoms of decreased thyroid function. Bilirubin excretion of cholesterol and bile acids is depressed. Cholesterol stores in tissues appear to be increased, although the number of LDL receptors on cells is decreased. Activity of hepatic lipase is markedly decreased, and atherogenesis is accelerated by myxedema. The hyperlipidemia responds dramatically to treatment with thyroxine.

**NEPHROSIS**

As described in the section on secondary hypertriglyceridemias, nephrosis produces a biphasic hyperlipoproteinemia. The earliest alteration of lipoproteins in nephrosis is elevation of LDL. Increased secretion of VLDL by liver is probably involved. Because the lipids of the lipoprotein surfaces are altered by enrichment with sphingomyelin, lysolecithin, and FFA, the catabolism of LDL could be impaired. Perhaps the low metabolic rate in affected patients introduces metabolic changes similar to those associated with hypothyroidism. The hyperlipidemia may be an important element in the markedly increased risk of atherosclerosis in these patients. The treatment of choice is a reductase inhibitor or bile acid–binding resin with niacin.

**IMMUNOGLOBULIN DISORDERS**

One of the lipoprotein abnormalities that can be associated with monoclonal gammapathy is elevation of LDL. A gamma lipoprotein that is a stable complex of immunoglobulin and lipoprotein may be observed on electrophoresis. Cryoprecipitation, often in the temperature range encountered in peripheral tissues when the environmental temperature is low, may occur. Patients may have symptoms from the vascular effect of complement fixation resulting from complex formation and may have hyperviscosity syndrome from the elevated immunoglobulins per se. Planar xanthomas may be present.

Treatment is directed at the underlying process. Plasmapheresis is often effective. If cryoprecipitation occurs at critical temperatures near or above room temperature, the procedure must be carried out in a special warm environment. Transfusion of whole blood or serum may be dangerous in these patients because of rapid production of anaphylatoxins from fresh complement in the serum, resulting from interaction with circulating antibody-antigen complexes. This risk can be minimized by the use of packed red blood cells and albumin in place of whole blood.

**ANOREXIA NERVOSA**

About 40% of patients with anorexia nervosa have elevated LDL, and levels of cholesterol may reach 400 to 600 mg/dL (10.4-15.6 mmol/L). The hyperlipidemia, which persists despite
The hyperlipidemia associated with obstruction of bilary flow is complex. Levels of cholesterol in these patients exceeding 400 mg/dL (10.4 mmol/L) usually are associated with extrahepatic obstruction or with intrahepatic tumor. Several types of abnormal lipoproteins are present. The most abundant, termed Lp-X, is a bilayer vesicle composed of unesterified cholesterol and lecithin, with associated apolipoproteins but no Apo B. Lp-X is apparent on electrophoresis as a band of zero to gamma mobility that shows metachromatic staining with Sudan black. It is these vesicular particles that cause the serum phospholipid and unesterified cholesterol content to be extremely high. Another abnormal species, called Lp-Y, contains appreciable amounts of triglycerides and Apo B. The LDL in cholestasis also contains an unusually large amount of triglycerides.

Patients may have planar xanthomas, especially at sites of minor trauma, and xanthomas of the palmar creases. Occasionally, eruptive xanthomas are present. Xanthomatus involvement of nerves may lead to symptoms of peripheral neuropathy, and the abnormal lipoproteins may be atherogenic. Whereas bilirubin levels are nearly normal in some patients with chronic cholestasis, all have elevated serum alkaline phosphatase activity.

Neuropathy or evidence of atherosclerosis is the chief indication for treatment of the hyperlipidemia. Bile acid–binding resins are of some value, whereas fibric acid derivatives may cause an increase in cholesterol. Plasmapheresis is the most effective treatment. Large doses of vitamin E are indicated to overcome severe impairment of absorption. Deficiency of other fat-soluble vitamins also occurs.

THE PRIMARY HYPOLIPIDEMIAS

Although the clinician is confronted less frequently by the problem of a striking deficiency in plasma lipids, it is important to recognize the primary and secondary hypolipidemias. A serum cholesterol less than 110 mg/dL (2.9 mmol/L) is noteworthy. Because levels of triglycerides in normal fasting serum may be as low as 25 mg/dL (0.29 mmol/L), significance is limited to cases in which they are virtually absent.

PRIMARY HYPOLIPIDEMIA DUE TO DEFICIENCY OF HIGH-DENSITY LIPOPROTEINS

1. TANGIER DISEASE

Etiology and Pathogenesis

Severe deficiency of HDL occurs in Tangier disease. Heterozygotes lack clinical signs but have about one-half or less of the normal complement of HDL and Apo A-I in plasma. Homozygotes lack normal HDL, and Apo A-I and Apo A-II are present at extremely low levels. Serum cholesterol is usually below 120 mg/dL (3.12 mmol/L) and may be half this value. Mild hypertriglyceridemia is usually present, and LDL is greatly enriched in triglycerides. Mutations in the ATP-dependent transporter ABCA1 underlie this disorder, causing defective efflux of cholesterol from peripheral cells.

Clinical Findings

The clinical features of this rare autosomal recessive disease include large, orange-colored, lipid-filled tonsils, accumulation of cholesteryl esters in the reticuloendothelial system, and an episodic and recurrent peripheral neuropathy with predominant motor weakness in the later stages. The course of the disease is benign in early childhood, but the neuropathy may appear as early as age 8 years. Cholesteryl ester accumulates most prominently in peripheral nerve sheaths. Carotenoid pigment may be apparent in pharyngeal and rectal mucous membranes. Splenomegaly and corneal infiltration may also be present. There is some increase in risk of coronary atherosclerosis.

Treatment

Because some of the lamellar lipoprotein material in plasma is believed to originate in chylomicrons, restriction of dietary fats and cholesterol is suggested.

2. FAMILIAL HYPOALPHALIPOPROTEINEMIA

Etiology and Pathogenesis

This phenotypic pattern is a partial deficiency of HDL that may involve heterogeneous mechanisms. These presumed constitutional disorders must be differentiated from the condition in which moderately low levels of HDL are seen in individuals consuming a diet very low in fat. White and Asian men on such diets usually have HDL cholesterol levels of 38 to 42 mg/dL (1-1.1 mmol/L) by ultracentrifugal analysis, in contrast to a median value of 49 mg/dL (1.3 mmol/L) when consuming a typical North American diet. Such levels are common in Asiatic populations and among vegetarians, where the risk of coronary disease is usually small. HDL cholesterol must also be interpreted in the light of the amount of triglyceride-rich lipoproteins in plasma. Because cholesteryl esters are progressively transferred to the cores of triglyceride-rich lipoproteins as triglyceride levels rise, HDL cholesterol decreases as an inverse function of the triglyceride level.

Etiologic Factor in Coronary Disease

Familial hypoalphalipoproteinemia is fairly common and is an important risk factor in atherosclerosis. This abnormality may be the only apparent risk factor in many cases of premature coronary or peripheral vascular disease and accelerates the appearance of coronary disease in patients with FH or other hyperlipidemias.
Hypoalphalipoproteinemia shows a strong familial incidence. Mutations in several genes have been associated, including Apo A-I (the principal protein of HDL), PCPE-2 (a protease involved in the maturation of Apo A-1), and the WW domain oxidoreductase (a transcriptional regulator involved in HDL metabolism). Although several mechanisms and modes of transmission may be involved, many kindreds show distributions consistent with autosomal dominance. HDL cholesterol levels are usually below 35 mg/dL (0.9 mmol/L).

**Treatment**

Increases in HDL cholesterol in several coronary intervention trials have been independently associated with plaque regression. Only limited means of raising HDL levels are at hand. Findings that HDL is composed of as many as 20 discrete species further complicate this problem. It is not yet known which of these species may be involved in protecting against atherosclerosis or whether their levels can be increased. Although alcohol ingestion may increase total HDL, it appears that the effect is primarily on the HDL₃ ultracentrifugal fraction, which correlates poorly with decreased risk. No recommendation for increased alcohol consumption should be made.

Heavy exercise is associated with increases in HDL in some individuals but must be approached with caution in patients who may have coronary disease. Niacin increases total HDL in many subjects, chiefly the HDL₂ ultracentrifugal fraction. Smaller increments in HDL occur with reductase inhibitors and fibrinoid derivatives.

The most important reason for measuring HDL cholesterol is to identify patients who are at increased risk. Thus, just as with patients who have premature vascular disease or a family history of early atherosclerosis, patients with low HDL should be treated more aggressively for elevated levels of the atherogenic lipoproteins. Furthermore, vigorous efforts should be directed at the control of other risk factors such as hypertension. Smoking and obesity are known to decrease HDL significantly.

**3. DEFICIENCY OF LECITHIN-CHOLESTEROL ACYLTRANSFERASE**

This rare autosomal recessive disorder is not expressed in clinical or biochemical form in the heterozygote. In the homozygote, clinical characteristics are variable. The diagnosis is usually made in adults, although corneal opacities may begin in childhood. Proteinuria may be an early sign. Deposits of unesterified cholesterol and phospholipid in the renal microvasculature lead to progressive loss of nephrons and ultimate renal failure. Many patients have mild to moderate normochromic anemia with target cells. Hyperbilirubinemia or peripheral neuropathy may be present. Red blood cell lipid composition is abnormal, with increased content of unesterified cholesterol and lecithin. Most have elevated plasma triglycerides (200-1000 mg/dL [2.3-11.2 mmol/L]), and levels of serum cholesterol vary from low normal to about 500 mg/dL (13 mmol/L), only a small fraction of which is esterified. The large triglyceride-containing lipoproteins are unusually rich in unesterified cholesterol and appear to have abnormal surface monolayers. LDL are rich in triglycerides, and abnormal vesicular lipoproteins are present in the LDL density interval. Two abnormal HDL species are present: bilayer disks and small spherical particles. Marked restriction of dietary fat and cholesterol delays the onset of renal disease.

**PRIMARY HYPOLIPIDEMIA DUE TO DEFICIENCY OF Apo B–CONTAINING LIPOPROTEINS**

**1. RECESSIVE ABETALIPOPROTEINEMIA**

**Etiology and Pathogenesis**

This disorder could represent a number of mutations involving the processing of Apo B or the secretion of Apo B–containing lipoproteins. The predominant cause is mutations involving the microsomal triglyceride transfer protein. Patients heterozygous for mutations have no abnormalities of lipoproteins or clinical signs. In homozygotes, all forms of Apo B are essentially absent. No chylomicrons, VLDL, or LDL are found in plasma, leaving only HDL. Plasma triglycerides are usually less than 10 mg/dL (0.12 mmol/L) and fail to rise after a fat load. Total cholesterol is usually less than 90 mg/dL (2.3 mmol/L). There is a defect in the incorporation of newly synthesized triglycerides into chylomicrons. However, at low levels of fat intake, about 80% of the ingested triglycerides are absorbed, probably by direct absorption of fatty acids via the portal vein.

**Clinical Findings**

Clinical features include a paucity of adipose tissue associated with malabsorption of long-chain fatty acids due to failure of the intestine to secrete chylomicrons. Red blood cells may be acanthocytic, with a high cholesterol-phospholipid ratio. There may be progressive degeneration of the central nervous system, including cerebellar degeneration and posterior and lateral spinal tract disease. Retinal degeneration may be severe. Levels of fat-soluble vitamins in plasma may be very low. The neurologic and ophthalmologic defects are due to deficiency of vitamin E (normally transported largely in LDL). Patients are apparently normal at birth and develop steatorrhea with impaired growth in infancy. The neuromuscular disorder often appears in late childhood with ataxia, night blindness, decreased visual acuity, and nystagmus. Cardiomyopathy with arrhythmias has been reported and may be a cause of death.

**Treatment**

Treatment includes administration of fat-soluble vitamins and essential fatty acids. Very large doses of mixed tocopherols (vitamin E; 1000-10,000 IU/d) limit the progressive central nervous system degeneration. Although vitamin A seems to correct the night blindness, it does not alter the course of retinitis pigmentosa. Vitamins D and K may also be indicated. Restriction of dietary fat minimizes steatorrhea.
2. FAMILIAL HYPOBETALIPOPROTEINEMIA

This disorder is usually attributable to defects at the Apo B locus, resulting in decreased ability of intestinal epithelial cells to secrete chylomicrons. A selective inability of intestinal epithelial cells to secrete chylomicrons is often present at about half of normal levels. If a mutant allele resulting in the complete inactivation of Apo B synthesis is present in the homozygous state, the clinical and biochemical features may be indistinguishable from those of recessive abetalipoproteinemia, and treatment is the same as for that disorder. Very short truncations of Apo B-100 only allow the formation of abnormally dense, small LDL. Longer truncations permit the formation of larger lipoproteins, even including VLDL-like particles. Mutations in the ANGPTL3 gene can cause deficiency of LDL, HDL, and triglycerides.

Clinical features may be absent in patients who produce at least low levels of LDL-like particles. However, signs and symptoms of tocopherol deficiency may be present. Treatment with mixed tocopherols (800 IU/d) is recommended for all patients.

3. CHYLOMICRON RETENTION DISEASE

This disorder presents in the neonate and appears to be based on the selective inability of intestinal epithelial cells to secrete chylomicrons. Affected individuals have severe malabsorption of triglycerides with steatorrhea. Levels of LDL and VLDL are about half of normal, presumably secondary to malnutrition. Tocopherol levels may be very low and may be associated with neurologic abnormalities. Clinical symptoms diminish somewhat with time if the patient is managed with a low-fat diet and tocopherol supplementation.

SECONDARY HYPOLIPIDEMIA

Hypolipidemia may be secondary to a number of diseases characterized by chronic cachexia (eg, advanced cancer). Myeloproliferative disorders can lead to extremely low levels of LDL, probably owing to increased uptake related to rapid proliferation and membrane synthesis. A wide variety of conditions leading to intestinal malabsorption produce hypolipidemia. In these situations, levels of chylomicrons, VLDL, and LDL in serum are low but never absent. Because most of the lipoprotein mass of fasting serum is of hepatic origin, massive parenchymal liver failure (eg, in Reye syndrome) can cause severe hypolipidemia. A precipitous fall in lipoprotein levels during drug treatment of hyperlipidemia can signal hepatic toxicity. Secondary hypobetalipoproteinemia occurs in orotic aciduria.

The hypolipidemias associated with immunoglobulin disorders result from diverse mechanisms. Affected patients usually have myeloma or macroglobulinemia but may have lymphomas or lymphocytic leukemia. Any of the major classes of immunoglobulins may be involved. In many cases, the immunoglobulins are cryoprecipitants; thus, the diagnosis may be missed if blood is not drawn and serum prepared at 37°C and observed for cryoprecipitation. Immunoglobulin-lipoprotein complexes may precipitate in various tissues. When this occurs in the lamina propria of the intestine, a syndrome of malabsorption and protein-losing enteropathy may result. Monoclonal IgA in myeloma may precipitate with lipoproteins, causing xanthomas of the gingiva and cervix. Xanthomas in the skin are usually planar and may involve intracutaneous hemorrhage, producing a classic purple xanthoma. Planar xanthomas occurring in cholestasis may be confused with this condition because the abnormal lipoprotein of cholestasis (Lp-X), like the circulating lipoprotein complex of immunoglobulin and lipoprotein, has gamma mobility on electrophoresis.

OTHER DISORDERS OF LIPOPROTEIN METABOLISM

THE LIPODYSTROPHIES

Classification

Classification of the lipodystrophies is based on their familial or acquired origin and the regional or generalized nature of the fat loss. To date, mutations in eight gene loci have been associated with phenotypes of lipodystrophy. Insulin resistance is a common feature.

Familial generalized lipodystrophy (Seip-Berardinelli syndrome) is a rare recessive trait associated with mutations in the gene for seipin. It may be diagnosed at birth and is associated with macrosomia. Genital hypertrophy, hypertrichosis, acanthosis nigricans, hepatomegaly, insulin resistance, hypertriglyceridemia, and glucose intolerance are regularly observed.

Familial lipodystrophy of limbs and trunk (Köberling-Dunnigan syndrome) appears to be transmitted as a dominant trait associated with mutations in the lamin A gene. Because sequence anomalies in other regions of the gene are associated with muscular dystrophy, cardiac conduction defects, cardiomyopathy, or axonal neuropathies, overlapping phenotypes may occur. It affects women predominantly and is not evident until puberty. The face, neck, and upper trunk are usually spared. Growth is normal, but otherwise this syndrome shares features of the generalized form noted earlier. It is frequently associated with Stein-Leventhal syndrome and often progresses to fatal cirrhosis.

Acquired forms of lipodystrophy, generalized (Lawrence syndrome) and partial (Barraquer-Simmons syndrome), usually begin in childhood, affect females predominantly, and often follow an acute febrile illness. The generalized type commonly shares the features described earlier, invariably involving the trunk and extremities but sometimes sparing the face. A sclerosing panniculitis, as seen in Weber-Christian syndrome, may appear at the outset. The partial type usually begins in the face and then involves the neck, upper limbs, and trunk. In this disorder, reduced levels of C3 complement are frequently encountered. Most patients have proteinuria, and some develop overt vascular nephritis.

Associated Disorders

Because a number of patients with disorders resembling both familial and acquired types of lipodystrophy have tumors or other lesions of the hypothalamus, appropriate neurologic
evaluation should be obtained. Similarly, the physician should be alert to the association of HIV disease and collagen-vascular disorders, including scleroderma and dermatomyositis, with some cases of acquired lipodystrophy.

**RARE DISORDERS**

**Autosomal Recessive Hypercholesterolemia**

In autosomal recessive hypercholesterolemia (ARH), LDL levels are markedly elevated, resulting in total cholesterol levels between 400 and 700 mg/dL (10.4 and 18.1 mmol/L). It is attributed to mutations in the gene for the ARH protein that is involved in endocytosis of the LDL receptor. Very large xanthomas (tuberosous, tendinous, and planar) are frequently present. Arcus and xanthelasmas are also common. Statins and bile acid sequestrants appear to be effective.

**PCSK9 Variants**

The protease, PCSK9, plays a role in processing the LDL receptor. Gain of function mutations in this gene are associated with hypercholesterolemia, presumably due to reduction in the number of effective receptors. More commonly, loss of function mutations that result in longer residence time of the LDL receptor are associated with low levels of LDL cholesterol.

**Werner Syndrome, Progeria, Infantile Hypercalcemia, Sphingolipidoses, and Niemann-Pick Disease**

These disorders may be associated with hypercholesterolemia, but levels of triglycerides may be normal. Among the sphingolipidoses, HDL deficiency is typical of Gaucher disease, in which hypertriglyceridemia may also occur. Niemann-Pick disease is attributable in most cases to mutations in the NCP1 gene and may be associated with hypercholesterolemia or hypertriglyceridemia. However, a similar disorder results from mutations in the NCP2 locus. The NCP1 gene product is involved in the postlysosomal transport of lipids. The neurological manifestations of Niemann-Pick disease type C are mitigated by an inhibitor of glycosphingolipid synthesis, miglustat.

**Wolman Disease and Cholesteryl Ester Storage Disease**

These recessive lipid storage disorders involve the absence and partial deficiency, respectively, of lysosomal acid lipase, resulting in abnormal cholesteryl ester and triglyceride stores in liver, spleen, adrenals, small intestine, and bone marrow. Most patients have elevated levels of both LDL and VLDL. Wolman disease may be fatal in infancy but appears to respond to hematopoietic cell transplant. Cholesteryl ester storage disease responds at least partially to combined statin-ezetimibe therapy.

**Cerebrotendinous Xanthomatosis**

In this recessive disorder, impaired synthesis of bile acids due to mutations in the sterol 27-hydroxylase gene results in increased production of cholesterol and cholestanol that accumulate in tissues. Plasma levels of cholesterol and cholestanol are normal or elevated. Cataracts, tendonous xanthomas, progressive neurologic dysfunction, and premature coronary atherosclerosis are hallmarks of this disease. Its central nervous system effects include dementia, spasticity, and ataxia. Death usually ensues before age 50 from neurologic degeneration or coronary disease. Treatment with chenodeoxycholic acid appears useful. Resins must be avoided because they aggravate the underlying defect.

**Phytosterolemia**

Mutations in the cassette half transporters ABCG5 or ABCG8 underlie this disorder, which is characterized by normal or elevated plasma cholesterol levels; high concentrations of plant sterol in serum, adipose tissue, and skin; and prominent tendonous and tuberous xanthomas. Substantially larger fractions of phytosterols and cholesterol are absorbed from the intestine than in normal individuals. Serum cholesterol levels may be as high as 700 mg/dL (18.2 mmol/L), reflecting an increase in LDL that contain phytosterol esters in addition to cholesteryl esters. Diagnosis is established by quantitation of phytosterols in plasma by gas-liquid chromatography. Premature coronary disease is common, as is polyarthritis and leukocytoclastic vasculopathy. Treatment consists of a diet restricted in plant sterols and cholesteryl and the use of bile acid-binding resins, reductase inhibitors, and ezetimibe.

**Cholesteryl Ester Transfer Protein Deficiency**

Mutations have been identified that impair the function of CETP, resulting in the retention of cholesteryl esters in HDL. Total HDL cholesterol is increased by 30% to 50% in heterozygotes and by as much as 200 mg/dL in homozygotes. The risk of atherosclerosis may be moderately increased in homozygotes.

**TREATMENT OF HYPERLIPIDEMIA**

Initial therapy in all forms of hyperlipidemia is an appropriate diet. In most cases, a universal diet (see later) is indicated. In many subjects with lipemia or with mild hypercholesterolemia, compliance with diet is sufficient to control lipoprotein levels. Most patients with severe hypercholesterolemia or lipemia require drug therapy. Diet must be continued to achieve the full potential of the medications. LDL cholesterol and triglycerides should be below 70 mg/dL (1.8 mmol/L) and 130 mg/dL (1.5 mmol/L), respectively, in patients with known atherosclerosis. C-reactive protein, lipoprotein-associated phospholipase A2, and other emerging biomarkers are useful in predicting risk.
**Caution Regarding Drug Therapy**

Women of childbearing age should be advised of the potential risk of teratogenicity of statins and possibly other hypolipidemic agents. Treatment should be given only if pregnancy is being actively avoided. Nursing mothers should not be treated. Estrogen-containing contraceptives should be avoided or used with caution in patients with hypertriglyceridemia.

In children, hyperlipidemias other than FH and severe cases of the metabolic syndrome usually do not require medication before age 16 years. Factors in the decision to start drug treatment include: the child’s age and levels of lipoproteins; the severity and age at onset of symptomatic coronary disease in the child’s family; and the presence in the child of other risk factors, especially diabetes or compound dyslipidemias [including hypoalphalipoproteinemia, hyper-Lp(a)lipoproteinemia, FH, and FCH]. Dietary treatment is indicated for all children with hyperlipidemia and should be started after the second year. The exception is primary chylomicronemia, in which an appropriate diet should be instituted as soon as the disease is detected.

**DIETARY FACTORS IN THE MANAGEMENT OF LIPOPROTEIN DISORDERS**

**Restriction of Caloric Intake**

The secretion of VLDL by liver is greatly stimulated by caloric intake in excess of requirements for physical activity and basal metabolism. Therefore, the total caloric content of the diet is of greater importance than its specific composition in treating endogenous hyperlipemia. There is a positive correlation between serum levels of VLDL triglyceride and various measures of obesity, but many obese patients have normal serum lipids. On the other hand, most patients with hypertriglyceridemia—except those with lipoprotein lipase deficiency—are obese. As obese patients lose weight, VLDL stabilize at lower levels. There is a modest correlation of LDL levels with body weight in the general population.

**Restriction of Fat Intake**

In primary chylomicronemia, all types of fats must be restricted rigidly. In the acute management of mixed lipemia with impending pancreatitis, elimination of dietary fat leads to a rapid decrease in triglycerides.

The cholesterol-lowering effect of a significant reduction in total fat is well known. It has also been shown that a 10% to 15% fall in cholesterol is achieved when individuals who have been consuming a typical North American diet restrict their intake of saturated fats to 8% of total calories. Most saturated and trans fatty acids cause increased levels of LDL cholesterol by downregulating hepatic LDL receptors. Whereas polyunsaturated fatty acids do not have this effect, they may reduce levels of HDL and are potentially carcinogenic. Monounsaturated fatty acids increase HDL but do not increase LDL. Moderate use of monounsaturated fats such as olive oil, oleic acid–rich safflower oil, or canola oil is indicated.

**Marine Omega-3 Fatty Acids**

The omega-3 fatty acids are ligands for peroxisome proliferator–activated receptor alpha. Those found in fish oils have special properties relevant to the treatment of hypertriglyceridemia and may protect against fatal arrhythmias in ischemic myocardium. Substantial decreases in triglyceride levels can be induced in some patients with severe endogenous or mixed lipemia at doses of 3 to 4 g/d of eicosapentaenoic (EPA) and docosahexaenoic (DHA) acids, combined. This should be given in divided doses with meals. EPA and DHA are potent inhibitors of platelet reactivity.

**Reduction of Cholesterol Intake**

The amount of cholesterol in the diet affects serum cholesterol levels, but individual responses vary. Restriction of dietary cholesterol to less than 200 mg/d (5.2 mmol/d) in normal individuals can result in a decrease of up to 10% to 15% in serum cholesterol, primarily reflecting a decrease in LDL. Dietary cholesterol and saturated or trans fat content have independent effects.

**Role of Carbohydrate in Diet**

When a high-carbohydrate diet is consumed, hypertriglyceridemia often develops within 48 to 72 hours, and levels of triglycerides rise to a maximum in 1 to 5 weeks. Persons with higher basal triglycerides and those consuming hypercaloric diets show the greatest effect. In persons with type 2 diabetes, a high-carbohydrate diet tends to increase insulin resistance. Substitution of monounsaturated fats for the carbohydrate improves insulin resistance and lipoprotein levels.

**Alcohol Ingestion**

Ingestion of alcohol is a common cause of secondary hypertriglyceridemia owing to overproduction of VLDL. Some individuals with familial hypertriglyceridemia are particularly sensitive to the effects of alcohol, and abstinence may normalize their triglycerides. Occasionally, chronic alcohol intake may also be associated with hypercholesterolemia. Increased cholesterol synthesis and decreased conversion to bile acids have been observed. Alcohol may account for alimentary lipemia persisting beyond 12 to 14 hours. This possibility should be excluded by the history or a repeat lipid analysis. A positive correlation has been found between alcohol intake and HDL cholesterol levels in some individuals. Because alcohol-induced changes in HDL appear primarily to involve the HDL3 subfraction, there is no justification for the use of alcohol to increase the protective effect of HDL against atherosclerosis. If the low HDL cholesterol is secondary to hypertriglyceridemia, alcohol must be avoided.

**Antioxidants**

Both alpha and gamma tocopherols (vitamin E) have recognized roles in the elimination of free radicals. Vitamin C assists this activity by restoring the tocopherol radical to active tocopherol. These vitamins have been shown to restore normal vascular reactivity in hyperlipidemic patients, and some epidemiologic evidence suggests that they have an antiatherogenic effect. It is...
A significant percentage of Americans carry at least one allele for reduction in LDL cholesterol is associated with the addition of oat required. Knowledge of the dietary factors mentioned earlier species of super oxide dismur ase. Diers rich in fruits and vegetables and have not been shown to have antiarherogenic potential. and 250 mg of vitamin C in the diet each day. Larger doses may diminishes its efficiency by reducing its affinity for folic acid. This, and certain other mutations, may lead to significantly elevated levels of a metabolite of methionine—homocysteine—that has toxic effects on endothelium. Supplementation with 0.4 to 2 mg of folic acid mitigates this problem. Vitamins B₉ and B₁₂ participate in the metabolism of homocysteine. Thus, a B complex supplement should be used. Dietary protein should be restricted to the amount required for replacement of essential amino acids (about 0.5-1 g/kg) in patients with hyperhomocysteinemia. Oral administration of betaine, a methyl donor, can mitigate homocysteine levels in severely affected patients (2 g 3 times daily).

**B Vitamins**

A significant percentage of Americans carry at least one allele for mutations in the methylene tetrahydrofolate reductase gene that, and certain other mutations, may lead to significantly elevated levels of a metabolite of methionine—homocysteine—that has toxic effects on endothelium. Supplementation with 0.4 to 2 mg of folic acid mitigates this problem. Vitamins B₉ and B₁₂ participate in the metabolism of homocysteine. Thus, a B complex supplement should be used. Dietary protein should be restricted to the amount required for replacement of essential amino acids (about 0.5-1 g/kg) in patients with hyperhomocysteinemia. Oraladministration of betaine, a methyl donor, can mitigate homocysteine levels in severely affected patients (2 g 3 times daily).

**Other Dietary Substances**

Several other nutrients have been studied in relation to atherosclerosis. Caffeine and sucrose have negligible effects on serum lipids, and their statistical relationship to CHD is generally unimpressive when data are corrected for cigarette smoking. However, when coffee is prepared by protracted boiling of the grounds, a lipid substance (cafeïnol) is extracted that contributes to hypercholesterolemia. Lecithin has no effect on plasma lipoproteins. A minor reduction in LDL choles tetrol is associated with the addition of oat bran and certain other brans to the diet.

**The Universal Diet**

Dietary treatment is an important aspect of the management of all forms of lipoprotein disorders and may in some cases be all that is required. Knowledge of the dietary factors mentioned earlier allows selection of appropriate modifications for an individual. However, a basic diet is useful in the treatment of most patients, the elements of which are as follows:

(1) A normal BMI should be achieved and maintained.
(2) Fat should provide less than 35% and saturated fat less than 7% of total calories. Monounsaturated oils should predomi nate and be used for all high-temperature cooking.
(3) Cholesterol should be reduced to less than 200 mg/d.
(4) Complex carbohydrates should predominate among total carbohydrates.
(5) Alcohol should be avoided in patients with hypertriglyceri-demia or those requiring weight loss.
(6) Intake of trans fatty acids should be avoided.
(7) Peroxidized fats resulting from protracted heating should be avoided.

Caloric restriction and reduction of adipose tissue mass are particularly important for patients with increased levels of VLDL and IDL. During periods of substantial weight loss, levels of VLDL and LDL tend to be lower than they would be under iso-caloric conditions, even at ideal body weight.

**DRUGS USED IN TREATMENT OF HYPERLIPOPROTEINEMIA**

**BILE ACID SEQUESTRANTS**

**Mechanism of Action and Efficacy**

Cholestyramine, colestipol, and colesevelam are cationic resins that bind bile acids in the intestinal lumen. They are not absorbed and, therefore, increase the excretion of bile acids in the stool up to 10-fold. LDL levels decrease as a consequence of increased expression of high-affinity receptors on hepatic cell membranes. These agents are useful only in disorders involving elevated LDL. Patients who have increased levels of VLDL may have further increases in triglycerides during treatment with resins. In combined hyperlipidemia, where the resins may be given to reduce LDL, a second agent such as niacin may be required to control the hypertriglyceridemia. Levels of LDL fall 15% to 30% in compliant patients with heterozygous familial hypercholesterolemia who are receiving maximal doses of the resins. These agents can contribute an incremental effect in the management of insulin resistance by an incretin-mediated mechanism. When given as a single agent, a modest reduction in new coronary events can result. When given in combined regimens with a statin and/or niacin, regression of coronary artery plaques has been demonstrated by quantitative angiography.

**Drug Dosage**

In disorders involving moderately high levels of LDL, 20 g of cholestyramine or colesipol daily may reduce cholesterol levels effectively. Treatment should commence at one-half this dosage to minimize gastrointestinal side effects. Maximum doses (30 g colestipol, 32 g cholestyramine, 3.75 g colesevelam daily) are required in more severe cases. These agents are only effective if taken with meals.

**Side-Effects**

Because the resins are not absorbed, systemic side-effects are absent. Patients frequently complain of a bloated sensation and constipation, both of which may be relieved by the addition of psyllium to the resin mixture. Malabsorption of fat or fat-solu ble vitamins with a daily dose of resin up to 30 g occurs only in individuals with preexisting bowel disease or cholestasis. Hypoprothrombinemia has been observed in patients with malabsorption due to these causes. Cholestryamine and colesipol bind thyroxine, digitalis glycosides, and warfarin and impair the absorption of iron, thiazides, beta-blockers, ezetimibe, and other drugs. Absorption of all these (except ezetimibe) is
ensured if they are administered 1 hour before the resin. Colesevelam does not bind digoxin, warfarin, or reductase inhibitors. Because they change the composition of bile micelles, bile acid sequestrants theoretically may increase the risk of cholelithiasis, particularly in obese subjects. In practice, this risk appears to be very small. The resins should not be used as single agents in patients with hypertriglyceridemias and should be avoided in those with diverticulitis.

**NIACIN (NICOTINIC ACID)**

**Mechanism of Action and Efficacy**

Niacin (but not its amide) is able to effect major reductions in triglyceride-rich lipoproteins and, to a lesser extent, in LDL. It inhibits secretion of VLDL. It increases sterol excretion acutely, mobilizes cholesterol from tissue pools until a new steady-state is established, and decreases cholesterol biosynthesis. That it can cause a continued decrease in hepatic cholesterol production even when given with bile acid–binding resins is probably an important feature of the complementary action of these agents. Levels of HDL, particularly HDL₃, are usually significantly increased, reflecting a decrease in their fractional catabolic rate. Niacin stimulates production of tissue plasminogen activator, an effect that may be of value in preventing thrombotic events. Small, dense LDL are converted to particles of larger diameter during treatment. Niacin is the only available agent that can reduce levels of Lp(a) significantly. Niacin, as a single agent, was given in only one large intervention study which found a significant decrease in nonfatal, recurrent coronary events. In four angiographic studies in which niacin was given with a resin, a statin, or both, significant regression or decreased progression of coronary lesions was reported.

**Drug Dosage**

The dose of crystalline niacin required varies with the diagnosis. Optimal effect on LDL in heterozygous FH is usually achieved only when 4.5 to 6 g of niacin daily is combined with a resin or reductase inhibitor. For other forms of hypercholesterolemia, dysbetalipoproteinemia, hypertriglyceridemia, and hyperalphalipoproteinemia, 1.5 to 3.5 g/d often has a dramatic effect. Because niacin causes cutaneous flushing, it is usually started at a dosage of 100 mg 3 times daily with meals, increasing to the desired dose within 7 to 10 days. Many patients have no or only occasional flushing when stabilized on a given dose, but most must reach about 3 g/d before flushing ceases. Because the flush is prostaglandin mediated, 0.3 g of aspirin given 20 to 30 minutes before each dose when treatment is initiated or the dose increased (or equivalent doses of other cyclooxygenase inhibitors) may mitigate this symptom. It is important to counsel the patient that the flushing is a harmless cutaneous vasodilatation and that the drug should be taken with meals 2 or 3 times daily. A daily dose of 6.5 g is the maximum under any circumstances. Niaspan, a prescription extended-release niacin, appears to be safe in doses up to 2 g daily.

**Side-Effects**

Some patients have reversible elevations of serum glutamic aminotransferase or alkaline phosphatase activities up to 3 times the upper limit of normal that do not appear to be clinically significant. In a group of patients treated continuously for up to 15 years, no significant liver disease developed despite such enzyme abnormalities. Rarely, patients develop a chemical hepatitis signaled by malaise, anorexia, and nausea. Aminotransferase levels are significantly elevated, and levels of lipoproteins may fall precipitously. Treatment should be stopped immediately. About one-fifth of patients have mild hyperuricemia that tends to be asymptomatic unless the patient has had gout. In such cases, allopurinol can be added to the regimen. A few patients have moderate elevations of blood glucose during treatment. Again, this is reversible except in some patients who have latent type 2 diabetes. The use of niacin should be considered carefully in patients with insulin resistance. Diabetic patients receiving insulin can often be treated successfully. A more common side-effect is gastric irritation, which responds well to H₂ blockers and antacids. Antacids that contain aluminum should be avoided. Rarely, patients develop acanthosis nigricans, which usually clears if the drug is discontinued. Some patients can have cardiac arrhythmias, mostly atrial, while taking niacin. Reversible macular edema has been described rarely.

Niacin should be avoided in patients with peptic ulcer or hepatic parenchymal disease. Liver function, uric acid, and blood glucose should be evaluated before commencing treatment and periodically thereafter.

Most over-the-counter sustained-release preparations should be avoided because of the risk of fulminant hepatic failure. However, if the daily dose is limited to 2 g or less, this rare consequence is probably unlikely.

**FIBRIC ACID DERIVATIVES**

**Mechanism of Action and Efficacy**

Gemfibrozil and fenofibrate, which are ligands for peroxisome proliferator–activated receptor alpha, decrease lipolysis in adipose tissue, reduce levels of circulating triglycerides, and cause modest reductions in LDL. However, in some patients, reductions in VLDL levels are attended by increased LDL levels. They cause moderate increases in levels of HDL, including the protein moiety. One primary prevention, and one secondary prevention trial using gemfibrozil as monotherapy showed reduction in new coronary events.

**Drug Dosage**

The fibrates may be useful in the treatment of patients with severe endogenous lipemia, familial dysbeta­lipoproteinemia, and some patients with combined hyperlipidemia who are intolerant of niacin. The usual dose of gemfibrozil is 600 mg twice daily. That of fenofibrate varies with the preparation.
Side-Effects

Skin eruptions, gastrointestinal symptoms, and muscle symptoms have been described as well as blood dyscrasias and elevated levels of aminotransferases and alkaline phosphatase. These drugs enhance the effects of the coumarin and indanedione anticoagulants and increase lithogenicity of bile. Concomitant use of fibrates with certain reductase inhibitors increases the risk of myopathy. Fenoﬁbrate is most compatible with pravastatin or rosuvastatin with respect to cytochrome metabolism. Fibrates should be avoided during pregnancy and lactation and are contraindicated if hepatic or renal disease is present.

HMG-CoA REDUCTASE INHIBITORS (TABLE 19–2)

Mechanism of Action and Efficacy

Several closely related structural analogs of HMG-CoA act as competitive inhibitors of HMG-CoA reductase, a key enzyme in the cholesterol biosynthetic pathway. Of these, lovastatin, pravastatin, simvastatin, ﬂuvastatin, atorvastatin, pitavastatin, and rosuvastatin are approved for use in the United States. Inhibition of cholesterol biosynthesis induces an increase in high-affinity LDL receptors in the liver, increasing removal of LDL from plasma and decreasing production of LDL. The latter results from increased uptake of lipoprotein precursors of LDL by hepatic receptors. Modest increases in HDL cholesterol and limited decreases in VLDL levels can be achieved. These drugs have no appreciable effect in patients with severe hypertriglyceridemia. Some of the cholesterol-independent effects of reductase inhibitors appear to involve enhanced stability of atherosclerotic lesions and decreased oxidative stress and vascular inflammation, with improved endothelial function. Institution of treatment with a reductase inhibitor should begin immediately in all patients with acute coronary syndromes regardless of cholesterol level. One angiographic trial with statin monotherapy and three with combined regimens including statins yielded signiﬁcant reduction in the size of coronary atheromas. A number of primary and secondary trials with statins as monotherapy have demonstrated signiﬁcant reduction in endpoints including primary or recurrent myocardial infarction, coronary revascularization, atherosclerotic stroke, or cardiac death. In these trials, reduction of LDL cholesterol levels to or below currently accepted goals produced an approximate 35% reduction in new coronary events over the 3 to 5 year duration of the trials. Longer term follow-up suggests that the impact on new coronary events will deepen over time, consistent with observations on individuals with familial hypobetalipoproteinemia or loss of function variants in the PCSK9 gene.

Drug Dosage

These drugs are the most effective individual agents for treatment of hypercholesterolemia. Their effects are amplified signiﬁcantly when combined with niacin, ezetimibe, or resin. Daily dosage ranges are presented in Table 19–2. Patients with heterozygous FH usually require higher doses. Because information on long-term safety is lacking, use of these agents in children should be restricted to those with homozygous FH and selected heterozygotes that are at particularly high risk. Women who are lactating, pregnant, or likely to become pregnant should not be given these drugs.

Side-Effects

These agents are generally well tolerated. Side-effects, often transient, include rashes and changes in bowel function. Myopathy with markedly elevated creatine kinase (CK) levels occurs infrequently. Rarely, myopathy can progress to rhabdomyolysis with myoglobinuria and renal shutdown. There is an increased incidence of myopathy in patients receiving certain reductase inhibitors with cyclosporine, ﬁbric acid derivatives, macrolides, HIV protease inhibitors, nefazodone, verapamil, and ketoconazole. Other drugs that compete for metabolism by cytochrome P450 3A4 can be expected to have the same effect. Because pravastatin and rosuvastatin do not compete with these agents for metabolism by cytochrome P450 enzymes, they appear to be compatible with them. Fuvastatin is chiefly metabolized by cytochrome P450 2C9. Thus, competitors for that pathway may cause accumulation of this reductase inhibitor. The myopathy is rapidly reversible on cessation of therapy. Minor elevations of CK activity in plasma are noted more frequently, especially with unusual physical activity. CK levels should be measured before starting therapy and monitored at regular intervals in selected patients. Older patients, those taking higher doses and multiple other drugs, those who have diabetes, those with renal insufficiency, and those with baseline elevated CK levels should be observed more frequently. A form of statin-associated myopathy can occur in the absence of CK elevations. Moderate, often intermittent elevations of serum aminotransferases (up to 3 times normal) occur in some patients. If the patient is asymptomatic, therapy may be continued if activity is measured frequently (at 1- to 2-month intervals) and the levels are stable. In about 2% of patients, some of whom have underlying liver disease or a history of alcohol use, aminotransferase activity may exceed 3 times the normal limit. This usually occurs after 3 to 16 months of continuous therapy and may portend more severe hepatic toxicity such as that described in the section on niacin. The reductase inhibitor should be discontinued promptly in these patients.

patients. These agents are contraindicated in the presence of active liver disease and should be used with caution in patients with a history of liver disease. They should be discontinued temporarily during hospitalization for major surgery.

**CHOLESTEROL ABSORPTION INHIBITORS**

**Mechanism of Action and Efficacy**

Ezetimibe, the first of this class, inhibits the absorption of cholesterol and phytosterols by enterocytes. By interrupting the enterohepatic circulation of sterols secreted in bile, it increases sterol elimination. No outcome studies with this agent as monotherapy have been reported.

**Drug Dosage**

Ezetimibe is useful in treating primary hypercholesterolemias and phytosterolemia. Concomitant use of fibric acid derivatives can increase the blood concentration of this drug. Resins can decrease its absorption. It should be avoided in pregnant or lactating women and in patients with liver disease, and used with caution in patients receiving cyclosporine. A single dose of 10 mg daily reduces cholesterol by 15% to 20%.

**Side-Effects**

Very few side-effects have been reported. The prevalence of elevated liver enzymes may be modestly increased when ezetimibe is given with a reductase inhibitor. Biopsy-proven myopathy has been described rarely.

**COMBINED DRUG THERAPY (TABLE 19–3)**

Combinations of drugs may be useful (1) when LDL and VLDL levels are both elevated; (2) in cases of hypercholesterolemia in which significant increases of VLDL occur during treatment with a bile acid–binding resin; (3) where a complementary effect is required to normalize LDL levels, as in familial hypercholesterolemia or familial combined hyperlipidemia; and (4) when a hyperlipidemia is accompanied by primary HDL deficiency or an elevated level of Lp(a).

**Niacin with Other Agents**

The combination of a fibrate with niacin may be more effective than either drug alone in managing marked hypertriglyceridemia. Niacin usually normalizes triglycerides in individuals who have increased levels of VLDL while taking resins. The combination of niacin and resins is more effective than either agent alone in decreasing LDL levels in FH. The combination is also very useful in the treatment of FCH. The absorption of niacin from the intestine is unimpeded by the resin. Niacin is complementary with ezetimibe in treating combined hyperlipidemia.

**HMG-CoA Reductase Inhibitors with Other Agents**

The addition of resin or niacin to a reductase inhibitor further decreases plasma levels of LDL in patients with primary hypercholesterolemias. Liver function and plasma CK activity should be monitored frequently when the combination includes niacin.
These three drugs used together are more effective, frequently at lower doses, than any of their binary combinations in reducing LDL. Ezetimibe is synergistic with reductase inhibitors. The compatibility of rosuvastatin or pravastatin with fenofibrate makes these combinations useful in combined hyperlipidemia.

DEFINITION AND EPIDEMIOLOGY

Definition

Obesity and overweight categories have been defined by examining longitudinal study data that associate a given weight with future adverse health effects. The currently accepted surrogate measure of body fatness is body mass index (BMI) which is measured as weight in kilograms divided by height in meters squared. For adults, a BMI <18.5 kg/m² is underweight, 18.5 to 24.9 kg/m² is healthy weight, 25.0 to 29.9 kg/m² is overweight, and ≥30 kg/m² is obese. For children and adolescents, a BMI between the 85th and 95th percentile for age and sex is considered at risk of overweight, and BMI at or above the 95th percentile is considered overweight or obese.

However, BMI does not account for ethnic differences in skeletal structure or musculature. Body frame size varies dramatically by race/ethnicity from small-framed East Asian adults to larger framed Pacific Islanders. Moreover, conventional cut-points for adult overweight (BMI ≥25 kg/m²) and obesity (BMI ≥30 kg/m²) do not correspond to similar absolute or relative metabolic risk in all ethnic group. As a result, the World Health Organization (WHO) and International Obesity Task Force proposed a lower BMI cut-point to define obesity in South and East Asian adults: 23 kg/m² for overweight and 25 kg/m² for obesity.

Prevalence and Projections

National surveys performed by the Centers for Disease Control and Prevention in the United States have found a significant
increase in the prevalence of overweight and obesity over the past 30 years. In 2003 to 2004, according to data from the National Health and Nutrition Examination Survey (NHANES), 32.2% of adults were obese. Trends among adults have been tracked by repeat NHANES surveys, showing that the percent of overweight or obese have climbed from 47.0% in 1976 to 1980 to 66.2% in 2003 to 2004, and the prevalence of obesity alone has more than doubled from 15.0% to 32.9% overall. The prevalence of obesity was 45.0% among non-Hispanic blacks, 36.8% among Mexican Americans, and 30.6% among non-Hispanic whites.

The trends in obesity have been most striking among children and adolescents with two- to threefold increases in rates over the past three decades in all age groups. In the NHANES 2003 to 2004 survey, a total of 17.1% of US children and adolescents were overweight (BMI ≥95th percentile). Among children aged 2 to 5 years, the prevalence increased from 5% in the 1976 to 1980 NHANES to 12.4% in 2003 to 2006 NHANES. Similarly, the prevalence in age 6 to 11 years increased from 6.5% to 17.0%, and for ages 12 to 19 years increased from 5% to 17.6% in the most recent national survey.

While the United States leads most of the world with high prevalence of overweight and obesity, these conditions are becoming more prevalent worldwide even in developing countries. In China, overweight prevalence in adults increased from 14.6% to 21.8% between 1992 and 2002, with greatest increases seen among men, urban residents, and high-income groups. In India, the prevalence of overweight ranged from 9.4% in rural men to 38.8% in urban women in 2003 to 2005.

Globally, according to a pooled analysis, in 2005 there were an estimated 937 million (95% CI, 922-951 million) overweight adults and 396 million (388-405 million) obese adults. Using conservative projections, by 2030 the number of overweight adults was estimated to be 1.35 billion and 573 million obese individuals without adjusting for secular trends. The authors warned that if recent secular trends continue unabated, the absolute numbers may total 2.16 billion overweight and 1.12 billion obese adult individuals. Among US residents, projections forecast that by 2030, 86.3% adults will be overweight or obese (51.1%) with black women (96.9%) and Mexican American men (91.1%) being most affected. Wang et al estimate that by 2048, all American adults would become overweight or obese, and in children, the prevalence of overweight (BMI ≥95th percentile) would almost double to 30%.

Possible Explanations for the Increased Obesity Rates

Several hypotheses have been proposed to explain the rapid rise in overweight/obesity in developed and developing countries. The simple explanations start with changes in lifestyle behaviors, primarily the lack of regular physical activity and increased caloric intake that tip the energy balance equilibrium. The reality of the factors promoting the obesity epidemic is clearly more complex and involves multiple layers of determinants including social norms and values, several sectors of influence from governmental to media to the food/entertainment industries, behavioral settings including the work/home/neighborhood environment, to individual factors that include genetic, socioeconomic, cultural, and psychosocial factors. In a novel social network analysis of the Framingham cohort, investigators found that weight status (gain, loss, or stability of weight) for an individual was highly influenced by his/her friends and family extending out to three degrees of separation. A multifaceted approach will be required to meaningfully curb the obesity epidemic globally.

PATHOPHYSIOLOGY AND GENETICS OF OBESITY

Regulation of Food Intake and Energy Expenditure

Obesity is an increase of energy stored as fat that occurs when caloric intake exceeds caloric expenditure. What causes this imbalance is less clear, but recent advances in our understanding of the physiological systems responsible for the maintenance of energy stores in response to variable access to nutrition and demands for energy expenditure have provided some insights into the pathophysiology of obesity. The physiological system controlling food intake and energy expenditure is composed of (1) long-term and short-term afferent signals that allow for sensing the energy status of the individual; (2) integrating brain centers, most importantly within the hypothalamus, where the level of the efferent response is determined; and (3) efferent signals including those regulating the intensity of hunger and the level of energy expenditure.

One common misconception is that this physiological system is dedicated to the prevention of obesity. Instead, this system’s essential role is in the prevention of starvation (ie, ensuring adequate energy intake to compensate for the energy requirements of basal metabolism, physical activity, growth, and reproduction). As a result, this physiological system is more strongly biased toward prevention of energy deficiency rather than excess storage.

Informing the Brain of the Energy Status: Leptin and Short-Term Gastrointestinal Signals

Leptin. The major afferent signal allowing the brain to sense the level of energy stores is the hormone leptin. Discovered in 1994, this cytokine-like 167 amino acid protein is released by adipocytes. Under basal conditions the circulating levels of serum leptin are correlated with fat mass (r = 0.8) and decrease after weight loss. Decreasing leptin levels inform the brain of diminishing fat storage resulting from negative energy balance. This results in compensatory effects on appetite and energy expenditure, aimed at replenishing the stores and reestablishing energy balance. The role of leptin is best understood from the phenotype of rare cases of humans with complete leptin deficiency. Despite early-onset, extremely severe obesity, these patients show behaviors and physiological signs of starvation. This includes hyperphagia, decreased immune function, and hypogonadotropic hypogonadism. The latter reflects deficiency
of the leptin signal informing the brain that sufficient energy stores are available for reproduction. Hormonal replacement of leptin-deficient patients corrects all these abnormalities, abolishing the hyperphagia leading to normalization of weight and maturation of the reproductive axis.

Leptin's action is mediated by the leptin receptor (LepR). This receptor is a member of the class I cytokine receptor family which also includes the growth hormone, prolactin and erythropoietin receptors (see Chapter 1). These receptors have a single transmembrane domain and homodimerize upon binding of the ligand. Leptin binding to LepR leads to phosphorylation of the JAK2 receptor-associated kinase followed by recruitment and phosphorylation of the signal transducer and activator of transcription STAT3. Upon activation STAT3 dimerizes and translocates to the nucleus, where it activates transcription of target genes. The LepR is expressed in almost every tissue but only one of five isoforms, LepRb, contains the STAT3 recruitment domain. This isoform is expressed specifically in leptin-responsive brain regions.

In summary, leptin functions as a long-term signal of energy balance by informing the brain of changes in the level of energy stored as fat. A perceived decrease in leptin levels increases the amount of food consumed and minimizes energy expenditure. Leptin levels do not change with meals, and leptin does not acutely change meal size.

**Signals from the gastrointestinal tract.** In addition to leptin, which represents a long-term adiposity signal, a number of other hormones, most of which are secreted by the gastrointestinal (GI) system, regulate appetite on a short-term basis (i.e., in response to a meal) (Table 20–1). These hormones act on satiety (the feeling of fullness that contributes to the decision to stop eating) rather than on satiety (the prolongation of the interval until hunger or a drive to eat reappears). Some of these hormones have been shown to act on the same brain centers as leptin does. Altered secretion of or response to these GI hormones may directly contribute to the pathogenesis or the maintenance of obesity. Cholecystokinin (CCK) is secreted by duodenal I cells into the bloodstream. Its secretion is stimulated by the presence of fat and protein in the duodenum. CCK stimulates gut motility, contraction of the gallbladder, pancreatic enzyme secretion, gastric emptying, and acid secretion. CCK acts locally, stimulating vagal sensory nerves through the CCK1 receptor (CCK1R) and informs the brain that fat and proteins are being processed and will soon be absorbed. This message is conveyed to the hypothalamus via the hindbrain. Circulating CCK levels increase after meals and infusion of a CCK1R agonist (CCK33), to postprandial levels, suppresses food intake. Conversely, infusion of a CCK1R antagonist increases calorie intake. CCK is also a proximal mediator of the broader satiation process, attenuating meal-induced changes of more distal GI hormones, such as ghrelin and peptide YY (PYY).

Glucagon-like peptide 1 (GLP1) is a 30 amino acid peptide derived from the proglucagon gene. GLP1 is secreted into the bloodstream by the intestinal L-cells of the ileum and colon in response to the presence of nutrients in the lumen. GLP1 has a very short half-life (2 minutes), and is degraded by dipeptidyl peptidase-4. It increases insulin secretion in a glucose-dependent manner, decreases glucagon secretion, increases beta cell mass, inhibits gastric emptying, and decreases food intake. GLP1 is thought to signal through the hindbrain via stimulation of the GLP1 receptor (GLP1R) on the vagus nerve.

PYY, a 36 amino acid peptide is released into the bloodstream by intestinal endocrine L-cells of the distal gut (ileum and colon) after food ingestion and in response to the presence of fat in the lumen. PYY3-36, the major form of circulating PYY, binds to the hypothalamic NPY-Y2 receptor and reduces food intake. Obese individuals have lower PYY levels after a test meal than nonobese controls.

Ghrelin, a 28 amino acid octanoylated peptide, is secreted into the bloodstream by endocrine cells lining the fundus of the stomach. Ghrelin secretion is stimulated by fasting, increases preprandially, and is suppressed by food intake. Ghrelin is orexigenic, increasing food intake when administered peripherally, and acts in part by directly modulating the activity of the NPY (neuropeptide Y)/AGRP (agouti-related peptide) neurons in the arcuate nucleus of the hypothalamus.

### Central Integration of Energy Homeostasis Signals

The major challenge of adapting food intake to energy expenditure lies in the discontinuous availability of the first and the continuous

and variable levels of the second required for survival, growth, and reproduction. The current prevailing model is that the concentration of circulating adiposity signals, primarily leptin, influences the response to short-term satiation signals thereby allowing for sufficient energy intake to maintain a constant level of stored energy. Genetic studies in mice and humans have outlined several critical neuronal populations and circuits that translate information provided by afferent circulating hormonal signals into neural responses that regulate appetite and energy expenditure. The primary locus for the integration of peripheral signals that influence energy balance is the hypothalamus (Figure 20-1). Specifically, two adjacent groups of neurons in the arcuate nucleus (ARC) of the hypothalamus, characterized by their production of specific neuropeptides, act as the primary site in the brain for receiving the humoral signals that reflect body energy status. The AGRP/NPY neurons are orexigenic. They are inhibited by leptin and their activity is also modulated by GI hormones, such as ghrelin and PYY. The pro-opiomelanocortin (POMC) neurons are anorexigenic and are activated by leptin. In these neurons, POMC is processed by the specific proteases proconvertase-1 and proconvertase-2 to the anorexigenic neuropeptide α-melanocyte-stimulating hormone (α-MSH). Interactions between these neurons within the ARC allows for cross talk and modulation of the neuronal output.

These first-order neurons send projections to second-order neurons in other regions of the hypothalamus, specifically the paraventricular nucleus (PVN) and the lateral hypothalamic area (LHA), as well as to the hindbrain. Both α-MSH and AGRP act on a common receptor, the melanocortin-4 receptor (MC4R) expressed on PVN neurons. α-MSH binds to and activates the melanocortin 4 receptor (MC4R) and by competing with α-MSH for the MC4R, AGRP inhibits MC4R-bearing neurons. The MC4R neurons then innervate neurons in other areas of the hypothalamus and brain stem to produce an integrated inhibition of appetite and increase in energy expenditure.

**Leptin Resistance in Obesity**

While recombinant leptin can correct the exceptionally rare cases of obesity due to genetic leptin deficiency, all other obese patients have leptin levels that are proportional to their fat mass. In addition, recombinant leptin injections in obese patients do not lead to weight loss. Therefore, despite the presence of elevated leptin concentrations, which should reduce food intake and body fat, obese patients appear to be insensitive or resistant to leptin. Both genetic and environmental factors have been shown to contribute to this leptin resistance, and a number of specific alterations in the downstream leptin effector pathways have been suggested to participate in this obesity-associated leptin resistance. Understanding the nature of this leptin resistance may allow for the development of novel obesity treatments but its molecular basis is probably heterogenous and different in each patient.

**Genetics of Obesity**

Excess caloric intake and the tendency toward a more sedentary lifestyle are certainly to blame for the increased prevalence of obesity, but individuals exposed to the same environmental pressures have different levels of vulnerability. Indeed, genetic epidemiologic studies, such as twin studies and adoption studies have implicated genetic factors in the susceptibility to obesity. These studies have shown that genetic factors account for 40% to 70% of the population variation in BMI and that the heritability of obesity increases...
Indeed a number of single gene defects that cause human obesity have been uncovered. These defects have provided more insight into the genetic predisposition and pathophysiology of obesity. Certain mutations can cause obesity as part of a complex syndrome, in which developmental phenotypes are prominent (Table 20–3). However, most single gene defects causing Mendelian forms of obesity are in genes of the leptin-melanocortin system (Table 20–4). The description of patients with these mutations has both provided insight into the genetic predisposition to obesity and has confirmed that the hypothalamic leptin-melanocortin system is critical for energy balance in humans. Mutations in leptin and the LepR cause severe obesity associated with hypogonadotropic hypogonadism. Mutations in POMC cause severe obesity, due to absent synthesis of α-MSH in the hypothalamus, and neonatal adrenal insufficiency, due to lack of ACTH production in the anterior pituitary gland. These recessive syndromes are extremely rare. In contrast, mutations in MC4R represent the most common genetic cause of severe obesity accounting for 2.5% of all cases. Patients who carry such mutations do not have specific clinical or biological characteristics that differentiate them from other patients with severe obesity; genetic testing is the only reliable method to identify these patients. At present, such testing is not recommended since the presence or absence of one of these mutations carries no specific implications for the clinical management of these patients.

*Only variants replicated in multiple studies and with odds ratios of obesity above 1.05 are indicated.*

Large and comprehensive genome-wide association studies find that a number of common genetic variants are associated with obesity (Table 20–2). These variants are near genes that are expressed in the central nervous system further suggesting a role for an alteration of central regulatory pathways in the pathogenesis of obesity. However, since these variants are not located within the protein-coding regions of these genes, the exact mechanism by which they predispose to obesity remains to be elucidated. More importantly, the individual as well as the combined effects of these common variants only explain a small fraction of the inherited variability in obesity (10%-20%), suggesting that rare variants may contribute more significantly to the genetic predisposition to this condition.

**HEALTH CONSEQUENCES OF OBESITY**

**Mechanism Underlying Obesity**

**Complications: Adipose Tissue as an Endocrine Organ**

The massive public health burden of obesity is due to the psychological, behavioral, and medical consequences of this chronic increase in adipose tissue mass. Pathophysiological mechanisms...
underlying the complications of obesity include the psychological and behavioral responses to the image projected in a society in which obesity is considered cosmetically unattractive, the mechanical effects of increased adipose mass on weight-bearing joints as well as other organs, and the metabolic consequences of increased circulating free fatty acids (FFAs).

It is also now clear that the adipose cell is not simply dedicated to inertly storing energy as triglycerides and releasing free fatty acids and glycerol during periods of increased energy needs. In addition to leptin, described earlier, which informs the brain of the level of energy stores, adipose cells secrete a number of factors, known as adipokines, which can play a role in the pathophysiology of obesity and its complications (Figure 20–2). For example, adiponectin is an abundant plasma protein, structurally related to the complement C1q family, that is secreted exclusively from adipose tissue. Adiponectin circulates in serum as a range of multimers from low-molecular-weight trimers to high-molecular-weight (HMW) dodecamers. Circulating levels of adiponectin are negatively correlated with fat mass and are reduced in obesity. Adiponectin improves whole-body insulin sensitivity through its receptor-mediated actions on the muscle and the liver. Specifically, adiponectin stimulates fatty acid oxidation and glucose uptake in skeletal muscle and suppresses glucose output in the liver.

In addition, a number of factors secreted by adipose tissue, particularly in the context of obesity, are proinflammatory cytokines. It is now generally accepted that obesity is a state of chronic, low-grade inflammation. These inflammatory molecules exert their effects through both paracrine and endocrine pathways. Initially thought to be secreted by adipocytes, most of these factors are actually produced by other cells such as macrophages, which infiltrate the adipose tissue in obesity. Tumor necrosis factor-α (TNF-α) was the first adipose-derived factor suggested to represent a link between adiposity and the insulin resistance associated with type 2 diabetes. Released by activated macrophages, which infiltrate expanding adipose tissue in obesity, this cytokine has been strongly implicated in the pathogenesis of insulin resistance, directly impairing insulin signaling in hepatocytes and adipocytes. Other adipokines involved in obesity-associated inflammation include interleukin 6 (IL-6), monocyte-chemoattractant protein-1 (MCP-1), plasminogen-activated inhibitor (PAI-1), and colony-stimulating factor (CSF).

**Metabolic Complications of Obesity: Insulin Resistance and Type 2 Diabetes**

Hyperinsulinemia is characteristically associated with obesity. This hyperinsulinemia is linked to insulin resistance (ie, the decrease in insulin-stimulated glucose utilization, which increases proportionally with fat mass). One of the major consequences of this obesity-associated insulin resistance is the requirement for increased insulin secretion. While the majority of obese individuals can secrete sufficient insulin to accommodate the insulin-resistant
state, this increased burden on the insulin-producing pancreatic beta cells increases the susceptibility to failure, resulting in type 2 diabetes (T2DM) in genetically predisposed individuals. Indeed, over 80% of T2DM patients are obese. In comparison with a normal-weight individual, BMI greater than 40 (obesity class 3) in a person under 55 years of age increases the risk of T2DM by 18.1-fold in men and 12.9-fold in women. Classification as overweight (BMI 25-30) increases the prevalence of T2DM three- to fourfold in both men and women under 55 years of age. The relative risks associated with excess body weight are weaker in older individuals but are still present (eg, about twofold for overweight and three- to sixfold for obesity class 3).

The increased rate of T2DM is the most worrisome public health issue linked to the increased rates of obesity. The anticipated health outcomes such as premature heart disease, peripheral vascular disease, renal failure, blindness, are deeply concerning and place this among our highest contemporary public health priorities. Some recent studies have estimated that the current generation of American youth will be the first to exhibit shorter life spans than their parents, because of the impact of obesity on T2DM.

Dyslipidemia

Obesity is associated with dyslipidemia characterized by increased levels of very low density lipoprotein (VLDL) cholesterol, triglycerides, and total cholesterol as well as a decrease in HDL cholesterol and an increase in small dense LDL particles. The difference in serum triglyceride concentrations between individuals with BMI less than 21 and those with BMI greater than 30 is about 65 mg/dL (in women) and 62 to 118 mg/dL (in men, depending on age). For HDL cholesterol, each 1-unit BMI change is associated with an HDL-cholesterol decrease of 1.1 mg/dL for young men and 0.7 mg/dL for young women. All of the components of this obesity-associated dyslipidemia have been shown to be atherogenic and play a major role in the development of atherosclerosis and cardiovascular disease in obese individuals.

Weight loss and exercise, even if they do not result in normalization of body weight, can improve this dyslipidemia and thus reduce CVD risk. In addition, obese individuals should be targeted for intense lipid-lowering therapy, when necessary.

The Metabolic Syndrome

The concept of the metabolic syndrome was first introduced in 1923 by Kylin who described the clustering of hypertension, hyperglycemia, and gout as a syndrome. Reaven and others redefined this concept as the insulin resistance syndrome, a clustering of glucose intolerance, high triglycerides, low HDL cholesterol, and hypertension. The two most consistent characteristics of persons with the syndrome are insulin resistance and central abdominal obesity. There is strong epidemiologic and pathophysiologic evidence linking visceral adiposity with insulin resistance and diabetes, with dyslipidemia, hyperinsulinemia, and decreased fibrinolysis as possible mediators of the relationship between visceral fat and type 2 diabetes and cardiovascular disease risk.

The earliest attempt to create a definition for this constellation of metabolic disorders was by the WHO wherein an individual with glucose intolerance or insulin resistance was required to have two or more criteria (elevated triglycerides, low HDL cholesterol, high BMI or waist-hip ratio, hypertension, or microalbuminuria) in order to be categorized as having metabolic syndrome. The next attempt at a clinical definition was by the National Cholesterol Education Program (NCEP)-Adult Treatment Panel III in 2001 that required three or more of the following criteria for the metabolic syndrome definition: high fasting glucose, high triglycerides, low HDL, high blood pressure or waist circumference. More recently, the International Diabetes Federation (IDF) proposed further refined criteria that require central abdominal obesity, and two more criteria as proposed by the NCEP. The IDF criteria were the first ones to account for the heterogeneity of body size among different ethnic groups, and the committee recommended different waist circumference cut-points based on ethnicity with a revised definition for South Asians, Chinese, and Japanese recommending similar waist circumference cut-points in men (≥90 cm) and in women (≥80 cm) compared to the European cut-points of ≥94 cm in men and ≥80 cm in women. More recently, the utility of the metabolic syndrome has been questioned, given that there are no treatment options available, and rather each cardiometabolic risk factor (eg, blood pressure control) is treated individually.

Cardiovascular Complications

Higher cardiovascular disease risk has been linked to visceral adiposity with several distinct mechanisms including inflammation, thrombosis, hyperglycemia, atherogenic dyslipidemia, and adipocytokines (hormones and proteins exclusively secreted by adipose tissue). Obesity has been implicated as one of the major risk factors for hypertension, heart failure, and coronary heart disease. Other cardiovascular conditions associated with obesity include peripheral arterial disease and atrial fibrillation.

Altered hemodynamics of obesity due to increases in total blood volume, systemic arterial pressure, and cardiac output increase the workload of the heart and can lead to adverse effects on cardiovascular structure and function. Overweight individuals develop left ventricular dilation and hypertrophy and left atrial enlargement. These structural abnormalities increase the risk of heart failure and of atrial fibrillation. In the Framingham Heart Study, every 1-unit increase in BMI increased the risk of heart failure by 5% in men and 7% in women. However, several recent studies have also found an obesity-cardiovascular disease paradox where overweight and obese individuals with existing heart failure or heart disease have a lower risk of mortality than those who are underweight or normal weight. These findings suggest that obese individuals may have the metabolic reserve to withstand high catabolic needs as exist in heart failure.

Pulmonary Complications

Obesity can cause alveolar hypoventilation, increased pulmonary blood volume, and mechanical effects on the respiratory system. Obstructive sleep apnea (OSA) is associated with obesity and
other features of the metabolic syndrome, with the most closely correlated factor being hypertension. Intermittent upper airway obstruction results in hypoxia, sympathetic nervous system surges, and airway inflammation. Patients with sleep apnea have higher risk of systemic and pulmonary hypertension, heart failure, dysrhythmias, myocardial infarction, and overall mortality. Mechanisms that have been implicated in the development of cardiovascular disease in obstructive sleep apnea include increased oxidative stress and inflammation that cause endothelial dysfunction. While significant weight loss can improve OSA and associated metabolic features, mechanical therapies used to treat sleep apnea with constant positive airway pressure have not been found to improve hypertension or other metabolic features.

**Gastrointestinal Complications**

Nonalcoholic fatty liver disease (NAFLD) is commonly seen with insulin resistance or obesity and includes a spectrum of liver disease from steatosis to nonalcoholic steatohepatitis, advanced fibrosis, and rarely, cirrhosis. Fat accumulates within the liver with recruitment of inflammatory cells and fibrosis. The prevalence of NAFLD in obesity is 50% to 85%. Risk factors associated with NAFLD besides obesity include advancing age, visceral adiposity, atherogenic dyslipidemia, and hypertension. NAFLD is the leading cause of chronic liver disease in the United States, and given the high rates of obesity, approximately one-third of US adults are estimated to have NAFLD.

NAFLD has been observed in overweight children and adolescents with prevalence estimated at 6% to 23% in population-based US samples. In children, there seems to be a clear male predominance for NAFLD which suggests distinct pathophysiologic mechanisms for NAFLD between adults and children. Histologic criteria have been proposed to distinguish adult (type 1) and pediatric (type 2) NAFLD. In a large study of German children, the three main factors that contributed to NAFLD by principal components analysis included an insulin resistance/visceral adiposity factor, a body fat distribution/CRP factor, and lastly a sex steroid hormone factor.

Other GI complications of abdominal obesity include gastroesophageal reflux disease and hiatal hernia. Both of these conditions can cause erosive mucosal changes in the lower esophagus leading to higher risk of Barrett esophagus.

**Reproduction and Gynecologic Complications**

Obesity has been associated with both female and male infertility. In women, polycystic ovarian syndrome (PCOS) is the main cause of female infertility associated with obesity. Women with PCOS have ovulatory dysfunction and hyperandrogenemia. PCOS is reviewed in more detail in Chapter 13. In men, obesity can cause reduced sperm counts and motility. Hormonal changes with obesity and associated metabolic disorders may lead to poor sperm production. Obesity is also associated with erectile dysfunction through proinflammatory mechanisms and decreased testosterone levels.

**Cancer**

Several cancers have been linked to obesity, including breast, endometrial, colorectal, prostate, and renal cell carcinomas. Putative mechanisms for breast and endometrial cancer include higher circulating levels of unopposed estrogen and ovarian hyperandrogenism, causing higher levels of testosterone and lower levels of luteinizing hormone. The relationship between obesity and colon cancer is stronger in men than women.

**MANAGEMENT OF THE OBESE PATIENT**

**Screening and Prevention of Complications**

Periodic health screening with a measurement of both height and weight to calculate BMI is recommended by many organizations including the National Heart, Lung, and Blood Institute (NHLBI), the US Preventive Services Task Force, and the WHO. Furthermore, the NHLBI also recommends waist circumference measurement routinely to find persons at risk of metabolic complications of overweight. Patients who are found to be in the overweight or obese categories of BMI are recommended to have other risk factors checked as well, including blood pressure, fasting glucose, and lipoprotein levels.

**Therapeutic Approaches for Weight Loss**

Several behavioral, pharmacologic, and surgical therapies for weight loss have been studied in randomized controlled trials. In general, behavioral interventions with lifestyle change including diet and exercise and pharmacologic therapies work to achieve modest amounts of weight loss while patients adhere to the intervention. Recommended for more severe levels of obesity, bariatric surgery does lead to larger amounts of weight loss, but requires lifelong medical supervision and management of the side effects associated with the surgery.

**A. Behavior, diet, and exercise therapies** While many believe that long-term weight loss with lifestyle change is not achievable by most patients, longitudinal studies have found that 20% of overweight individuals are successful at weight loss defined as losing at least 10% of initial body weight and maintaining the loss for at least 1 year. Individuals enrolled in the National Weight Control Registry have lost an average of 33 kg and maintained the loss for more than 5 years. Behaviors that have been most effective for long-term weight loss include high levels of physical activity (>1 hour/day), self-monitoring weight, eating a low-calorie, low-fat diet, eating breakfast regularly, and maintaining a consistent eating pattern throughout the week.

**Dietary interventions.** Several commercial, fad, and therapeutic dietary interventions exist for weight loss. Recent dietary trends have focused on relative changes in macronutrient composition of the diet to achieve weight loss, such as low-fat or low-carbohydrate diets. Few have been rigorously tested, and no
trials have long-term outcome data (defined as the occurrence of comorbidities or mortality). A recent randomized trial comparing four popular diets (Atkins, Zone, Weight Watchers, and Ornish diet) found that weight change did not significantly differ between participants assigned to any of the four diets, and better dietary adherence predicted higher amount of weight loss. The most difficult diets for participants to adhere to were the very low-fat diet (Ornish) and the low-carbohydrate diet (Atkins). In a recent meta-analysis of five dietary trials for weight loss, low-carbohydrate non-energy-restricted diets were found to be as effective as low-fat, energy-restricted diets for weight loss up to 1 year. The weighted mean difference in weight loss was greater in the low-carbohydrate diets (−3.3 kg, 95% CI −5.3 to −1.4 kg, p = 0.02) in the first 6 months, but there was no difference in weight loss after 12 months between the two types of diet (−1.0 kg, 95% CI −3.5 to 1.5 kg, p = 0.15). Additionally, there was no clear benefit on cardiovascular risk factors with either type of diet.

**Physical activity interventions.** The Institute of Medicine recommends physical activity of 60 min/d for most days of the week for weight loss and/or control of weight. The recommendations for heart disease prevention are 30 min/d of moderate-intensity physical activity on most days per week, or at least 150 min/wk.

In a systematic review of trials of an aerobic physical activity intervention in overweight populations, body weight decreased significantly in seven of nine trials, but weight increased in two trials. The two studies that combined diet with aerobic training had the largest amounts of weight loss (> 10 kg each). However, these trials were uncontrolled and of relatively short duration. It remains unclear whether long-term lifestyle change with physical activity can decrease risk of cardiovascular disease or mortality in obese individuals.

**Pharmacologic intervention/CAM.** Weight loss medications have mixed results with most delivering modest amounts of short-term weight loss, often associated with many undesirable side effects. Currently there are four main categories of weight loss medications approved by the FDA: adrenergic agents, serotonergic agents, combination of both adrenergic/serotonergic agents, and lipase inhibitors. Other medications available for off-label use include some antidepressants and anticonvulsant agents. A majority of available obesity treatments work by suppressing appetite centrally. One approved medication, orlistat, prevents digestion and absorption of dietary fat by inhibiting the gut enzyme lipase. There are several different sites of action under investigation for potential medications including specific neurotransmitter targets to decrease appetite and/or promote satiety, endocannabinoid system antagonists and opioid receptor targets to reduce food intake, and peripheral targets that work at the level of the intestines or pancreas to modulate food intake.

Table 20–5 shows specific medications in each category, the amount of weight loss reported in trials compared to placebo from a recent review and meta-analysis, and the common side effects of each agent. The two most frequently studied weight loss medications, sibutramine and orlistat, have had the best efficacy in longer-term trials (52 weeks). However, both of these drugs are associated with significant side effects which limit their use. Other obesity medications in the drug development pipeline include lorcaserin, an agonist that targets serotonin 2C receptors to cause appetite suppression. An endocannabinoid receptor

**TABLE 20-5 Medications for treatment of obesity.**
antagonist, rimonabant, was successful in producing modest weight loss and improving metabolic complications. However, adverse central nervous system side effects of rimonabant including depression and anxiety precluded introduction of this drug into clinical practice.

Complementary and alternative medications such as herbs, vitamins, nutritional supplements, and meal replacement therapies are commonly used by the general public for weight loss. However the efficacy and safety of these herbal remedies has not been well studied. A recent meta-analysis of trials found that compounds containing ephedra, *Cissus quadrangularis*, ginseng, bitter melon, and zingiber had some short-term efficacy with weight loss with mostly mild adverse effects. However, longer-term randomized controlled trials are needed to prove efficacy and safety.

**B. Bariatric surgery** Surgical treatment for weight loss has been performed for the past 50 years, and these procedures are increasing in popularity. Approximately 20,000 weight-loss surgeries were performed in 1995 and over 140,000 were done in 2004, a sevenfold increase. There are three main types of bariatric surgeries: restrictive, malabsorptive, and those that have both a restrictive and a malabsorptive component. Purely restrictive surgeries include horizontal gastroplasty, vertical banded gastroplasty, silastic ring vertical gastroplasty, and adjustable gastric banding. Purely malabsorptive surgeries include the oldest of all bariatric procedures, the jejunoileal bypass, biliopancreatic diversion, duodenal switch, and long limb gastric bypass. The combination of restrictive and malabsorptive surgical procedure is the most commonly used bariatric surgery worldwide, the Roux-en-Y gastric bypass procedure (RYGB), which involved stapling the upper stomach into a small 30-mL pouch and attaching it to the jejunum bypassing the lower stomach and duodenum. This procedure can be done with an open surgical approach, or now more commonly with a laparoscopic approach.

Several studies have examined the effects of different types of bariatric surgeries on various outcomes including weight loss, comorbid disease, complication rates, and mortality. There are very few randomized controlled trials comparing different surgical procedures, so most of the outcomes data come from case series, prospective cohort analyses, or nonrandomized trials. The largest and longest double cohort study to date is the Swedish Obese Subjects (SOS) study in which obese adults who voluntarily underwent bariatric surgery were matched to a control group of medically treated patients. After 10 years of follow-up of 1703 participants, those treated with surgery had a 16% weight loss compared to 2% in the controls (*p < 0.001*). They compared the different types of bariatric surgery approaches in this study and found that those who had gastric bypass lost more weight than those who received banding procedures or the vertical banded gastroplasty.

An earlier meta-analysis determined the effect of bariatric surgery on weight loss, mortality, and four comorbid diseases including diabetes, hyperlipidemia, hypertension, and sleep apnea. The mean excess weight loss was 61.2% (58.1%-64.4%), highest in those who had the biliopancreatic diversion or duodenal switch (70.1%) and lowest in those who underwent gastric banding (47.5%). Operative mortality within 30 days of the surgery was 0.1% for purely restrictive procedures and 0.5% for gastric bypass, and 1.1% for biliopancreatic diversion or duodenal switch procedures. Type 2 diabetes resolved in approximately 77% of patients after surgery, hyperlipidemia improved in 70%, hypertension resolved in 62%, and obstructive sleep apnea resolved in 86%.

Much attention has focused on determining the mechanisms involved in the dramatic weight loss associated with bariatric surgery. Previous hypotheses that restrictive procedures reduce the quantity of food ingested at any one time, malabsorptive procedures cause wasting of fat calories, with RYGB employing a combination of both mechanisms, have not been supported by studies. More recent thinking attributes weight loss after bariatric procedures to a substantial decline in hunger and increase in satiety that is regulated through neuroendocrine mechanisms and gut hormones such as ghrelin and PYY. The effect of RYGB surgery on ghrelin levels is controversial since some studies have found increased levels, no change, or decreased levels after surgery. These inconsistent results may be explained by the timing of ghrelin sampling after surgery. After purely restrictive surgeries, ghrelin levels increase, which may help explain the more dramatic weight loss observed following RYGB vs purely restrictive surgeries. PYY levels rise to those of a nonobese person following vertical banded gastroplasty. However, with RYGB, there is an early exaggerated response in PYY secretion, approximately two- to fourfold greater than that observed in lean, obese, or gastric banded patients, which may contribute to the sustained weight loss seen with this type of procedure.

Defining appropriate patient criteria to minimize risks and maximize the benefits from bariatric surgery have been debated. Some studies have concluded that surgical intervention is more effective for weight loss and control of comorbid diseases than nonsurgical treatments in patients with a BMI ≥40 kg/m². In 2004, with extensive scientific input, the National Coverage Advisory Committee panel concluded that bariatric surgery could be offered to Medicare beneficiaries with BMI ≥35 kg/m² who have at least one comorbid disease associated with obesity and have been unsuccessful previously with medical treatment of obesity. Other criteria for patient selection proposed by leading associations include adequate patient commitment with medical follow-up and use of dietary supplements, no other reversible endocrine disorders causing obesity, no current substance abuse, and no severe psychiatric illness.

**C. Interventions with efficacy in children** Several studies have investigated behavioral and lifestyle intervention programs for pediatric weight loss. Most randomized controlled trials of overweight children and adolescents have found positive, but small- to -moderate effects, of combined lifestyle interventions on BMI. Family-based behavioral weight loss programs have produced larger effects that persist for several months of follow-up. Less is known about the long-term safety and efficacy of pharmacologic agents for treatment of pediatric obesity.

HUMORAL MANIFESTATIONS

Some of the most challenging endocrine problems occur in patients with malignancies of diverse cell types, because both endocrine and nonendocrine tumors secrete polypeptide hormones. As it became recognized that a polypeptide hormone could be produced by tumor cells derived from a tissue that normally did not secrete the hormone, the notion of ectopic hormone production developed. Most tumors associated with ectopic hormone syndromes are derived from cells that are normally capable of producing peptide hormones. Initially, it was thought that ectopic hormone production by tumor cells was a rare event. Interestingly, both the frequency and the original conception of this syndrome have been redefined over the last few decades. It has come to be appreciated—through the use of modern biochemical and molecular biologic techniques—that the synthesis of peptide hormones and the transcription of their genes by tumor cells are in fact quite common occurrences. Tumor cells may differ from normal cells in their ability or inability to process precursor molecules, which may account for the presence or absence of hormone excess states and for the profile of peptide hormone forms and fragments present in the circulation and in tumor cell extracts. However, tumor production of hormone fragments or precursors is much more common than the clinical syndromes of hormone excess.

The classic criteria used to confirm that a tumor is the source of a hormone excess state include the following: (1) evidence of an endocrinopathy in a patient with a tumor; (2) remission of the endocrinopathy after tumor resection; (3) detection of an arteriovenous gradient across the tumor; and (4) documentation of protein and messenger RNA encoding the hormone being produced by tumor tissue.

In addition to classic hormone excess states resulting from the ectopic or inappropriate secretion of a hormone by an endocrine or nonendocrine tumor, endocrinopathies can result from the ectopic expression of a hormone's receptor. This is well illustrated, for example, by the occurrence of Cushing syndrome in pregnancy or in relation to meals, due to the ectopic expression of luteinizing...

hormone (LH) or gastric inhibitory polypeptide receptors in adrenal tissue, respectively. Several other examples of ectopic receptor syndromes have been documented. Some of these will be discussed later, particularly as a cause for unusual forms of adrenocorticotropic hormone (ACTH)-independent Cushing syndrome.

A variety of peptides are produced by both benign and malignant tumors as listed in Table 21–1. The biochemical pathways and machinery leading to the synthesis, processing, and secretion into the circulation of a peptide hormone are present in all cells. In contrast, the multiple enzymatic steps that lead to the production of a highly active steroid hormone (eg, cortisol or 1,25-dihydroxyvitamin D [1,25-(OH)2 D]) are restricted, with rare exceptions, to steroid-producing cells or their precursor cells. Hence, the occurrence of 1,25-(OH)2 D excess caused by a tumor is distinctly unusual, being observed infrequently in hematologic malignancies and only in those with the ability to 1-hydroxylate 25-OH D, the immediate precursor of 1,25-(OH)2 D. Ectopic hormone syndromes—the most common of the paraneoplastic syndromes—thus predominantly reflect peptide hormone excess states. The most common ectopic peptide hormone syndromes are described in greater detail in subsequent sections of this chapter.

APUD Concept of Neuroendocrine Cell Tumors

Over the years since the initial recognition that nonendocrine tumors were the source of the ectopic hormones produced in these endocrine syndromes, the notion developed that the hormones originated from highly specialized neuroendocrine cells in tumors. These cells were thought to derive from the neural crest and were postulated to be able to synthesize and store biogenic amines and were thus designated as amine precursor uptake and decarboxylation (APUD) cells. Neuroendocrine cells, like calcitonin-secreting C cells and adrenal chromaffin cells, clearly had these properties, and tissues giving rise to ectopic hormone syndromes (eg, lung and gastrointestinal tract) also had APUD cells scattered throughout them. It was originally thought that the tumor cells producing excessive amounts of polypeptide hormones were derived exclusively from APUD cells in the tissue of origin (eg, ACTH-producing cells of the lung).

Newer insights into tumor cell biology have led to a better understanding of the pathogenesis and etiology of the ectopic hormone production states. Studies have shown that not all APUD cells are derived from the neural crest. Some of these cells are of endodermal origin. Furthermore, with careful examination of tumors, it has become clear that peptide hormones are often produced by non-APUD cells. It has, however, been appreciated that the clinically evident hormone hypersecretion states are typically caused by tumors that are in fact derived from APUD cells. These cells are the ones with full capacity to produce and store peptide hormones efficiently in dense secretory granules and then release biologically significant quantities of active hormones in circulating plasma.

HYPERCALCEMIA OF MALIGNANCY

Hypercalcemia is the most common paraneoplastic endocrine syndrome, occurring in 25% of malignancies. In the great majority of patients (98%), the identity of the tumor is apparent at the time of presentation, and the prognosis is poor, as most patients with hypercalcemia of malignancy do not survive beyond 6 months.

Pathogenesis

Elevated serum calcium levels result primarily because of excessive osteoclast-mediated bone resorption. Ectopic hormones produce this effect in bone via two distinct mechanisms: (1) humoral effects of systemically elevated tumor-derived factors and/or (2) local effects of peptide hormones produced by tumor cells within the marrow. When the syndrome of hypercalcemia of malignancy was first described, local effects within bone tumors were thought to be causative. However, in the 1980s, a humoral basis was identified as the most frequent cause (80%), even in settings where focal lytic bone metastases were present. Decreased renal calcium excretion may also contribute to pathogenesis, either because of the hypocalciuric effects of certain humoral mediators of hypercalcemia, such as parathyroid hormone (PTH)-related protein (PTHrP) (discussed later), or because of the decreased glomerular filtration that occurs with hypercalcemia-induced nephrogenic diabetes insipidus.

Humoral Mediators

A humoral cause of hypercalcemia of malignancy was first proposed by Fuller Albright in the 1940s when describing a case
occurring in the absence of significant bone metastases. It would take another 50 years for this humoral factor to be identified. It was appreciated early on that the basic biochemical parameters of this syndrome (high serum calcium, low serum phosphorus, elevated nephrogenous cAMP) were suggestive of ectopic PTH production. However, PTH was not the culprit, as serum PTH levels in these cases were actually suppressed. Ultimately, and unlike most other paraneoplastic endocrine syndromes that are caused by well-described hormones of known function, a novel peptide, PTH-related protein (PTHRP), was identified as the humoral mediator of this syndrome in a majority of cases.

As denoted by its name, PTHrP has much in common with PTH. PTHrP was initially so named because of shared biochemical and metabolic effects with PTH. The amino terminal portion of PTHrP bears strong homology to PTH, such that the two peptides bind with similar affinity to PTH receptors (now known as the PTH/PTHRP-1 receptor subtype) in bone and kidney. Therefore, the biochemical markers of PTHrP-mediated hypercalcemia in vivo, when it is produced by tumors in an unregulated fashion, are similar to those of hyperparathyroidism. Some unexplained differences, however, are seen in PTHrP-mediated hypercalcemia of malignancy (vs primary hyperparathyroidism), including normal or suppressed 1,25-(OH)₂ D levels and an uncoupling of bone resorption and formation that results in severe bone loss. The reasons for these differences are not understood but are speculated to include: (1) the ability of chronic PTHrP (vs intermittent PTH) stimulation or profound hypercalcemia per se to suppress 1,25-(OH)₂ D levels; and (2) the contributions of additional tumor-derived cytokines, such as interleukin (IL)-1α or IL-6, to the process of bone resorption.

Subsequent study of this previously unknown peptide has demonstrated that PTHrP and PTH actually diverge in many critical ways, beginning evolutionarily. Both hormones arose from ancient duplication of a common gene, but evolved separately such that in higher vertebrates, PTH now regulates calcium homeostasis, while PTHrP has critical developmental roles, including endochondral bone growth, tooth eruption, and development of the mammary gland and cardiovascular system. As with other developmentally regulated proteins, PTHrP plays less of a role in adult homeostasis, but can be reexpressed in response to specific changes in gene programming, including pregnancy (calcium regulation by the lactating mammary gland and placenta), injury and inflammation (regulation of vascular tone in ischemia, sepsis, and inflammation-associated bone resorption), and/or tumorigenesis (hypercalcemia of malignancy).

When tumor expression of PTHrP results in inappropriately high levels of PTHrP that reaches bone cells through the circulation or following synthesis in the bone microenvironment, a vicious cycle can ensue. PTHrP stimulates the expression of RANKL (receptor activator of NF-κB ligand) by osteoblasts. RANKL, the primary gatekeeper modulating bone resorption in health and disease, stimulates osteoclast differentiation and function via binding to its receptor, RANK, on osteoclasts and their precursors. Increased numbers of activated osteoclasts are generated both by the local release of PTHrP, in the case of bone metastases, or by high levels of the hormone produced by tumor cells in extraskeletal sites. Both mechanisms cause enhanced bone resorption. In the case of bone metastases, sequestered growth factors, such as transforming growth factor (TGF)-β1, released locally from the bone matrix during resorption, further enhance tumor cell secretion of PTHrP.

Although PTHrP is by far the most common mediator of hypercalcemia of malignancy, other calcitropic hormones can also cause the syndrome. When hypercalcemia occurs with lymphoma, increased circulating levels of 1,25-(OH)₂ D are a common cause, due to increased 1α-hydroxylase activity in lymphoproliferative cells and/or tumor-adjacent macrophages. Other tumor-derived bone-resorbing factors, such as prostaglandins, may also contribute to hypercalcemia of malignancy with certain tumors, like renal cell carcinoma. In contrast, ectopic production of PTH is extremely rare, but has occasionally been reported for neuroendocrine tumors and other solid tumors.

### Solid Tumors Associated with Hypercalcemia of Malignancy

The majority of cases of hypercalcemia occurring with solid tumors (80%) are associated with two common tumor types: squamous cell lung carcinoma and breast carcinoma (see Table 21–1). Hypercalcemia is also frequently seen in renal cell carcinoma. Indeed, PTHrP was first isolated and identified by independent research groups each using one of these three tumor types. In contrast, hypercalcemia is rarely seen in other commonly occurring cancers (eg, colon, gastric, thyroid, and small cell lung carcinomas), including some tumors that are frequently metastatic to bone (eg, prostate cancer).

#### A. Squamous cell carcinomas

Squamous cell carcinomas account for more than one-third of all cases of hypercalcemia of malignancy. Humoral effects of tumor-derived PTHrP account for most cases of hypercalcemia in this setting, even when bone metastases are present. Twenty-five percent of patients with squamous cell lung carcinomas develop PTHrP-mediated hypercalcemia, and other sites of squamous cell carcinoma (head, neck, esophagus, cervix, vulva, and skin) are similarly associated with a high incidence of hypercalcemia.

#### B. Breast carcinoma

The majority of patients with breast cancer bone metastases (ie, 70% of those with advanced disease) do not have hypercalcemia. However, hypercalcemia does occur in 30% of advanced-stage breast carcinoma cases and is only rarely seen in the absence of bone metastases. PTHrP is causative, as both a local and/or humoral factor to stimulate bone resorption. Most breast cancer bone metastases (92%-100%) express PTHrP and cause lytic bone destruction. In addition, humoral effects of PTHrP, as evidenced by elevated circulating levels of PTHrP associated with increased nephrogenous cAMP, have been documented in a majority of cases of hypercalcemia occurring in the absence of bone metastases and two-thirds of those cases occurring with bone metastases.

Despite this close association of PTHrP with advanced disease, the prognostic significance of PTHrP expression in primary breast
carcinomas, which has been documented in two-thirds of primary tumors in multiple series, is not clear. Reasons for the lack of a simple direct correlation are probably multifactorial and may include: (1) the ability of tumors to modulate PTHrP expression once they metastasize to bone (eg, TGF-beta released from the bone matrix by invading tumor cells is thought to enhance PTHrP expression in the tumor cells, even when the primary tumor is PTHrP-negative); and (2) the tendency for expression of PTHrP to correlate with estrogen receptor and progesterone receptor status, which influences treatment and response to therapy. Additionally, locally produced bone cytokines such as IL-1alpha, IL-6, and tumor necrosis factor (TNF)-alpha likely act in concert with PTHrP at sites of bone metastases to enhance osteoclast activity. Additionally, locally produced bone cytokines such as IL-1alpha, IL-6, and tumor necrosis factor (TNF)-alpha likely act in concert with PTHrP at sites of bone metastases to enhance osteoclast-mediated lytic bone destruction and thus contribute to hypercalcemia. Hypercalcemia seen in late stages of breast cancer is usually unremitting and associated with a survival time of weeks to months.

C. Renal cell carcinoma  Renal cell carcinoma, while less common than squamous cell or breast carcinoma, is also frequently associated with hypercalcemia in advanced cases. While bone metastases are common in advanced disease, hypercalcemia appears to be due primarily to humoral effects of PTHrP. In some series, 100% of renal cell tumors have been reported to stain positively for immunoreactive PTHrP. However, hypercalcemia is reported in less than 20% of cases.

D. Other solid tumors  Hypercalcemia is also associated with other solid tumors, although less frequently. In most of these cases, humoral effects of PTHrP are causative. Bladder carcinoma, large cell and adenocarcinoma of the lung, and endocrine tumors (including islet cell tumors, pheochromocytoma, and carcinoid tumors) have also been reported to secrete PTHrP. PTHrP-mediated hypercalcemia has also been reported for ovarian carcinomas. A case of ectopic PTH production by an ovarian carcinoma has also been reported.

### Hematologic Malignancies Associated with Hypercalcemia of Malignancy (Table 21-2)

#### A. Multiple myeloma
Hypercalcemia and lytic bone lesions are among the diagnostic criteria for multiple myeloma, a hematologic malignancy characterized by infiltration of the bone marrow with malignant plasma cells. Lytic bone lesions and active bone resorption occur adjacent to tumor cells, which secrete multiple factors capable of stimulating osteoclast differentiation and activity. A major effect of these factors, which include macrophage inflammatory peptide-1, TNF-alpha, IL-1, and IL-6, is to induce RANKL expression in osteoblasts. Evidence of RANKL expression by plasma cells also exists. Locally increased RANKL causes bone lysis by binding to its cognate receptor on osteoclasts (RANK) and stimulating their differentiation and activity. More recently, it has been appreciated that defects in bone formation, due to suppression of the Wnt signaling pathway by other tumor factors (eg, Dickkopf-1), also accompany lytic bone disease in multiple myeloma. In 30% of cases, bone lysis leads to hypercalcemia. Because renal disease occurs frequently in myeloma due to the filtration of Bence Jones proteins (light chain fragments of IgG), it is hypothesized that patients with renal impairment may be particularly predisposed to development of hypercalcemia in this setting of increased bone resorption.

#### B. Lymphoma and leukemia
Hypercalcemia has been reported in up to 15% of patients with lymphoma; is seen primarily in patients with bone involvement; and can occur with a variety of cell types. In most cases, the etiology is evenly divided between: (1) local lytic effects of tumor-derived factors within the marrow, analogous to the mechanisms discussed for myeloma, or (2) humoral effects of tumor-derived 1,25-(OH)2D. D1, 25(OH)2D-mediated hypercalcemia of malignancy is unique to lymphoma. Its underlying pathology is analogous to that seen in hypercalcemia in granulomatous disorders where 1α-hydroxylase activity in the abnormal hematopoietic cells or infiltrating macrophages results in unregulated conversion of 25-(OH)2D to active 1,25-(OH)2D. D. Increased intestinal calcium absorption and increased bone resorption are both thought to contribute to hypercalcemia in this setting. In addition, there are also numerous case reports of humoral effects of tumor-derived PTHrP as a cause of hypercalcemia in non-Hodgkin lymphomas (particularly B cell), acute lymphoblastic leukemia, and blast crises in chronic myeloid leukemia. So the clinician confronting such tumors must be cognizant of the different etiologies for the observed hypercalcemia.

Patients diagnosed with adult T cell leukemia or lymphoma induced by HTLV-1 (human T cell lymphotrophic virus-1), the first identified human retrovirus, must be considered separately

The diagnosis of hypercalcemia is discussed in detail in Chapter 8. Primary hyperparathyroidism and hypercalcemia of malignancy account for more than 90% of all causes of hypercalcemia. Because the incidence of primary hyperparathyroidism is twice that of hypercalcemia of malignancy, primary hyperparathyroidism must always be considered as a potential cause of hypercalcemia in patients with malignancy and can be screened for by simply determining intact PTH levels using a standard two-site immunoradiometric assay. In the setting of hypercalcemia of malignancy with normal renal function, PTH levels are suppressed. Further evaluation can be guided, in part, by the tumor type, which is usually known prior to presentation with hypercalcemia. Elevated PTHrP is detected in a majority of cases of hypercalcemia of malignancy associated with solid tumors, including breast carcinoma with or without bone metastases, and in HTLV-1–induced T cell lymphomas. Measurement of 1,25-(OH)2 D should be considered in all cases of lymphoma-associated hypercalcemia. Lytic bone lesions are usually identified during tumor staging.

**Diagnosis**

The diagnosis of hypercalcemia is discussed in detail in Chapter 8. Primary hyperparathyroidism and hypercalcemia of malignancy account for more than 90% of all causes of hypercalcemia. Because the incidence of primary hyperparathyroidism is twice that of hypercalcemia of malignancy, primary hyperparathyroidism must always be considered as a potential cause of hypercalcemia in patients with malignancy and can be screened for by simply determining intact PTH levels using a standard two-site immunoradiometric assay. In the setting of hypercalcemia of malignancy with normal renal function, PTH levels are suppressed. Further evaluation can be guided, in part, by the tumor type, which is usually known prior to presentation with hypercalcemia. Elevated PTHrP is detected in a majority of cases of hypercalcemia of malignancy associated with solid tumors, including breast carcinoma with or without bone metastases, and in HTLV-1–induced T cell lymphomas. Measurement of 1,25-(OH)2 D should be considered in all cases of lymphoma-associated hypercalcemia. Lytic bone lesions are usually identified during tumor staging.

**Treatment**

The treatment of hypercalcemia is discussed in detail in Chapter 8. Because bone resorption is central to all causes of hypercalcemia of malignancy, bisphosphonates are currently a mainstay of therapy. Glucocorticoids may be efficacious in the treatment of hypercalcemia due either to the local lytic effects of neoplastic plasma cells in multiple myeloma or to the increased production of 1,25-(OH)2 D in lymphoma. Recent and ongoing clinical trials are also evaluating the utility of humanized antibodies directed against PTHrP or RANKL in preventing hypercalcemia and other adverse skeletal events in patients with multiple myeloma, breast cancer, and/or other solid tumors. While bisphosphonates are already a mainstay of palliative care for patients with hypercalcemia and have a demonstrated ability to decrease skeletal-related events (metastases and pathologic fractures) and ameliorate bone pain in these patients, their possible use as adjuvants in order to delay or prevent bone metastases in breast and other cancers is currently a very active area of clinical research.

**ECTOPIC CUSHING SYNDROME**

Many malignant tumors produce the ACTH precursor proopiomelanocortin (POMC) but lack the enzymes necessary to process this precursor to biologically active ACTH. Therefore, only a fraction of such tumors release sufficient ACTH to cause Cushing syndrome. Initially, the tumors recognized to cause this syndrome were of nonpituitary but endocrine origin, such as islet cell carcinomas and pheochromocytomas. Subsequently, a wide variety of different tumor cell types, both endocrine and nonendocrine, have been associated with the ectopic ACTH syndrome.

The classic description of the ectopic ACTH syndrome was made by Grant Liddle and coworkers in the early 1960s and was based on a series of patients who mostly had highly malignant tumors (eg, small cell carcinoma of the lung). More recently, the ectopic ACTH syndrome has been recognized with increasing frequency with benign tumors, specifically carcinoids. Benign lesions typically present in a more subtle clinical manner, often over months to years, before the tumor is identified. The more gradual development of the clinical syndrome plus the more subtle biochemistry have led to considerable challenges in distinguishing this form of the ectopic ACTH syndrome from pituitary tumors causing Cushing disease. This subtle variant of tumor-induced ACTH excess has been dubbed the occult ectopic ACTH syndrome. In addition, it is now recognized that tumors can cause an ectopic ACTH-like syndrome through production of corticotropin-releasing hormone (CRH). Indeed, some of the tumors that make the latter cosecrete ACTH as well. Ectopic CRH production has been seen in bronchial carcinoids, medullary thyroid carcinoma, and metastatic prostatic cancer.

**Differential Diagnosis**

Cushing syndrome—signs and symptoms resulting from unregulated production of glucocorticoids—is caused by a number of underlying disturbances. These must be differentiated to ensure successful treatment. Causes include pituitary ACTH-dependent Cushing disease, adrenal tumors or ACTH-independent Cushing syndrome, and the ectopic ACTH syndrome. In several large series, 50% to 80% of patients with Cushing syndrome have a pituitary cause. Adrenal adenomas (and very rarely carcinomas) account for 5% to 30% of cases of Cushing syndrome. The ectopic ACTH syndrome comprises approximately 10% to 20% of cases of Cushing syndrome.

A wide variety of tumors cause ectopic ACTH syndrome (Table 21–3). In the classic and initial descriptions of this syndrome, there was a preponderance of malignant tumors, particularly small cell carcinomas of the lung. It is now clear that most cases of ectopic ACTH syndrome are due to benign tumors. Most recently, microscopic carcinoid tumorlets, particularly in the lung, have been recognized to cause occult ectopic ACTH syndrome. These tumors may be exceptionally difficult to diagnose by standard techniques.

The diagnosis of Cushing syndrome requires a rigorous approach. Cushing syndrome should be suspected first on solid clinical grounds and then established biochemically. This is accomplished by demonstrating the presence of hypercortisolism—a frankly elevated 24-hour urinary free cortisol level or the lack of suppression of plasma cortisol levels after a 1-mg overnight dexamethasone suppression test (see Chapter 9). In Cushing syndrome due to any cause and often in ectopic ACTH syndrome, random cortisol levels are elevated. Once hypercortisolism is established, plasma ACTH levels are measured. These levels are

markedly elevated in classic forms of the ectopic ACTH syndrome, typically secondary to malignant lung neoplasms. There is, however, considerable overlap between the milder cases of the ectopic ACTH syndrome, caused by benign and slowly growing tumors, and Cushing disease due to a pituitary tumor. In the former case, the tumors are often small and clinically silent—hence the descriptor occult ectopic ACTH syndrome. For these reasons, rigorous biochemical criteria must be applied in appropriate clinical situations to make certain that the correct diagnosis is made.

Plasma ACTH levels in patients with clinically evident tumors are often strikingly elevated (390-2300 pg/mL [87-511 pmol/L] by radioimmunoassay). Individuals with ectopic ACTH syndrome due to occult tumors have ACTH levels that overlap with pituitary-dependent Cushing disease (42-428 pg/mL [9.3-95 pmol/L]). It is said that patients with plasma ACTH levels greater than 200 pg/mL (44.4 pmol/L) typically have the ectopic ACTH syndrome, although further testing is required to prove this and to localize the tumor.

After hypercortisolism and ACTH excess are established, the degree of suppressibility of ACTH with exogenous glucocorticoid is determined. In classic Cushing disease due to a pituitary tumor, supraphysiologic doses of dexamethasone usually suppress the elevated plasma ACTH and cortisol levels. Tumors responsible for the ectopic ACTH syndrome are classically unresponsive to these same doses of dexamethasone. High-dose dexamethasone suppression testing, as this diagnostic maneuver is called, is accomplished by (1) administering 2 mg of dexamethasone every 6 hours for 2 days and measuring urinary free cortisol or plasma cortisol on the second day, or (2) administering 8 mg of dexamethasone the night before obtaining an 8 AM plasma cortisol level. In both tests, the expected suppression of baseline urinary free cortisol and plasma cortisol should be 50% or greater if the Cushing syndrome is due to a pituitary adenoma (i.e., Cushing disease). However, between 15% and 33% of patients with ectopic ACTH syndrome also meet these suppression criteria (false positives), mimicking Cushing disease. In addition, 10% to 25% of patients with Cushing disease fail to suppress with high-dose dexamethasone (false negatives). The overnight test probably has greater sensitivity and accuracy than the classic 2-day test, but neither test is considered useful any longer (see Chapter 9).

Additional provocative tests have been developed to improve the diagnostic discrimination between Cushing disease and ectopic ACTH syndrome using ovine CRH. Pituitary corticotrophs are normally responsive to CRH in Cushing disease and unresponsive when ectopic ACTH production or an adrenal lesion is responsible for the cortisol excess. A positive response to CRH is defined as a 50% or greater increase in plasma ACTH and a 20% or greater increase in the plasma cortisol concentrations in the periphery. An increase in ACTH of 100% and in cortisol of more than 50% greatly reduces the likelihood of ectopic ACTH syndrome; however, false-positive and false-negative tests (up to 10%) have been reported. Moreover, in the rare instance of ectopic production of CRH (without concomitant ACTH) by a tumor, a false-positive result may be seen, leading to the erroneous diagnosis of pituitary-dependent Cushing disease.

For these reasons, most centers prefer inferior petrosal sinus sampling for ACTH before and after CRH administration, and this test is now the gold standard. The inferior petrosal sinuses drain the pituitary gland. Concomitant peripheral and petrosal sinus samples are obtained and the central: peripheral ACTH ratio is calculated. In Cushing disease, the ratio should be greater than or equal to 2.0 in the basal state. After CRH administration, this ratio should be greater than or equal to 3.0 in pituitary-dependent Cushing disease. In the ectopic ACTH syndrome, the basal ratio is typically less than 2 and does not rise after the CRH. In rare instances of ectopic CRH syndrome, the basal ratio may be 2.0. The stimulation by CRH gives close to 100% discrimination between ectopic ACTH production and a pituitary tumor secreting ACTH. Generally, a combination of tests is performed to reach a biochemical diagnosis before extensive radiologic studies are undertaken.

The majority of patients (70% or more) with ectopic ACTH syndrome also cosecrete other hormones or tumor marker peptides, among them are carcinoembryonic antigen, somatostatin,
calcitonin, gastrin, glucagon, vasoactive intestinal peptide (VIP), bombesin, pancreatic polypeptide, alpha-fetoprotein, and many others. The presence and secretion of these other hormones (in addition to ACTH) suggests that the source of ACTH is nonpituitary in these patients. Given the variety of peptides and the expense inherent in any screening paradigm, measuring these hormones in patients suspected of ectopic ACTH syndrome is not recommended.

The path to localize the tumor responsible for ectopic ACTH production generally starts with a chest radiograph. Most tumors are in the chest or abdomen. Small cell carcinomas of the lung are usually visible on chest radiograph, whereas bronchial carcinoids are often difficult to detect on plain radiographs. In some situations, these tumors may require a long period (as many as 4 or 5 years) of close follow-up before the tumors are detected. Chest computed tomography (CT) scanning should be employed in all subjects with ectopic ACTH to rule out a chest or mediastinal lesion (such as a thymic carcinoid). Abdominal CT scanning is also performed in these patients to confirm the presence of bilateral adrenal enlargement, a sine qua non of the ectopic ACTH syndrome, and to screen for other possible abdominal tumors responsible for the syndrome (eg, pheochromocytoma, islet cell tumor). In the radiologic evaluation of Cushing syndrome, it is always important to bear in mind that the presence of a pituitary microadenoma on magnetic resonance imaging (MRI) does very little to support the diagnosis of pituitary-dependent Cushing disease—as opposed to an ectopic tumor producing ACTH—because of the great numbers (10%–20%) of normal individuals with incidental pituitary microadenomas (see Chapter 4).

OctreoScan scanning, another important diagnostic technique, can successfully localize tumors responsible for ectopic ACTH production because up to 80% of such tumors express somatostatin receptors. Iodinated or, more recently, indium-111\(^{[111\text{In}]}\)-labeled octreotide scanning has demonstrated medullary carcinomas of the thyroid, small cell lung cancers, islet cell tumors, pheochromocytomas, and other tumors.

The ideal imaging algorithm for occult tumors causing ectopic ACTH syndrome is controversial. Functional imaging with higher than standard doses of the somatostatin analog \([{[111\text{In}]}\)-diethylenetriamine pentaacetic acid-D-Phe-pentetreotide (OctreoScan) or with \([\text{[18F]}\) fluorodeoxyglucose positron emission tomography (FDG-PET) was prospectively evaluated in 17 patients with the ectopic ACTH syndrome (based on inferior petrosal sinus sampling) in whom standard imaging studies were inconclusive. Nieman and colleagues found that FDG-PET did not uncover tumors that were not seen on CT or MRI scans. These investigators, however, found OctreoScans to be useful (enhanced sensitivity) in combination with CT/MRI imaging and advocated this diagnostic approach.

Clinical Features

Cushing syndrome causes truncal obesity, violaceous striae, hypertension, fatigue, glucose intolerance, osteopenia, muscle weakness, moon facies, easy bruising, buffalo hump, depression, hirsutism, and edema. Patients with ectopic ACTH syndrome may show some, all, or none of these features depending on the underlying tumor. It has been appreciated from the initial descriptions of this syndrome that these patients typically present with myopathy, weight loss, and electrolyte and metabolic disturbances more commonly than with the classic features of slowly developing Cushing disease. Hyperpigmentation is also recognized as more common in the ectopic ACTH syndrome than in Cushing disease. Cortisol excess in older men, especially those at risk for lung tumors, is most commonly due to ectopic ACTH production, whereas ACTH-producing pituitary tumors predominate in young and middle-aged women. Glucose intolerance or frank diabetes and hypokalemic alkalosis are typical metabolic disturbances of the ectopic ACTH syndrome. Because of the extreme elevation in plasma cortisol levels in many of these patients, they are at considerable risk for and often succumb to overwhelming opportunistic infections, often with fungal pathogens.

A critical caveat to remember in the clinical evaluation of patients with ACTH-dependent Cushing disease is that slowly growing and occult tumors producing ACTH may present in exactly the same way as classic Cushing disease due to a pituitary tumor. Therefore, both the clinical findings and the laboratory studies summarized earlier show considerable overlap and may engender confusion in distinguishing these occult tumors from a pituitary lesion.

Increasing numbers of patients who have classic features of Cushing syndrome have been shown to have abnormal expression of receptors in their adrenal glands as the cause of their hypercortisolism. The pathophysiology of this form of Cushing syndrome is ACTH-independent, because other hormones are driving the glucocorticoid hypersecretion. This has been likened by Lacroix and colleagues to a *gain of function* mutation causing constitutive activation of a G protein-coupled receptor. Ectopic expression of receptors for gastric inhibitory peptide, vasopressin (V\(_2\) and V\(_3\)), serotonin (5-HT\(_4\)), and ß-adrenergic agonists have been reported. Altered activity or greater expression of eutopic receptors for serotonin (5-HT\(_{3}\)), LH, and vasopressin (V\(_1\)) in adrenal tissue can also cause cortisol excess. In the case of gastric inhibitory peptide, food-stimulated cortisol hypersecretion has been described. In a case report of excessive LH receptor expression in the adrenals associated with macronodular adrenal hyperplasia, the patient had mild Cushingooid features with pregnancy and the gradual development of full-blown Cushing syndrome with menopause. It is noteworthy that many patients with ectopic or eutopic receptor-mediated Cushing syndrome have macronodular adrenal hyperplasia.

**SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE SECRETION**

The syndrome of inappropriate antidiuretic hormone (SIADH) secretion is characterized by inappropriate retention of water such that hypertonic or inappropriately concentrated urine is excreted in the presence of hyponatremia. There are many well-recognized causes of this syndrome (Table 21–4).
Clinical and Laboratory Features

SIADH is the most common cause of hyponatremia in hospitalized patients. It may present with symptoms due to water intoxication and hyponatremia. Although many patients are asymptomatic, depending on the magnitude and chronicity of their hyponatremia, symptomatic individuals usually have fatigue, headache, nausea, and anorexia initially, which can progress to altered mental status, seizures, coma, and even death. Most patients experience weight gain due to water retention but do not have edema. Significant clinical symptoms usually do not develop unless the serum sodium is 125 mEq/L or less, and there is usually a correlation between the level of symptomatology in these patients and their serum sodium values.

Patients with SIADH exhibit hyponatremia, serum hypoosmolality, a less than maximally dilute urine, and the presence of sodium in the urine. Clinically, the diagnosis of SIADH cannot be made unless there is euvoiemia with intact renal, adrenal, and thyroid function. Cirrhosis, nephrosis, and congestive heart failure must be excluded. Generally, the diagnosis is made by the presence of hyponatremia, low serum osmolality, and urine osmolality that is less than maximally dilute. Urinary sodium levels are usually high, and urea nitrogen levels are typically low, as are serum uric acid levels. Rarely is it necessary or even helpful to measure vasopressin levels to make this diagnosis. Although these determinations are available, they are even sometimes misleading, and routine testing is not recommended. It is also rarely, if ever, necessary to perform a water-loading test, which can be dangerous in these patients because of their impaired ability to excrete a free water load and their propensity to become water intoxicated. Once the diagnosis of SIADH is made, all possible causes should be considered (see Table 21-4).

Water restriction and demeclocycline are the traditional therapies. Several studies support the efficacy of vasopressin antagonists in the treatment of SIADH, and this approach may be considered. In acutely symptomatic patients or when the serum sodium is reduced to dangerously low levels, infusion of hypertonic saline and administration of loop diuretics (eg, furosemide) are the treatments of choice. Many patients with SIADH due to neoplasms improve and even remit with effective therapy for their underlying cancer.

Modified, with permission, from Verbalis JG. Disorders of body water homeostasis. Best Pract Res Clin Endo Metab. 2003;17:471.

Etiology and Pathogenesis

Tumors are a common cause of SIADH (see Table 21-4). Bronchogenic carcinoma, particularly small cell carcinoma, has been associated with this syndrome since its initial description in 1957. Small cell carcinoma accounts for 80% of lung tumors associated with SIADH, but only 3% to 15% of patients with this tumor have SIADH. Most of these tumors, even from patients without the clinical syndrome, contain ADH by immunostaining. Other tumors that cause the syndrome include breast, pancreatic, and thymic carcinomas in addition to those listed in Table 21-4. These tumors typically produce vasopressin, oxytocin, and the carrier protein neurophysin.

Excessive production of vasopressin by tumors leads to an inability to excrete free water. This is due to the fact that tumors release vasopressin independent of serum osmolality. In addition to the production of vasopressin, many tumors also contain the mRNA for the hormone atrial natriuretic peptide (ANP).

NON-ISLET CELL TUMOR-INDUCED HYPOGLYCEMIA

Tumor-induced hypoglycemia is rare, with the most common cause being eutopic insulin production by pancreatic islet cell tumors (insulinomas). Ectopic hormone production leading to tumor-induced hypoglycemia is estimated to occur in over 20% of cases, and is primarily due to overproduction of insulin-like growth factor-2 (IGF-2). Ectopic insulin secretion by tumors has only rarely been reported. Solid tumors of mesenchymal (mesothelioma, leiomyosarcoma, and fibrosarcoma) or epithelial origin (hepatoma) in the chest or abdomen are the most common source of ectopic IGF-2 (85%). These tumors are usually slow-growing and well-differentiated, often weighing over 2 kg at diagnosis.
Subtle signs of fasting hypoglycemia may be the presenting symptom in these cases, or hypoglycemia may be detected during the course of tumor treatment. As discussed fully in Chapter 18, signs and symptoms of fasting hypoglycemia include sweating, intense hunger, anxiety, altered consciousness, and visual and behavioral changes.

The first case suggestive of non-islet cell tumor IGF-induced hypoglycemia was described in 1929. However, the pathogenesis of this condition has been elucidated only in the last few decades in parallel with our increased understanding of IGF biology. IGF-2 gene expression is increased in these tumors; however, posttranslational processing is disrupted such that the majority of circulating IGF-2 is a precursor pro-IGF-2 protein (big IGF-2). Big IGF-2 is less likely to form normal ternary complexes with IGF-binding proteins (IGF-BP), and therefore is more bioavailable. In addition, it is postulated that big IGF-2 may displace normal IGF-1 and IGF-2 from IGF-BP, as free levels of these hormones are also increased in some patients. In addition, big IGF-2 is thought to feedback inhibit growth hormone (GH) secretion, thus resulting in even lower levels of IGF-BP. This vicious cycle thus enhances the bioavailability of free IGF peptides whose affinity for the insulin receptor is only 10-fold lower than that of insulin itself. The typical hormonal profile of patients with this syndrome thus includes suppressed levels of insulin, C-peptide, and total IGF-1; and normal or only slightly elevated levels of total IGF-2, while levels of free IGF-2 are markedly (20-fold) increased.

Stimulated glucose disposal in skeletal muscle by IGF binding to the insulin receptor is thought to be a major contributor to hypoglycemia in this syndrome. Diminished hepatic glucose production may also contribute to hypoglycemia, either due to hepatic insulin receptor-mediated IGF effects and/or direct infiltration of the liver by tumor. While GH levels are suppressed, some acromegalic features, thought to be secondary to IGF-2 binding to the type 1 IGF receptor, can also be present (skin tags, rhinophyma).

Treatment of this paraneoplastic syndrome usually involves curative resection or debulking of the tumor. Preoperatively, patients often require continuous glucose infusions to control their symptoms, and glucagon can be used acutely to raise blood-glucose levels. If the lesion is benign, surgery usually brings relief of the hypoglycemia or even definitive cure. In the absence of a surgical cure, additional palliative measures to control hypoglycemic symptoms have been used with some success, including (1) glucocorticoid treatment to suppress tumor production of IGF-2 and induce hepatic gluconeogenesis, and/or (2) GH treatment to increase serum levels of IGF-BP, as well as to induce hepatic gluconeogenesis.

**OTHER HORMONES SECRETED BY TUMORS**

**1. GROWTH HORMONE–RELEASING HORMONE AND GROWTH HORMONE**

Acromegaly, in over 95% of cases, is due to eutopic production of GH by pituitary adenomas. Ectopic GH overproduction is extremely rare, but has been reported for pancreatic islet cell tumors, a bronchial carcinoid tumor, and also by a non-Hodgkin lymphoma. In contrast, ectopic production of GHRH is more common and accounts for 1% of cases of acromegaly. Ectopic secretion of growth hormone–releasing hormone (GHRH) was first described in 1974. Indeed, this hypothalamic hormone was first isolated a decade later from patients with pancreatic GHRH-producing tumors. Extrapituitary tumors produce several biologically active forms of GHRH (37-, 40-, and 44-amino acids) as compared to hypothalamic GHRH (1-40) or (1-44) peptides. Excessive peripheral production of GHRH causes hyperplasia of somatotrophs in the pituitary. Resultant elevated levels of circulating GH and IGF-1, lack of suppression of GH by an oral glucose load, and clinical features of acromegaly in this setting are indistinguishable from those caused by GH-secreting pituitary adenomas (see Chapter 4). Ectopic GHRH as a cause of acromegaly can be simply and specifically diagnosed by documentation of elevated circulating GHRH levels. However, because ectopic GHRH is rarely a cause of acromegaly, this assay is best reserved for atypical presentations associated with additional signs and symptoms specific to those tumors that are the most frequent source of ectopic GHRH (carcinoid and pancreatic tumors). It should also be noted that in rare instances, hypothalamic GHRH-secreting tumors (hamartomas, gliomas, and gangliocytomas) can also produce excessive GHRH and acromegaly. Because the site of GHRH production is within the hypothalamus, these cases do not represent ectopic GHRH secretion. Moreover, from a diagnostic standpoint, circulating GHRH levels in these cases are not elevated.

Carcinoid tumors of the lung, gastrointestinal tract, and thymus are the most frequent peripheral source of GHRH (66%). Interestingly, while 50% of carcinoid tumors are immunoreactive for GHRH, a minority of these tumors are associated with elevated circulating levels of bioactive GHRH. Slow-growing GHRH-producing carcinoid tumors, the majority of which are bronchial in origin, are responsible for an insidious presentation of acromegaly that is often associated with additional symptoms specific to the tumor (eg, wheezing). These tumors can be easily detected by routine imaging. Pancreatic islet cell tumors are the second leading cause of ectopic GHRH secretion. Other tumors associated with this syndrome include small cell lung cancer, adrenal adenoma, pheochromocytoma, medullary thyroid carcinoma, endometrial cancer, and breast cancer. Because somatostatin receptors are often present in GHRH-secreting tumors, octreotide scanning may be helpful in localization of extra-pituitary tumors. In addition to surgical resection, the management of ectopic GHRH-induced acromegaly can also include treatment with somatostatin analogs, particularly those that bind to multiple somatostatin receptor subtypes.

**2. CALCITONIN**

Calcitonin and its precursor, procalcitonin, are frequently produced by malignancies (10%-30%). Consistent with our lack of knowledge regarding the precise physiologic role of calcitonin, there is often no clinical syndrome associated with its ectopic
production. However, after an initial diagnosis, calcitonin levels have been used as a tumor marker to follow responses to treatment. Neuroendocrine tumors are the primary cause of both eutopic (medullary thyroid carcinomas, as discussed in Chapters 7 and 24) or ectopic secretion of calcitonin. While small cell cancer is the lung malignancy most frequently (60%) associated with calcitonin hypersecretion, at least 20% of all lung malignancies may have associated elevated calcitonin levels. This is believed to be due either to tumors arising from the pulmonary neuroendocrine cells (small cell and carcinoid) or to calcitonin expression by neuroendocrine cells within or adjacent to tumor cells, as in large cell lung cancer. Calcitonin is also secreted by neuroendocrine tumors of the pancreas. In patients with these tumors, other hormones such as somatostatin and VIP are often produced as well. Approximately half of the patients with these tumors, in a small series by Fleury and colleagues, had diarrhea, presumably due to the effects of calcitonin alone or in combination with other gut peptides. A significant number of these tumors are malignant with liver metastases. In some cases, symptoms of diarrhea may respond to primary therapy of the tumor.

3. GONADOTROPINS

The gonadotropins (luteinizing hormone [LH], follicle-stimulating hormone [FSH], and human chorionic gonadotropin [hCG]) are composed of two (alpha and beta) subunits. The alpha subunits of these glycoproteins share a common amino acid sequence and differ only in their carbohydrate moieties, while their beta subunits are completely distinct. The first two hormones are pituitary products, and the latter is primarily a product of the trophoblastic cells of the placenta during pregnancy. However, hCG is also expressed in other normal tissues, including the pituitary, which appears to be the primary source of detectable circulating hCG in nonpregnant individuals. While LH and FSH are rarely produced ectopically, elevated circulating hCG levels can be produced by multiple tumor types including those of gonitourinary system (ovary, prostate, testes, bladder), lung cancers (particularly small cell cancers), gastrointestinal cancers (colon, pancreas, esophagus), breast cancer, melanomas, teratomas, and hepatoblastomas. Ectopic hCG production must be distinguished from eutopic secretion by trophoblastic tumors (hydatidiform mole, choriocarcinoma). However, in both cases, hCG can serve as an important tumor marker for initial diagnosis and monitoring for tumor size and/or evidence of recurrence.

Trophoblastic tumors often secrete excessive amounts of intact hCG heterodimers. In contrast, nontrophoblastic tumors primarily secrete lesser amounts of the free beta subunit of hCG. Serum hCG levels, which are detectable in 40% of ovarian or bladder cancers, often correlate with a less differentiated tumor cell phenotype and a poorer prognosis. Depending on the age and gender of the patient, the clinical signs and symptoms of hCG excess may vary. Importantly, not all patients manifest signs of their hCG excess. In susceptible individuals, however, elevated hCG may result in clear clinical findings. Children, for example, with malignant hepatoblastoma or pineal teratoma can present with precocious puberty. Women may have dysfunctional uterine bleeding. Men with high hCG levels may have signs of hypogonadism with impotence and gynecomasia. Because of the thyroid-stimulating effects of high hCG levels, these patients occasionally demonstrate hyperthyroidism.

ONCOGENIC OSTEOMALACIA

Etiology and Clinical Features

Oncogenic osteomalacia is a syndrome seen in association with unusual mesenchymal tumors and rarely with prostate cancer. These patients have hypophosphatemia, renal phosphate wasting, and typically low or inappropriately normal serum levels of 1,25-(OH)2 D. Alkaline phosphatase activity, reflecting bone turnover, is often elevated. Levels of calcium are typically normal, although in some cases PTH levels are elevated. Hypophosphatemia in this syndrome is due to reduced renal phosphate reabsorption. Clinical symptoms include bone pain, proximal muscle weakness, fractures, back pain, waddling gait, and progressive debility. The syndrome often poses a significant diagnostic dilemma to clinicians, because the tumors responsible for it may be very small, obscurely situated, and difficult to identify. Phosphate depletion and low 1,25-(OH)2 D levels lead to poor bone mineralization and osteomalacia. Typically, the diagnosis of osteomalacia is not suspected for years despite the presence of classic symptoms. The humoral basis for the syndrome is supported by the observation that the biochemical abnormalities remit and the osteomalacia heals when the tumor responsible for it is removed.

Pathology and Pathogenesis

Tumors responsible for this form of acquired osteomalacia are usually small and grow slowly. Because the histology of these tumors is unusual and their locations of ten unanticipated, this syndrome has been dubbed “strange tumors in strange places” by Weiss and colleagues. The range of locations for these tumors includes the lower extremities (45%), head and neck (27%), and upper extremities (17%). In a review of head and neck tumors that cause oncogenic osteomalacia, Gonzalez-Compta and coworkers noted that in 57% and 20% of cases, respectively, tumors were in the sinonasal and mandibular areas. Because these tumors are often small and difficult to find, careful physical examination combined with cranial, chest, and abdominal CT scanning are usually needed for diagnosis. In several instances, MRI skeletal surveys—and in some instances In-111 pentetreotide scanning and PET CT scans—have been instrumental in localizing the tumors at skeletal sites.

Most tumors causing this syndrome are benign, but malignant lesions have also been reported. The histologic spectrum of tumors has included hemangiomas, hemangiopericytomas, angiosarcomas, chondrosarcomas, prostate cancer, schwannomas, neuroendocrine lesions, mesenchymal tumors, and uncommonly multiple myeloma. Many of these tumors have been classified pathologically as mixed connective tissue tumors and are often located in bone. Osteoclast-like giant cells and stromal cells as well as highly vascular features characterize these tumors. Delays in diagnosis of
as long as 19 years have been reported, thereby supporting the hypothesis of slow growth of these tumors.

Many of the tumors responsible for this syndrome overproduce fibroblast growth factor (FGF) 23, a protein important in normal phosphate homeostasis (see Chapter 8). FGF 23 overexpression appears to be responsible for key aspects of oncogenic osteomalacia. FGF 23 levels fall in response to tumor resection, and the above-described biochemical changes and osteomalacia typically resolve after surgery. FGF 23 messenger RNA and protein have been shown to be expressed in many of these tumors. Other genes, however, have also been implicated in the pathogenesis of oncogenic osteomalacia. They include FGF 7, the matrix extracellular phosphoglycoprotein (MEPE), and frizzled related protein 4 (FRP 4).

Investigators in the field have long noted common features between tumor-induced osteomalacia and X-linked hypophosphatemic rickets. The latter condition is a dominant disorder characterized by rickets or osteomalacia, hypophosphatemia, low normal 1,25-(OH)2 D, and typically elevated FGF 23 levels. Despite these similarities, there are several unresolved differences between the two syndromes. One is that levels of 1,25-(OH)2 D are inappropriately normal in patients with X-linked hypophosphatemic rickets and frankly low in oncogenic osteomalacia. In addition, patients with X-linked hypophosphatemic rickets demonstrate osteosclerosis and enthesopathy (calcification of tendons and ligaments) which are not seen in oncogenic osteomalacia.

X-linked hypophosphatemic rickets is due to defective functioning or synthesis of the PEX gene product, or PHEX, a protein that is homologous to neutral, membrane-bound endopeptidases. PHEX is thought to activate or inactivate a circulating factor involved in phosphate metabolism, termed phosphatonin. It has long been proposed that the normal function of phosphatonin was to block renal phosphate reabsorption. FGF 23 has been shown to inhibit phosphate uptake in kidney cells. PHEX, the endopeptidase product of the PEX gene, can degrade FGF 23, but FGF 23 is not thought to be a substrate in vivo for PHEX. It has also been shown that PHEX may stabilize MEPE. Thus, there remain several crucial details to establish regarding the pathogenesis of oncogenic osteomalacia and X-linked hypophosphatemic rickets and the varied features of the two disorders.

GUT HORMONES

Gut hormones, including VIP, somatostatin, gastrin-releasing hormone, and pancreatic polypeptide can be produced ectopically, particularly by neuroendocrine tumors (carcinoid, pancreatic islet, and small cell lung cancer). Of these, only ectopic VIP is manifest clinically. Excess VIP can cause an impressive syndrome of voluminous secretory diarrhea, achlorhydria, and hypokalemia. This constellation of symptoms (Verner-Morrison syndrome) has been termed pancreatic cholera when caused by a pancreatic VIP-secreting islet cell tumor. A variety of nonendocrine and neuroendocrine tumors can express and release VIP, including small cell carcinomas of the lung, carcinoids, pheochromocytoma, medullary carcinomas of the thyroid, and some colonic adenocarcinomas.

Gut Hormones

A group of heritable syndromes characterized by aberrant growth of benign or malignant tumors in a subset of endocrine tissues have been given the collective term multiple endocrine neoplasia (MEN). The tumors may be functional (ie, capable of elaborating hormonal products that result in specific clinical findings characteristic of the hormone excess state) or nonfunctional. There are three major syndromes: MEN 1 is characterized by tumors involving the parathyroid glands, the endocrine pancreas, and the pituitary; MEN 2A includes medullary carcinoma of the thyroid (MCT), pheochromocytoma, and hyperparathyroidism; and MEN 2B, like MEN 2A, includes MCT and pheochromocytoma, but hyperparathyroidism is typically absent.

Hyperparathyroidism is the most common feature of MEN 1, with an estimated penetrance of 95% to 100% over the lifetime of an individual harboring the MEN 1 gene. The diagnosis of hyperparathyroidism is usually made through a combination of clinical and laboratory criteria similar to those used in the identification of sporadic disease (see Chapter 8). It is typically the first clinical manifestation of MEN 1, although this varies as a function of the patient population being examined. Hyperparathyroidism in MEN 1 is due to hyperplasia of all four parathyroid glands (or more, if supernumerary glands are present). However, involved glands may undergo metachronous enlargement, and selective resection of these glands often results in sustained clinical remissions. MEN 1 is a rare cause of hyperparathyroidism, accounting for only 2% to 4% of cases in the general population.

Enteropancreatic tumors in MEN 1 (~50% of all MEN 1 patients) can be either functional (ie, capable of producing a secreted product with biologic activity) or nonfunctional. Gastrinomas, frequently associated with Zollinger-Ellison syndrome (ZES), represent approximately 40% to 60% of the enteropancreatic tumors associated with this syndrome. Of equal importance, roughly 25% of patients with ZES are found in MEN 1 kindreds. Insulinomas constitute approximately 20% of the islet cell tumors, and the remainder represent a collection of functional (eg, glucagon- or vasoactive intestinal peptide [VIP]-producing tumors) and nonfunctional tumors. It is noteworthy that the gastrinomas of MEN 1 are often small, multicentric, and

### MULTIPLE ENDOCRINE NEOPLASIA TYPE 1

MEN 1, also known as Wermer syndrome, is inherited as an autosomal dominant trait with an estimated prevalence of 2 to 20 per 100,000 in the general population. Approximately 10% of MEN 1 mutations arise de novo. The term sporadic MEN 1 has been applied to this group. MEN 1 has a number of unusual clinical manifestations (Table 22–1) that occur with variable frequency among individuals within affected kindreds. The earliest age at which manifestations of MEN 1 have been reported is 5 years; penetrance is maximal by the fifth decade of life.
These imaging procedures are useful, however, in demonstrating ectopically located outside the pancreatic bed, most often in the duodenal submucosa. This latter feature can have a major impact reflexively increase serum gastrin levels and should be discontinued with preoperative localization studies. They can also be difficult ro

Glucagonomas, VIPomas, and somatostatinomas are diagnosed based on two fold or greater elevations in plasma glucagons, VIP, or somatostatin levels, respectively, in the presence of one or more pancreatic nodules. Nonfunctional tumors are typically diagnosed following imaging studies after exclusion of elevated levels of the plasma secretory products described above, or, more rarely, following measurement of pancreatic polypeptide levels.

Pituitary adenomas occur in approximately 25% of patients harboring the MEN1 gene. The majority secrete prolactin, with or without secretion of excess growth hormone, followed by those secreting growth hormone alone, nonfunctional tumors, and those secreting excessive amounts of adrenocorticotropic hormone (ACTH) (Cushing disease). A prolactinoma variant of MEN1 has been described (Burin variant). This variant is characterized by an increased frequency of prolactinomas, carcinoids, and hyperparathyroidism and infrequent appearance of gastrinomas in affected kindreds. It does not appear to be associated with a specific mutation of the MEN1 gene. In one instance it has been linked to a germline mutation in the gene encoding the cyclin-dependent kinase inhibitor p27Kip1, but this has not been confirmed in other patients. Pituitary tumors in MEN1 are rarely malignant, but recent studies suggest that they may be larger and more aggressive than their sporadic counterparts. There is a high incidence of macroadenoma, they display a propensity for making more than a single pituitary hormone, and there is a suggestion that these tumors do not respond as well to medical therapy as do their sporadic counterparts. Diagnosis and management are similar to that of their sporadic counterparts (see Chapter 4).

Adrenal adenomas, including cortisol-producing adenomas, are seen in MEN1, theoretically making the differential diagnosis of Cushing syndrome in this setting complex (ie, adrenal adenoma vs basophilic adenoma of the pituitary gland vs ectopic ACTH secretion from a carcinoid tumor, which is also commonly associated with this syndrome). Empirically, most hypercortisolemia in this setting is due to pituitary disease. Adrenal adenomas are often found together with islet cell tumors in affected patients, and at least in some series they appear to lack the MEN1 genetic defect. This has led to the suggestion that they represent a secondary rather than a primary manifestation of the underlying genetic defect. This, however, remains controversial. Pheochromocytomas harboring an MEN1 rather than an MEN2 mutation have been described in seven patients. Thyroid disease has been said to be more common in MEN1; however, with the possible exception of thyroid adenomas, this link remains obscure. Subcutaneous lipomas, skin collagenomas, and multiple facial angiofibromas (particularly on the upper lip and vermillion border of the lip) are seen in 30% to 90% of family members in affected kindreds. Although clinically of little importance, when present, they may prove useful in identifying affected individuals within a kindred and lead to more effective screening (discussed later). Carcinoid tumors are seen with increased frequency in MEN1. They are almost exclusively foregut carcinoids and may be found in the thymus, in the lung (bronchial carcinoids), or in the gastric mucosa. It is likely that chronic hypergastrinemia (eg, that resulting from coexistent ZES and proton pump inhibitor therapy) contributes to the increased incidence of gastric carcinoids in MEN1. For unclear

recess reasons, thymic carcinoids appear more commonly in males, bronchial carcinoids in females. They occasionally secrete hormonal products (eg, ectopic ACTH), are often malignant, and may behave aggressively. Leiomyomas have rarely been described in MEN1. Disease-specific mortality is due to pancreatic islet carcinoma and malignant thymic carcinoid.

Pathogenesis

MEN1 is inherited as an autosomal dominant trait. Traditional linkage studies localized the defective gene to the long arm of chromosome 11q13. Parallel analyses of DNA from endocrine tumors taken from MEN1 patients demonstrated allelic loss in this area, frequently resulting from large DNA deletions. This raised the possibility that the defective gene was a tumor suppressor gene involved in the control of cellular growth. In this paradigm (Figure 22-1), the inherited defective allele is silent in the presence of a normal, functioning allele on the second chromosome. A subsequent somatic mutation (often a deletion that removes the normal allele) results in a null genotype in which the suppressor gene locus is either absent or defective on both alleles. The high frequency with which such deletions occur is thought to account for the dominant nature of this particular genetic defect. Release of the tumor suppressor gene's growth regulatory activity results in a hyperplastic growth response in cells harboring the somatic mutation. This promitogenic state probably provides the substrate for subsequent somatic mutations that result in acquisition of a more aggressive, and at times malignant, phenotype, as occurs in gastrinomas associated with ZES. Recent studies have succeeded in identifying the gene, termed the menin gene, which appears to be responsible for MEN1 (Figure 22–2). Mutations have been identified throughout the entire 610-amino-acid length of the menin coding sequence and include nonsense mutations, missense mutations, and deletions. Over 400 independent mutations have been described in MEN1 kindreds to date. Nevertheless, 5% to 10% of presumed MEN1 mutations are not detectable using available methodology. Menin is a ubiquitously expressed tumor suppressor gene product which has been shown to interact with several components of the trithorax family histone methyltransferase complex, including the mixed lineage leukemia (MLL) proteins. Menin, through this complex, controls expression of the cyclin-dependent kinase inhibitors p27kip1 and p18ink4c. This complex also methylates the lysine 4 residue of histone 3 (H3K4), a modification which has been linked to transcriptional activation. Loss of function of menin (eg, through those mutations associated with MEN1) results in downregulation of p27kip1 and p18ink4c and deregulated cell growth. Menin also suppresses expression of the developmentally programmed transcription factor, HLBX9, which may also lead to increased growth in menin-deficient cells. Mice heterozygous for deletion of the menin gene locus (Men1+/-)
develop parathyroid dysplasia, adenomas, and carcinomas; pancreatic islet tumors, anterior pituitary tumors, and adrenal cortical tumors, all of which display loss of heterozygosity at the Men1 locus.

The Men1 gene is also the gene most frequently mutated in a variety of sporadic endocrine tumors. Parathyroid adenomas (20%), gastrinomas (40%), insulinomas (15%), VIP-secreting tumors (60%), nonfunctioning pancreatic tumors (15%), glucagonomas (60%), adrenal cortical tumors (<5%), angiofibromas (10%), lipomas (30%), bronchial carcinoids (35%), and pituitary tumors (<5%) often harbor somatic mutations at the Men1 locus. It is important to note that screening for germline mutations at the Men1 locus fails to detect mutations 5% to 10% of the time despite evidence for loss of heterozygosity at 11q13. It is thought that the relevant mutations may be in regulatory regions surrounding the Men1 gene. Haplotype testing or genetic linkage analysis can be useful in these cases to identify relevant Men1 carriers. Unlike MEN2 (see later), there is no clear association between specific Men1 gene mutations and the nature or extent of endocrine gland involvement, although nonsense mutations at Tyr312 and Arg326 have been shown to be more common with the Burin variant.

**Treatment**

Therapy of hyperparathyroidism in MEN1 is directed toward surgical extirpation of hyperplastic parathyroid tissue, typically with resection of three and one-half glands. This leaves one-half gland in situ in an attempt to preserve residual parathyroid function and avoid hypoparathyroidism. Alternatively, patients may be subjected to total parathyroidectomy with transplantation of the most normal appearing tissue to the nondominant forearm. There have been no head-to-head comparisons made between these approaches. Total parathyroidectomy (with transplant) is associated with a higher frequency of hypoparathyroidism, whereas subtotal parathyroidectomy has a higher rate of recurrence. Prophylactic near-total thymectomy is often performed at the time of neck exploration to remove potential intrathyric parathyroid glands as well as thymic carcinoid tumors.

Both persistence and recurrence of hyperparathyroidism occur more frequently in MEN1 than in sporadic disease. Persistence of hyperparathyroidism, defined as a failure to normalize serum calcium and parathyroid hormone (PTH) levels following the initial surgery, with removal of 3 to 3.5 parathyroid glands, occurs in 12% of cases of MEN1. Recurrent disease, defined as reappearance of hyperparathyroidism following at least 3 months of normocalcemia, is seen in as many as 44% of these cases 8 to 12 years following surgery. The high frequency of persistent hyperparathyroidism in MEN1 probably reflects the high frequency of supernumerary glands (prevalence as high as 30%) and ectopically located parathyroid tissue in patients carrying the Men1 gene. The increased frequency of recurrent disease is

---

**FIGURE 22-2** Some of the more common germline menin mutations from 56 MEN1 kindreds and somatic mutations from 24 endocrine tumors. Mutations above the bar cause protein truncations through stop codons or frameshifts leading to premature stop codons; two cause splice errors. Mutations below the bar cause missense or single-amino-acid codon changes. (Reproduced, with permission, from Marx S, et al. Multiple endocrine neoplasia type 1: clinical and genetic topics. Ann Intern Med. 1998;129:484.)
thought to result from the continued presence of the underlying mitogenic stimulus that drives parathyroid gland growth in this syndrome. Reoperation for recurrent disease in the neck is successful about 90% of the time, whereas autograft removal is successful in about 60% of patients.

Therapy of gastrinomas in MEN1 remains controversial. Suppression of gastric acid production with proton pump inhibitors (eg, omeprazole) remains a mainstay of therapy. Conservative medical management of these tumors has been predicated on their assumed low-grade malignant behavior, the dominance of complications related to gastric acid hypersecretion in contributing to morbidity and mortality, and the failure of most attempts at surgical resection to alter the natural course of the disease. More recently, recognition of the potential for more aggressive behavior in some of these tumors—-in a recent study, 14% of these tumors demonstrated aggressive growth—and the fact that many of these tumors are ectopically located in duodenal submucosa and peri-pancreatic lymph nodes rather than the pancreatic bed has renewed interest in the possibility of surgical cure. A number of small studies have reported encouraging results when measures to both localize and remove gastrinoma tissue in the pancreas, duodenum, and regional lymph nodes have been used. Although the nature of the underlying genetic lesion and the multicentricity of these tumors may place limits on the prospects for cure of this disease in most patients, the slow growth characteristics of these tumors permit long periods of symptom-free survival following reduction of the tumor burden. For patients with liver or other metastatic disease, symptoms related to hypergastrinemia may be controlled with the proton pump antagonists, as described earlier. More conventional cancer therapy (eg, systemic chemotherapy, radiation therapy, or selective chemoembolization of hepatic metastases) is palliative and reserved for advanced stages of the disease. Islet tumors more than 3 cm carry an increased risk of malignancy and are usually resected regardless of functional status.

It is important to remember that calcium stimulates gastric acid secretion. This may occur through gastrin-dependent and gastrin-independent pathways. In MEN1 patients with both hyperparathyroidism and ZES, correction of the hyperparathyroidism and attendant hypercalcemia frequently results in a reduction in both basal and maximal acid output and a decline in serum gastrin levels. Secretin stimulation tests often normalize following parathyroidectomy. More importantly, there is a reduction in the dose of medication (eg, proton pump inhibitor) required to control symptoms of ZES following parathyroid surgery in approximately 60% of patients.

Unlike gastrinomas, insulinomas are rarely localized outside the pancreatic bed. Therefore, a more aggressive approach can be directed toward the pancreas in planning surgical resection. Enucleation of the identifiable lesions in the pancreatic head and blind resection of the pancreatic body and tail are often more successful in correcting hyperinsulinemia than in restoring normal gastrin levels in patients with ZES. Nonsurgical candidates (eg, those with serious coexisting disease or those in whom candidate tumors cannot be identified) can be managed with conventional medical therapy (eg, diazoxide or verapamil). (See Chapter 18.)

Nonfunctional tumors, the most common pancreaticoduodenal neuroendocrine tumors in MEN1, are managed somewhat differently than the functional tumors. Surgical efforts to minimize spread of metastases are weighed against the need to avoid incurring surgical complications, including mortality, with little clinical benefit. In general, surgery is not recommended for tumors less than 2 cm in diameter. Life expectancy of MEN1 patients with nonfunctional tumors (–43 years) is similar to that of those with gastrinomas and considerably shorter than those with other types of functional tumors (–61 years).

Screening

MEN1 accounts for less than 1% of all pituitary tumors, 2% to 4% of cases of primary hyperparathyroidism, and about 25% of all gastrinomas. Thus, although routine screening for Men1 gene mutations is not indicated for sporadic cases of hyperparathyroidism or patients with pituitary tumors, screening of all cases of ZES is likely to be cost-effective in identifying carriers. The frequency of germline mutations in the Men1 gene in patients with tumors thought to be sporadic based on family analysis is about 5% for gastrinomas and 1% to 2% for other manifestations (eg, hyperparathyroidism, prolactinomas). Excluding those patients with ZES, screening for MEN1 outside affected MEN1 kindreds should be limited to those individuals for whom the index of suspicion for the syndrome is high (eg, familial history of endocrine tumors or hypersecretory states; history of multiple endocrine tumors or multigland involvement with hyperparathyroidism in the propositus). Identification of the carrier state should be performed with the intent of acquiring information that allows the clinician to focus screening on the relevant patient population (eg, members of an affected kindred who do not share the Men1 gene mutation need not be subjected to follow-up screening). Unlike the situation in MEN2 (see later), carrier analysis should not be used to support a major therapeutic intervention. Such interventions (eg, pancreatic exploration) may be associated with significant morbidity, and there is no evidence that they prolong patient survival. Patients with hyperparathyroidism should be screened for MEN1—even in the absence of a positive family history or any history of multiple endocrine tumors—if parathyroid hyperplasia is identified at the time of parathyroidectomy or if there is a history of recurrent hyperparathyroidism following parathyroidectomy. Patients with ZES should be screened for MEN1 given its high frequency (–25%) in such individuals. Patients with isolated pituitary lesions have a low probability of having coexistent MEN1 and probably do not require screening unless there are other clinical features suggesting the syndrome. Genetic screening is available commercially at a number of locations (see www. genetests.org).

Although most clinicians agree that screening for MEN1 in high-risk groups is worthwhile, details of the individual screening protocols vary considerably—from more focused, cost-effective approaches to broad-based screening designed to detect occult disease. One example of a moderately cost-effective protocol is presented in Figure 22–3. A complete examination and full family history should be obtained on all patients. In individuals within
FIGURE 22-3 Screening for MEN1. Testing is targeted to individuals with a high probability of harboring the MEN1 gene (eg, first-degree relatives of affected kindred members). If genetic testing is available and the specific mutation has been confirmed, screening would be limited to those individuals harboring the defective gene. Screening for other pancreatic (eg, insulinomas) or pituitary tumors (eg, somatotroph adenomas) is based on the prevalence of the specific lesion in the affected kindred or the presence of signs or symptoms suggesting a particular lesion (IGF, insulin-like growth factor).

Affected kindreds, ionized (or albumin-corrected) calcium and PTH levels should be checked at yearly intervals. Fasting serum gastrin levels should also be determined annually—or more frequently if ZES is a prominent component of the phenotype in the affected kindred. In kindreds in whom the disease is particularly aggressive, the secretin stimulation test (if available) can lend to additional diagnostic sensitivity. Determination of fasting glucose, insulin, and proinsulin levels may prove useful, particularly if symptoms of hypoglycemia are present. Pancreatic polypeptide measurements may identify an unsuspected pancreatic neuroendocrine tumor. Levels of chromogranin A, a secretory product of parathyroid glands and other neuroendocrine tissues, can also be
helpful in assessing nonspecific endocrine gland hypersecretion. Routine screening for other functional or nonfunctional islet cell tumors is probably not justified without clinical findings (e.g., watery diarrhea, hypokalemia). As noted earlier, these lesions are typically multifocal and may be very small, which makes detection difficult even with sophisticated imaging studies. The same holds true for the pituitary lesions. In the absence of obvious clinical findings (e.g., evidence of a hyper- or hyposecretory state or symptoms referable to a mass lesion in the sella turcica), routine screening should be confined to periodic measurements of serum prolactin and perhaps insulin-like growth factor-I. The former has been found to be useful in identifying pituitary disease in females harboring the Men1 gene defect. Imaging studies (e.g., MRI of the pituitary and anterior mediastinum, CT of the abdomen) should be performed at presentation and repeated at 3-year intervals. A thorough family history that excludes pituitary disease in the kindred may mitigate the need for pituitary imaging studies over the long term.

Follow-up screening in patients known to have MEN1 should include yearly fasting gastrin, calcium, albumin, PTH, chromogranin A, and pancreatic polypeptide levels from age 10 on. Some clinicians have argued that these patients should have annual CT or MRI studies of the abdomen and prolactin measurements plus MRI of the sella every other year; in addition, consideration should be given to performing an annual CT of the chest (see Glascock and Carty). Others have argued for imaging studies on presentation and every 3 years thereafter (see Schussheim et al).

Penetrance of MEN1 is greater than 95% by age 45. Screening should be continued at periodic intervals at least to age 45. If there is no evidence of typical endocrine organ involvement by that age, screening frequency might be reduced. It is important to note, however, that the risk is not reduced to zero at age 45. A minority of patients presents with their first manifestation of the syndrome well after age 45. Surgical resection of diseased tissue (e.g., parathyroidectomy) should be followed with continued screening looking both for recurrent disease and involvement of other organ systems.

Eighty percent to 100% of individuals at risk develop MCT at some point during their lifetime. The classic thyroid lesion of MEN2 is hyperplasia of the calcitonin-producing parafollicular cells, which typically serves as the precursor of MCT. These tumors in MEN2 patients tend to be multicentric and concentrated in the upper third of the thyroid gland, reflecting the normal distribution of parafollicular cells.

As much as one-fourth of all MCT is genetic in origin. Roughly 30% of the heritable fraction is attributable to MEN 2A; 65% occurs as an isolated entity (isolated familial MCT), and 5% is found in MEN 2B kindreds. Isolated familial MCT is defined as MCT presenting as the only clinical manifestation in more than 10 carriers in a kindred and multiple carriers or affected members over the age of 50 with adequate history and laboratory support.

**MEN2** is an autosomal dominant disorder with an estimated prevalence of 1 to 10 per 100,000 in the general population. It can be subdivided into two independent syndromes: MEN 2A (Sipple syndrome) and MEN 2B. Manifestations of MEN 2A include MCT, pheochromocytoma, and hyperparathyroidism. MEN 2B includes MCT, pheochromocytoma, and a number of somatic manifestations (Table 22–2; Figure 22–4), but hyperparathyroidism is rare. Penetrance of MEN2 is greater than 80% in individuals harboring the defective gene.

Medullary carcinoma of the thyroid is the most common manifestation of MEN2 and often represents the first clinical presentation in individuals with multiorgan involvement. It also dominates the clinical course of patients affected with the disease.

**FIGURE 22–4** Patient with MEN 2B syndrome. Note the multiple neuromas on the lips and tongue and the marfanoid facies.
to rule out the presence of pheochromocytoma or hyperparathyroidism. The disease tends to behave more aggressively in MEN 2B than with either MEN 2A or familial MCT, with earlier presentation (often before age 5) and more rapid progression.

Biochemical diagnosis depends heavily on the calcitonin-producing properties of the hyperplastic parafollicular cells or MCT. These lesions respond to pentagastrin or calcium infusions with significant increments in plasma calcitonin levels (see Chapter 8). Occasionally, immunohistochemical staining of poorly differentiated thyroid tumors for calcitonin reveals the identity of the malignancy. The presence of extracellular amyloid is also one of the identifying features of these tumors. This material reacts with anticalcitonin antisera, suggesting that it includes aggregated hormone released from neighboring tumor cells. MCT spreads initially within the thyroid bed and to regional lymph nodes. Distant metastases to liver, lung, and bone occur late in the course of the disease.

Pheochromocytomas develop in approximately 50% of individuals harboring the MEN2 gene. They are usually located in the adrenal bed, often are bilateral, and are rarely malignant. Diagnosis is based on standard clinical criteria (e.g., hypertension, presence of headaches, palpitations, diaphoresis), elevations in plasma or urine catecholamines or catecholamine metabolites (e.g., urinary or plasma metanephrine or normetanephrine), and demonstration of an adrenal mass on conventional abdominal imaging. As noted above for MCT, pheochromocytomas in MEN2 are preceded by a hyperplastic phase (adrenal medullary hyperplasia), although, unlike parafollicular cell hyperplasia, the adrenal precursor lesion can be difficult to detect with conventional biochemical testing.

As in MEN1, hyperparathyroidism in MEN2 is due to hyperplasia of the parathyroid glands. It is seen in about 25% of patients harboring the MEN2A gene and is reported, but rarely seen, as part of MEN 2B. The disease is usually less aggressive than its counterpart in MEN1 and approximates more closely the behavior of sporadic disease. It responds well to surgical management.

A number of other phenotypic features are associated with the MEN2 syndromes. Cutaneous lichen amyloidosis is a pruritic erythematous skin lesion that is seen coincident with or often preceding the development of MCT in MEN2. Amyloid in these lesions is composed of keratin rather than calcitonin, as seen in MCT. Cutaneous lichen amyloidosis is thought to result from an abnormality in cutaneous innervation that leads to hypopertusion and pruritis. Repeated scratching of the pruritic area results in epidermal thickening and increased pigmentation. It has been noted more frequently in association with specific mutations of the MEN2 gene (specifically Cys\(^{534}\) to Tyr\(^{634}\)). In a second variant, MEN 2A or familial MCT is associated with Hirschsprung disease (congenital megacolon). This is most frequently found with RET gene mutations involving Cys\(^{609}\), Cys\(^{615}\), and Cys\(^{620}\) (see below). The intestinal ganglioneuromatosis, mucosal neuromas, marfanoid habitus, and medullated corneal nerves seen in MEN 2B appear to be related to the underlying genetic defect. The intestinal lesions can disrupt gut motility, resulting in periods of severe constipation or diarrhea.

**Pathogenesis**

The pathogenesis of the MEN2 syndromes has been worked out in elegant detail. Traditional genetic linkage studies localized the defective genes in MEN 2A, MEN 2B, and familial MCT to the pericentromeric region of chromosome 10. Subsequent refinement in these analyses indicated that the defective gene was either closely linked or identical with the \(ret\) proto-oncogene. RET is a single transmembrane domain, tyrosine kinase-linked protein that forms part of the receptor for the glial cell line-derived neurotrophic factor (GDNF) (see Figure 22-5). This receptor, GDNFR (glial cell line–derived neurotrophic factor receptor), is a glycosyl phosphatidyl inositol-linked cell-surface protein. Additional ligands, neurturin, persephin, and arremin have been shown to associate with and activate RET through their cognate receptors GDNFR\(_{\alpha1-4}\). As depicted schematically in Figure 22-6, its most striking structural feature is a series of cysteine residues clustered just outside the membrane-spanning segment. These cysteine residues are thought to exert a tonic inhibitory control on RET activity in the normal cell. RET also has a cadherin-like domain in that portion of the molecule projecting into the extracellular space and a tyrosine kinase-like domain in the intracellular portion of the molecule. RET is expressed endogenously in a variety of cells of neural crest origin, and it appears to play an important role in development. Knockout of the \(RET\) gene locus in mice results in the absence of myenteric ganglia in the submucosa of the small and large intestine and a variety of genitourinary anomalies, implying an important role in renal development.

Characterization of the \(RET\) gene in patients with MEN 2A demonstrated a number of mutations in affected kindred members that were not present in their normal counterparts. The mutations were clustered in the cysteines located in RET's extracellular, juxtamembrane domain (see Figure 22-6). Structurally,
thyroid is frequently associated with mutations at the same cysteine residues of DNA, but in each case one of the aforementioned amino acids indicated above is linked to pheochromocytoma. It affected MEN 2A kindreds. It has been suggested that mutation arginine (Arg), phenylalanine (Phe), serine (Ser), glycine (Gly), tyrosine (Tyr), or tryptophan (Trp) in approximately 84% of affected cases have been demonstrated as somatic mutations in sporadic MCT (<30%-40%) and pheochromocytoma (<10%). Sporadic parathyroid disease due to these mutations is not known to occur. The presence of the Met918 mutation, in particular, is associated with a less favorable clinical outcome in sporadic MCT.

Independent studies have shown a close linkage between the RET gene locus and Hirschsprung disease, a disorder characterized by failure of myenteric ganglia to develop normally in the hindgut of affected individuals. This leads to impaired gut motility and, in severe cases, megacolon (a phenotype similar to that reported for the RET knockout mice). Examination of RET coding sequence in Hirschsprung kindreds revealed a variety of mutations in both the intracellular and extracellular domains, some of which (e.g., deletions) would be predicted to eliminate normal expression of the RET gene. This, together with findings from the RET, GDNF, and GDNFRα-1 knockout mice, suggests that Hirschsprung disease represents the null phenotype for the RET locus. Interestingly, several patients have been described who possess features of both MEN2 and Hirschsprung disease. The RET mutations in these cases have involved conversion of Cys609 to Arg634, which is almost uniformly associated with MEN 2A.

Several additional mutations have been identified that may be more specific for familial MCT (Figure 22-6). The observation that mutations of Cys634 have higher transforming potential than mutations at these other residues has led to the suggestion that MEN 2A represents the more severe phenotype (vs familial MCT) along a spectrum of disease resulting from RET activation. In fact, the noncysteine mutations, which are more common in familial MCT (as high as 60% of familial MCT in one series), are associated with delayed onset of parafollicular C cell disease, but other clinical features (tumor size, bilaterality, the presence of nodal metastases) were not different in patients harboring cysteine versus noncysteine mutations.

Interestingly, patients with MEN 2B do not harbor mutations in the same cysteine residues affected in MEN 2A and familial MCT. Instead, the majority possess a single-point mutation involving conversion of Met918 to Thr918. This mutation is found in more than 95% of cases of MEN 2B. A minority of patients have been shown to harbor an independent mutation of Ala883 to Phe883, Ser922 to Tyr922, or a mono-allelic combination of Val904 to Met904 plus Ser904 to Cys904. MEN 2B arises from spontaneous de novo mutations in as many as 50% of affected individuals. For unknown reasons, these mutations are found almost exclusively on the paternal allele.

A number of the germline mutations identified in MEN 2A and familial MCT and the Met918 mutation in MEN 2B have been demonstrated as somatic mutations in sporadic MCT (~30%-40%) and pheochromocytoma (~10%). Sporadic parathyroid disease due to these mutations is not known to occur. Interestingly, several patients have been described who possess features of both MEN2 and Hirschsprung disease. The RET mutations in these cases have involved conversion of Cys609, Cys618, or Cys620 to Arg634. These mutations, while promoting dimerization and increasing tyrosine kinase activity in the RET protein (see below), also appear to have difficulty trafficking to and accumulating in the plasma membrane. It is conceivable that predominance of one or the other of these mechanisms in different cell types could result in a...
phenotype characterized by both activation (eg, MEN2) and suppression (eg, Hirschsprung disease) of RET activity in the same individual.

By inference, the defect in RET function in MEN2 or familial MCT arises from increased or altered activity of the RET tyrosine kinase. In the case of RET MEN2A, the increase in activity appears to arise from interference with the tonic inhibition of RET tyrosine kinase activity by the clustered cysteine residues in the extracellular domain. This leads to increased dimer formation, autophosphorylation, and tyrosine kinase activity in the mutant RET molecules. In the case of RET MEN2B, there appears to be a change in substrate specificity of the tyrosine kinase that contributes to the phenotype. The activity of RET MEN2B—rather than being restricted to conventional RET substrates (RET substrates are similar to those recognized by the epidermal growth factor receptor)—is capable of phosphorylating substrates normally recognized by members of the Src and Abl families of cytoplasmic tyrosine kinases, signaling pathways which are closely identified with the regulation of cell growth. Thus, it appears that RET MEN2B has acquired the capacity for activation of a potent mitogenic pathway in the expressing endocrine cells merely by altering its selection of substrates for phosphorylation. RET MEN2B also potentiates phosphorylation of Tyr1022 more effectively than RET MEN2A. This tyrosine serves as a docking site for multiple effector proteins, including Shc and phosphatidyl inositol 3'-kinase, implying that RET MEN2B may be more effective in triggering downstream signaling pathways.

**Screening**

Genetic screening for MEN 2A, MEN 2B, or familial MCT is routinely carried out using polymerase chain reaction (PCR)-based tests designed to identify specific mutations in the RET coding sequence (Figure 22-7; see www.genetests.org for laboratories performing these tests). Known RET mutations account for more than 95% of all instances of MEN2, and selected mutations (eg, Cys634 to Arg634 in MEN 2A) account for a disproportionate number of affected individuals. Individuals lacking any of the known RET mutations can be tested using conventional haplotype analysis if informative genetic markers and affected family members are available.Biochemical testing using basal or stimulated plasma calcitonin levels has been largely supplanted by genetic screens. The biochemical tests remain useful, however, in identifying residual disease after thyroidectomy.

In view of the fact that a high proportion of cases of MCT are familial to begin with and as much as 60% of patients with apparently sporadic MCT harbor germline RET mutations, genetic testing for RET germline mutations is probably indicated for all patients presenting with MCT. Controversy persists, however, in terms of what should be done for patients once the mutation has been identified. Some investigators citing incomplete clinical penetrance (according to published data, 40% of gene carriers do not present symptomatically prior to age 70) have argued that employing solely genetic criteria in making the decision for operative intervention subjects a small minority of patients to premature thyroidectomy. They argue that genetic testing should be used to identify those patients who require close clinical and biochemical surveillance to assist with the timing of surgery. Ideally, such biochemical testing (eg, pentagastrin stimulation) should be performed on an annual basis. Exceptions to this general approach might include patients with MEN 2B or a particularly aggressive
FIGURE 22-7 Screening for MEN 2A. Genetic screening has largely supplanted biochemical testing in identifying individuals at risk. Details of decisions regarding treatment are discussed in the text. Preoperative plasma calcitonin levels are potentially useful for follow-up but should not supplant genetic testing in assessing the need for surgery (MIBG, metaiodobenzylguanidine; RET, rearranged during transfection proto-oncogene). (See also Figure 7-48.)

form of familial MCT where the potential for significant morbidity and mortality would justify operation in any patient harboring the genetic defect regardless of the physical or biochemical manifestations of the disease.

The more widely shared view is that the true penetrance of MCT—combined clinical and preclinical disease—in MEN 2A is closer to 100%. This, when coupled with the high degree of sensitivity and specificity of the PCR-based genetic screens, difficulties encountered in obtaining adequate long-term patient follow-up and biochemical screening, and the potential for false-positive pentagastrin stimulation tests—even within MEN2 kindreds—has led to the recommendation that total thyroidectomy should be performed in all individuals harboring an MEN2-associated RET mutation. This argument has now been supported by several clinical studies in which parafollicular cell hyperplasia as well as early MCT have been identified in operative specimens taken from genetically affected individuals despite normal pentagastrin stimulation tests. False-positive biochemical tests are also a concern. There are several reports in the literature of patients in affected kindreds who have undergone total thyroidectomy following positive pentagastrin stimulation tests but did not, in fact, harbor the MEN2 gene mutation. Histologic examination of excised tissues revealed parafollicular cell hyperplasia, presumably unrelated to MEN2, but no MCT. Collectively, these findings point out the relative deficiencies of biochemical versus genetic testing and offer a compelling argument for early operation as a means of reliably eradicating the disease.

OTHER DISORDERS CHARACTERIZED BY MULTIPLE ENDOCRINE ORGAN INVOLVEMENT

Carney Complex

Carney complex is an autosomal dominant disorder characterized by cardiac, endocrine, cutaneous, and neural tumors. Myxomas of the heart, breast, and skin are seen frequently in this disorder, as is
spotty pigmentation of the skin (lentiginosis) and ear canal trichofolliculo-epitheliomas. Additional rare manifestations include psammomatous melanotic schwannoma, breast ductal adenoma, and osteochondromyxoma. Endocrine tumors include primary pigmented micronodular adrenocortical hyperplasia (an ACTH-independent form of Cushing syndrome), follicular thyroid carcinomas, adrenocortical carcinoma, somatotroph (growth hormone–secreting) adenomas of the pituitary gland, large-cell calcifying Sertoli cell tumors of the testes, and ovarian cysts. In approximately half of the known Carney complex kindreds, the genetic lesion maps to 17q22-24, a locus that harbors the type I regulatory subunit of protein kinase A. This gene functions as a classic tumor suppressor, and loss of heterozygosity at this locus is associated with the Carney phenotype. A second locus, presumably accounting for the remaining approximately half of Carney complex kindreds, is located at 2p16. The nature of the genetic lesion at this locus remains unknown at present; however, the phenotype is indistinguishable from that found with the 17q22-24 mutations alluded to above.

**McCune-Albright Syndrome**

The central findings in McCune-Albright syndrome include bony fibrous dysplasia (either monostotic or polyostotic, café-au-lait spots, and gonadotropin-independent precocious puberty). However, affected individuals also develop tumors or nodular hyperplasia of a number of endocrine glands associated with hypersecretory syndromes. One may see involvement of the pituitary somatotrophs (acromegaly), thyroid gland (hyperthyroidism), or the adrenal cortex (hypercortisolism). Patients with McCune-Albright syndrome frequently demonstrate hypophosphatemic rickets. This is thought to result from secretion of fibroblast growth factor-23 that is produced in the mesenchymal cells associated with the dysplastic bone lesions. They also have nonendocrine organ involvement that leads to cardiomyopathy with sudden death and liver function abnormalities. The molecular lesion in McCune-Albright syndrome involves a somatic activating mutation of \( GNAS \) at the Arg\(^201\) position, converting the Arg to either Cys or His (see Chapter 1), that leads to ligand-independent activation of adenylyl cyclase and increased intracellular concentrations of cyclic AMP. This somatic mutation is thought to occur early in development, leading to genetic mosaicism for the mutant allele. The phenotype of an individual patient is determined by the tissue distribution of the mutation-bearing cells and the percentage of cells within a given tissue that harbor the mutation. Interestingly, \( GNAS \) mutations have been described in a subset of patients harboring intramuscular myxomas (Mazabraud syndrome) with or without associated fibrous dysplasia, a feature that is reminiscent of the Carney complex (see above), another genetic disease which seems to target the cyclic AMP-signaling pathway.

**Neurofibromatosis Type 1**

Neurofibromatosis type 1 (von Recklinghausen disease) is an autosomal dominant genetic disorder characterized by a variety of skin manifestations, including café-au-lait spots, subcutaneous neurofibromas, and axillary and inguinal freckles as well as neural gliomas (eg, optic nerve) and hamartomas of the iris (Lisch nodules). In addition, patients may have a number of endocrine neoplasias, including pheochromocytoma, hyperparathyroidism, MCT, and somatostatin-producing carcinoid tumors of the duodenal wall. The genetic lesion in neurofibromatosis type 1 is located at 17q11.2, a locus that harbors the neurofibromin gene. Neurofibromin is a homolog of the p21 Ras-dependent GTPase-activating proteins and is thought to function in a tumor suppressor mode through regulation of Ras-dependent signaling activity.

**Von Hippel-Lindau Disease**

Von Hippel-Lindau disease is a heritable autosomal dominant disorder characterized by retinal and cerebellar hemangioblastomas, renal cell carcinoma, islet cell tumors, pheochromocytomas, and renal, pancreatic, and epididymal cysts. The presence of pheochromocytomas and most of the islet cell tumors is confined to the type 2 variant of the disease, which accounts for 25% to 35% of affected kindreds. The genetic lesion has been localized to 3p25. The von Hippel-Lindau protein, which is normally encoded by this locus, participates in the formation of a multiprotein complex involved in the regulation of hypoxia-induced gene transcriptional activity, fibronecstin matrix assembly, and ubiquitin ligases.

**MEN2**

**Other Disorders**

Individuals over age 65 comprise the fastest-growing segment of the United States population; each day this group increases by more than 1000 people. This increase has led to a remarkable situation—of all the people who have ever lived to the age of 65, more than two-thirds are still alive. Thus, it is becoming increasingly important for the endocrinologist to understand how endocrine physiology and disease may differ in the elderly.

Before considering specific endocrinologic conditions in the elderly, however, it is worthwhile to review some general principles that account for many of the age-related changes in disease presentation in the elderly. First, aging itself—in the absence of disease—is associated with only a gradual and linear decline in the physiologic reserve of each organ system (Figure 23-1). Because the reserve capacity of each system is substantial, age-related declines have little effect on baseline function and do not significantly interfere with the individual’s response to stress until the eighth or ninth decade. Second, because each organ system’s function declines at a different physiologic rate and because 75% of the elderly have at least one disease, endocrine dysfunction in the elderly often presents disparately, with initial symptoms derived from the most compromised organ system. For example, hyperthyroidism in an elderly patient with preexisting coronary and conduction system disease may present with atrial fibrillation and a slow ventricular response, whereas in another equally hyperthyroid patient with a prior stroke, it may present with confusion or depression; neither patient may tolerate hyperthyroidism long enough for the classic thyroid-related manifestations (eg, goiter) to become apparent. Third, elderly patients often have multiple diseases and take many medications that may mimic or mask the usual presentation of endocrine disease.
THYROID FUNCTION AND DISEASE

The prevalence of thyroid disease in the elderly is approximately twice that in younger individuals, with hypothyroidism ranging from 2% to 7% and hyperthyroidism affecting up to 2% of older individuals. The Whickham Survey of 21,000 adults in Great Britain and its follow-up study, conducted between 1972 and 1993, reported that the incidence of overt hypothyroidism was increased 10-fold in women age 75 and older when compared to women in their twenties. In the NHANES 1999 to 2002 survey (N=4392) the overall prevalence of hypothyroidism was 3.7% (includes overt and mild) including a prevalence of 5.5% for individuals age 50 to 79 years and 12.1% for those age 80 and older. Individuals age 80 and older had five times greater probability for developing hypothyroidism (OR=5.0, p=0.0002) compared to those 12 to 49 years of age. In addition, some studies suggest that up to 9% of hospitalized elderly patients have overt thyroid disease.

Subclinical hypothyroidism—normal serum levels of thyroid hormones (thyroxine, \( T_4 \); triiodothyronine, \( T_3 \)) with an elevated level of thyroid-stimulating hormone (thyrotropin) (TSH)—is more prevalent, with estimates of 6% to 13% in the elderly (Figure 23–2), and is higher in women than in men. The NHANES III data (N=16,533) suggests that the distribution of TSH shifts to a higher concentration with age and therefore the prevalence of subclinical hypothyroidism may be overshadowed (see Figure 23–3). In the elderly, the progression from subclinical to overt hypothyroidism is roughly 2% to 5% per year. Subclinical hyperthyroidism—normal serum thyroxine with suppressed serum TSH levels—may be found in approximately 2% of elderly subjects (Figure 23–2). The rate of progression to overt hyperthyroidism is less clear. Finally, the overall prevalence of thyroid hormone use in older adults is approximately 7% (10% in women and 2% in men).

There are few major age-related changes in the physiology of the hypothalamic-pituitary-thyroid axis (Chapters 4 and 7). There are slight age-related increases in serum TSH levels (see Figure 23–3) and decreases in total \( T_4 \). TSH release remains pulsatile, although the nocturnal rise in serum TSH appears to be blunted with age. There is a slight age-related decline in serum \( T_3 \), but values usually remain within normal limits. The effect of age on the release of TSH by thyrotropin-releasing hormone is less clear, but most recent studies show little clinically relevant change in either sex. The 24-hour radioiodine uptake is also not significantly altered with age. Thyroid antibodies are common in older women (prevalence up to 25%, Figure 23–4), but their presence does not serve as a specific screening test for thyroid disease. The presence of thyroid antibodies (occult thyroid dysfunction) may skew the upper limit of TSH in the African American, Caucasian, and Mexican American ethnic groups (see Figure 23–4).

DISORDERS OF THE THYROID GLAND

The United States Preventive Services Task Force concluded that there was insufficient evidence to recommend routine screening for thyroid disease in adults. Furthermore, there is no consensus regarding screening in the elderly. A scientific review panel suggests case finding for screening older patients at high risk (eg, family history, personal history, radiation, and other risk factors). The American Thyroid Association recommends that adults be screened by serum TSH determination every 5 years. A consensus statement from the American Association of Clinical Endocrinologists, the American Thyroid Association, and the Endocrine Society recommends routine screening for subclinical thyroid dysfunction in adults. However, it is reasonable to measure TSH at any time in older individuals who present with atypical symptoms of thyroid disease such as exacerbation of cardiac symptoms, change in mental status, falling, or onset of depression. Despite the sensitivity of the TSH assay, further evaluation with a free \( T_4 \) or total \( T_4 \) is often required because up to 98% of elderly subjects with mildly suppressed TSH levels do not have thyrotoxicosis.
The physical signs of hyperthyroidism also differ in the elderly (see Table 23–1). Sinus tachycardia is less frequent; the thyroid feels normal in size or is not palpable in two-thirds of patients; and lid lag is uncommon. Ophthalmopathy is less common, not only because Graves disease occurs less often, but also because, even with Graves disease, ophthalmopathy occurs less frequently in the elderly. However, although they are less common in the elderly, some findings appear to be highly suggestive of hyperthyroidism. These include increased frequency of bowel movements, weight loss despite increased appetite, fine finger tremor, eyelid retraction, and increased perspiration. Lid lag is uncommon but if found, it is highly suggestive of hyperthyroidism (specific).

**Diagnosis**

As in younger patients (Chapter 7), the diagnosis is usually confirmed by standard thyroid function tests, beginning with a depressed TSH level as measured by a sensitive immunometric or chemiluminescent assay. There are potential pitfalls, however. Hospitalized elderly patients who are acutely ill (but euthyroid) may have a suppressed serum TSH. Further, other thyroid function tests should help rule out hyperthyroidism. T₃ toxicity may be

FIGURE 23–4 The panels show TSH percentiles (5th, triangles; 50th, circles; and 97.5th, squares) for the eight age groups for each ethnicity: left, B; middle, W; right, M. Solid symbols represent the TSH percentiles for antibody-positive subjects, and open symbols represent the TSH percentiles for antibody-negative subjects. In each panel, the solid line links the prevalence of TPOAb and/or TgAb of each age group.
more difficult evaluation to diagnose because concomitant nonthyroidal illness is common and can depress serum T₃.

Furthermore, iodide-induced hyperthyroidism, reflecting the Jod-Basedow phenomenon (see Chapter 7), is becoming more common in elderly patients with multinodular goiter because of increased exposure to radiocontrast studies; the resultant hyperthyroidism is generally transient.

Finally, because of screening tests with sensitive TSH assays, subclinical hyperthyroidism (normal T₄, T₃, free T₄ with a suppressed TSH) is being recognized more commonly. This is often found in older subjects with autonomous function of a multinodular goiter or nodule. Osteoporosis and atrial fibrillation are complications of subclinical hyperthyroidism that may be an indication for treatment. Recent studies suggest a possible increase in all-cause mortality in patients with subclinical hyperthyroidism with an increase beyond the age of 60, especially in aging men (Figure 23–5). If patients are not treated, careful follow-up is recommended.

**Treatment**

Beta-blocking agents are useful in alleviating symptoms, but radioactive iodine is the therapy of choice in elderly patients because it is efficient, uncomplicated, and inexpensive. Antithyroid drugs can be used prior to radioactive iodine treatment to render the patient euthyroid and to avoid radiation-induced thyroiditis, but they are not definitive treatment and are more toxic in this age group. Surgery has a more limited role because of its increased morbidity.

Following radioactive iodine treatment, patients become euthyroid over a period of 6 to 12 weeks. They should receive careful follow-up, because hypothyroidism develops in 80% or more of patients who have been adequately treated. Once hyperthyroidism has abated, the metabolic clearance rate of other medications may decrease, and doses may require readjustment. Older patients with subclinical hyperthyroidism require follow-up, especially if presented with an iodine load.

**2. HYPOTHYROIDISM**

Hypothyroidism in the elderly is most often due to Hashimoto thyroiditis, prior thyroid surgery, or radioactive iodine ablative therapy. Medications, including amiodarone, lithium, and interferon-α, can lead to hypothyroidism. The risk of developing hypothyroidism is significantly increased in older women when serum antithyroid antibodies or serum TSH are elevated.

**Clinical Features**

It is easy to overlook hypothyroidism in an older person, because many euthyroid elderly patients have the same symptoms. Moreover, elderly patients with hypothyroidism are more likely than younger patients to present with cardiovascular symptoms (eg, congestive heart failure or angina) or neurologic findings (eg, cognitive impairment, confusion, depression, paresthesias, deafness, psychosis, or coma). Finally, in the older hypothyroid patient, the physical findings are frequently nonspecific, although puffy face, delayed deep tendon reflexes, and myxedema support the diagnosis.

**Diagnosis**

Serum TSH is the most sensitive indicator of primary hypothyroidism and should be checked first. The diagnosis should then be confirmed with a low serum T₄ or free T₄. Measurement of serum T₃ is unnecessary and potentially misleading, because T₃ is the thyroid hormone most likely to decrease in nonthyroidal illness. Serum TSH should not be used alone to diagnose hypothyroidism because it does not always differentiate symptomatic from

*Approximated from graph of patients' ages.

*Includes five patients with normal sinus rhythm and two who had atrial fibrillation.

*This was transient in four of five patients with conversion to normal sinus rhythm.

**TABLE 23–1 Percentages of patients with symptoms and physical findings attributable to thyrotoxicosis.**
subclinical hypothyroidism. Furthermore, levels of TSH may be higher at night as a result of the nocturnal rise in serum TSH. Moreover, the pulsatile nature of TSH, resulting in serum TSH slightly above the normal ranges, may lead to a diagnosis of subclinical hypothyroidism in a euthyroid subject. Finally, in hypothyroid patients, serum TSH levels can be reduced to within the normal range by treatment with dopaminergic drugs and corticosteroids. In such patients, determination of free $T_4$ may help differentiate those with true hypothyroidism from those with nonthyroidal illness (Chapter 7).

**Treatment**

The doses of thyroid hormone required for adequate replacement decrease with age. Elderly patients should be started on approximately 25 to 50 $\mu$g of levothyroxine, and the dose should be increased by approximately 25 $\mu$g every 4 to 6 weeks until the serum TSH comes into the normal range. In patients with cardiovascular disease, even lower initial doses can be used (12.5 $\mu$g) and increased at a slower rate. Desiccated thyroid hormone and preparations containing $T_3$ should be avoided, because $T_3$ is rapidly absorbed and cleared and may be cardiotoxic. The metabolic clearance of other drugs changes as hypothyroidism is corrected, and their dosages may require readjustment. On average, the dose of levothyroxine in the elderly is roughly 1 $\mu$g/kg/d compared with 1.7 $\mu$g/kg/d in young adults. Overtreatment documented by a suppressed serum TSH should be avoided because of the potential adverse effects to the skeleton and cardiovascular system.

It is still not known whether treating subclinical hypothyroidism is beneficial. A Cochrane review of 12 small trials that included treatment of subclinical hypothyroidism with thyroid hormone did not find improved survival, decreased cardiac morbidity, or differences in quality of life or symptoms. Two-thirds of patients with subclinical hypothyroidism were chemically euthyroid for at least 4 years, and the absence of antimicrosomal antibodies may identify patients at lowest risk of progression. The presence of antithyperoxidase antibodies is associated with a higher risk of progression to overt hypothyroidism of 4.3%/year versus 2.6%/year in antibody-negative patients.

If patients are not treated, they need to be followed closely for progression of disease. Elderly patients previously treated with radioactive iodine are more likely to progress to overt hypothyroidism.

**3. MULTINODULAR GOITER**

The prevalence of multinodular goiter increases with age. However, if swallowing and breathing are not compromised and thyroid...
function tests are normal, the goiter can be observed without treatment. Levothyroxine therapy rarely shrinks the gland, and although it may prevent further enlargement, the risk of inducing iatrogenic hyperthyroidism is significant. This is compounded by the fact that multinodular goiters may independently develop areas of autonomous function.

### 4. THYROID NODULES AND CANCER

Thyroid nodules are more common in the elderly. The prevalence of nodules increases with age and is generally higher in women than in men. Furthermore, the prevalence of thyroid nodules detected by ultrasound may be as high as 40% in older women. Ninety percent of these nodules are benign, but the prognosis for elderly patients with malignant nodules may be worse than that for younger patients with malignant nodules. The approach is similar to the workup in a younger patient. The prognosis correlates with the size of the tumor. The outcome in elderly patients may therefore be substantially improved by early evaluation of nodules in patients who are good surgical candidates.

Papillary carcinoma is more common in young and middle-aged patients. However, it has a poorer prognosis in the elderly, possibly because it is detected at a more advanced stage. Follicular carcinoma accounts for 15% of thyroid cancers and usually occurs in middle-aged and older patients. Anaplastic thyroid carcinoma is found almost exclusively in middle-aged and older patients. It presents as a rapidly growing hard mass that is locally invasive, often associated with metastatic lesions, and has a very poor prognosis (Chapter 7).

### CARBOHYDRATE INTOLERANCE AND DIABETES MELLITUS

#### Introduction

Diabetes is an important health condition for the aging population. More than 20% of individuals over the age of 60 years have diabetes, and another 14% have impaired glucose tolerance (IGT). It is anticipated that these numbers will continue to increase in the coming decades. It is therefore almost certain that those involved in the care of patients in this age group will encounter those with some disorder of glucose tolerance.

Both IGT and diabetes are associated with enhanced morbidity and mortality due to macrovascular and cardiovascular disease (CVD); an increase in risk for microvascular complications (retinopathy, neuropathy) that impair the ability to maintain independence; changes in cognitive function; and depression. Older individuals with diabetes have more functional disability and coexisting illnesses such as hypertension, coronary heart disease (CHD), and stroke than those without diabetes. Older adults with diabetes are also at greater risk for urinary incontinence, injurious falls, and issues related to polypharmacy.

Early diagnosis and appropriate intervention can help to avoid some of the adverse consequences of hyperglycemia, while also improving health-related quality of life (HRQL) in this age group. In 2003, the American Geriatric Society published guidelines that are useful in guiding the care of the older person with diabetes. These recommendations are now included as part of the standards of care published annually by the American Diabetes Association.

#### Aging and the Physiology of Carbohydrate Intolerance

Normal aging is associated with a gradual increase in both fasting (1 mg/dL [0.6 mmol/L] per decade) and glucose-stimulated blood glucose (BG) (5 mg/dL [0.28 mmol/L] per decade) levels, even in lean, physically active individuals with normal body weight. Normoglycemic elderly subjects have higher glucose and insulin levels during an oral glucose tolerance test (OGTT) than body mass index (BMI)-matched young subjects. These changes in BG are more profound in those who have risk factors for abnormal glucose tolerance.

Type 2 diabetes is characterized by defects in both insulin secretion and sensitivity. Although the majority of people with type 2 diabetes are insulin-resistant, insulin resistance by itself is not sufficient to lead to hyperglycemia. Age-related impairments in beta cell function that include reduced conversion of proinsulin to insulin and abnormal insulin secretion are important contributors to the development of hyperglycemia in elderly individuals. Lean elderly patients with type 2 diabetes have a greater impairment in insulin secretion than insulin sensitivity while obese patients have both impaired insulin secretion and sensitivity in muscle and liver (Figure 23-6).

Several abnormalities of beta cell function contribute to the decline in insulin secretory capacity with advancing age. These include an accumulation of intracellular lipid within the beta cell; a decrease in glucose transporter (GLUT) 2 number; and a reduced sensitivity to the incretin hormones, glucagon-like peptide 1 (GLP1), and glucose insulino tropic peptide (GIP) that acts to augment the postprandial insulin response. Genetic susceptibility also plays a role. In individuals without diabetes who carry five or more risk alleles that are associated with development of diabet es, impairments in insulin secretion are observed at an earlier age than those with fewer alleles. Evidence of autoimmunity with antibodies directed against beta cell proteins has been demonstrated as a cause of impaired insulin secretion in up to 12% of elderly individuals.

These impairments in beta cell function can be unmasked by an increase in insulin resistance that occurs with normal aging. The insulin resistance that accompanies aging is associated with the accumulation of intracellular fat and a progressive decline in the number and function of mitochondria resulting in reduced oxidative glucose metabolism and phosphorylation activity. Insulin resistance is augmented by weight gain; reductions in lean body mass and increases in fat mass; physical inactivity; and use of some medications (ie, glucocorticoids and atypical antipsychotics). Insulin resistance occurs in muscle, where there is a reduction in insulin-mediated glucose uptake following a meal; in adipose tissue where impaired regulation of hormone-sensitive lipase results in increases in circulating levels of free fatty acids (FFA); and liver where there is overproduction of glucose in the fasting state and failure to adequately suppress glucose production after a meal.
More profound in lean elderly with type 2 diabetes

HYPERGLYCEMIA

Increased hepatic glucose production

Liver

Impaired insulin secretion

Pancreas

Decreased muscle glucose uptake

Muscle

More profound in obese elderly with type 2 diabetes

FIGURE 23-6 The pathogenesis of type 2 diabetes mellitus in obese elderly and lean elderly.

Metabolic Syndrome
The metabolic syndrome refers to a clustering of metabolic abnormalities outlined in Table 23-2 that are associated with an increase in risk for type 2 diabetes and CVD. This syndrome is more common in the elderly, increasing from approximately 7% of the population in the third decade to 44% in the seventh decade. Lifestyle interventions targeting modifications in dietary intake, regular exercise, and weight reduction are effective in reducing the progression to overt type 2 diabetes among individuals above age 60 years.

Establishing the Diagnosis of Diabetes Mellitus

A. Diagnostic criteria The majority of elderly individuals with diabetes will have type 2 diabetes. The typical symptoms usually associated with hyperglycemia may either not be present or may have developed so gradually that they may not be perceived as being abnormal. The use of diuretics can mask polyuria and polydipsia as manifestations of hyperglycemia. An age-related decrease in thirst may blunt these usual symptoms. It is therefore important that laboratory measurement of BG be performed on at least an annual basis in individuals above the age of 60.

A diagnosis of diabetes can be established by one of three established criteria outlined in Table 23-3. Oral glucose tolerance testing is performed infrequently in clinical practice and is not required to establish the diagnosis, particularly in elderly individuals. Measurement of an A1c is now accepted as an alternative tool in establishing a diagnosis of diabetes, with values ≥6.5% consistent with a diagnosis of diabetes. A1c values of 6.0% to 6.4% identify those at high risk for development of type 2 diabetes. A reasonable approach would be to measure an A1c in any elderly person with abnormal glucose values.

B. Glycemic goals Both the ADA and the American Geriatrics Society recommend that functional, cognitively intact older adults who have significant anticipated life expectancy be treated to similar glycemic goals as younger adults. This means guiding therapy to achieve HbA1c of <7% for the majority of people with diabetes.

TABLE 23-3 Criteria for diagnosis of type 2 diabetes.

- Fasting glucose ≥ 126 mg/dL (7.0 mmol/L)
- Any glucose ≥ 200 mg/dL (11.1 mmol/L) with symptoms
- 2-h PG ≥ 200 mg/dL (11.1 mmol/L) during a 75-g OGTT

Newly proposed criterion: A1c ≥ 6.5%

Note: Any single abnormal measure requires confirmation with a second test.
Achieving this level requires that fasting glucose levels be maintained between 80 and 130 mg/dL, and 2-hour postprandial BG at <180 mg/dL. These recommendations are not absolute. While the goal is to maintain an A1c value as close to normal (<6%) as possible, this goal can be modified in patients who are at high risk for hypoglycemia, who are older, who have comorbid conditions that limit life expectancies. These contingencies have particular relevance to the elderly population who may experience variability in appetite or food intake, or often have other medical problems requiring medications (eg, beta blockers, anxiolytics) that can increase vulnerability to hypoglycemia. On the other hand, uncontrolled diabetes is also associated with undesirable effects in elderly individuals, including fluid and electrolyte abnormalities, problems with urinary incontinence and cognitive function, indicating the need for a reasonable degree of glycemic control even with advanced age. Efforts to achieve A1c levels of <7% are reasonable in some elderly patients, provided that the risk for weight gain and hypoglycemia is minimized. Therapy can be modified to achieve A1c targets of 8% in others as a way of minimizing risk for treatment-associated concerns. However, symptomatic hyperglycemia that can increase risk for an acute hyperglycemic crisis should be avoided in all patients.

C. Glycemic control and complications Because the complications of diabetes mellitus are related to the duration of disease, elderly patients who live long enough suffer the same complications of nephropathy, neuropathy, and retinopathy as their younger counterparts. The United Kingdom Prospective Diabetes Study (UKPDS) examined the relationship between improved glycemic control and the prevention of complications in 3067 patients with type 2 diabetes (mean age 54 years) assigned to intensive (goal of fasting blood glucose <108 mg/dL) or conventional therapy. After a median follow-up of 10 years, the incidence of microvascular complications (retinopathy, neuropathy, and nephropathy) was reduced by 25% with intensive treatment. There was no difference in the incidence of macrovascular complications, but there was a tendency for fewer myocardial infarctions in the intensive therapy group. A 10-year follow-up report from the UKPDS demonstrated a significant favorable legacy effect of early intensive therapy in preventing both microvascular and macrovascular complications.

Elderly diabetic patients have an impaired counterregulatory response to hypoglycemia which can interfere with recovery from a hypoglycemic event. In addition, the ability to sense hypoglycemia declines, as does the ability to take corrective action. Coupled with the diminished cortical reserve due to the higher prevalence of age-associated conditions such as stroke, lacunar infarction, amyloid angiopathy, and Alzheimer disease, the older brain is less able to recover fully from hypoglycemic insult.

Cardiovascular Disease

CVD is a major cause of morbidity and mortality in elderly people with diabetes. For this reason, interventions recommended for the secondary prevention of recurrent coronary events in individuals without diabetes are recommended for all individuals with diabetes independent of known heart disease. This includes control of blood pressure, treatment of hyperlipidemia, and use of low-dose aspirin therapy in those without contraindications. While tight glycemic control has been demonstrated to reduce the risk for microvascular and neuropathic complications, the role of tight glycemic control for prevention of macrovascular disease and CVD has been addressed in several recent clinical trials.

Three recent large, randomized, prospective clinical trials with relevance to an elderly population were conducted in an effort to define the effect of lowering A1c to levels lower than those currently recommended by the ADA on cardiovascular outcomes in patients with type 2 diabetes. The average age of these subjects, all of whom had a history of a CVD event or were at high risk for an event, ranged from 60 to 66 years.

In the Action to Control Cardiovascular Risk in Diabetes (ACCORD) study, the goal of intensive glycemic therapy was to achieve an A1c <6% versus <8% with conventional treatment. The glycemic control study was stopped 18 months early due to the observation of a 22% increase in the relative risk for CVD death with intensive therapy. In the Action in Diabetes and Vascular Disease (ADVANCE) study, the goal of intensive therapy was to achieve an A1c <6.5% using the sulfonylurea, gliclazide (not available in the United States). A reduction in microvascular complications, primarily risk for proteinuria, was observed with intensive therapy, but there were no group differences for CVD events. In the Veterans Affairs Diabetes Trial (VADT), the goal of intensive therapy was to achieve an A1c <6%. There were no significant group differences in the composite outcome of CVD events; however, there were more CVD deaths (36 vs 29) and more sudden deaths in intensively treated subjects (11 vs 4) ($p = NZ). Severe hypoglycemia within the preceding 90 days was a predictor of CVD events and mortality.

What do these results mean to the practicing physician? It is important to note that all three trials included participants with long-standing type 2 diabetes and varying degrees of established atherosclerosis at time of study entry. In addition, the glycemic targets in these trials were well below what is recommended by the ADA (7%) and may not be appropriate in elderly individuals where the risk for hypoglycemia and related adverse sequelae is greater. Other CVD risk factors (eg, hypertension and hyperlipidemia) were treated to a moderate or high degree, resulting in rates of CVD events that were lower than predicted with standard therapy. This places emphasis on the importance of treating nonglycemic CVD risk factors in patients with diabetes.

Treatment Strategies for Achieving Glycemic Goals in the Elderly

The therapeutic goals for any patient with diabetes, including the elderly, are to avoid symptoms of hyperglycemia and hypoglycemia, to minimize risk for acute and chronic diabetes-related complications, and to achieve an optimal health-related quality of life. While the majority of newly diagnosed elderly individuals will have type 2 diabetes, many individuals with type 1 diabetes are enjoying longer survival, making it likely that these patients will require care during advancing years. Insulin therapy, either alone or in
combination with oral agents, is often required to maintain desired glycemic control in the face of progressive beta cell dysfunction in those with type 2 diabetes. For these reasons, knowledge of insulin and noninsulin injectable medications is as important as that of the five different classes or oral hypoglycemic agents (Table 23-4) indicated for the treatment of type 2 diabetes.

A. Therapeutic lifestyle intervention  The essential components of therapeutic lifestyle intervention (TLI) include dietary modifications and exercise. Weight reduction is recommended for overweight and obese individuals. Recommendations to obtain an adequate amount of sleep as either one uninterrupted sleep cycle or with daily naps may help reduce risk for progression to overt diabetes in those with impairments in glucose intolerance.

Dietary interventions for treatment of diabetes promote appropriate dietary caloric intake with an appropriate distribution of calories among carbohydrates, protein, and fat. There is contradictory information in the literature regarding the optimal diet that should be recommended for patients with diabetes. Studies comparing different diets for achieving weight loss have yielded inconsistent results. In general, obese patients can be encouraged to follow a weight reduction regimen that is most acceptable to their taste, as this is more likely to result in a reasonable degree of compliance.

The Mediterranean diet which emphasizes the intake of fresh fruits and vegetables, whole grains, beans, nuts, and olive oil, may have some advantages over traditional low-fat diets in the elderly population. In one European study of more than 2000 subjects aged 70 to 90 years, the integration of a Mediterranean style diet with other healthy lifestyle interventions reduced all-cause mortality by more than 50%. The Mediterranean diet not only promotes weight loss, but also has demonstrated favorable effects on circulating lipids and BG levels.

In the ongoing Look AHEAD Study, subjects with type 2 diabetes between the ages of 45 and 74 years were able to achieve a 9% weight loss and 21% increase in fitness level with 30 minutes of exercise and 1200 to 1800 calorie intake each day. Exercise prescriptions and encouragement to maintain a reasonable level of physical activity are as important in the elderly as in the younger population. There is no longer a requirement to perform cardiac stress testing before recommending an exercise program. To optimize compliance with exercise prescriptions, it is important to encourage activities that are enjoyed, that can be performed safely, and that can be incorporated into a daily routine. Some insurance companies now provide health club memberships as a way of encouraging activity. Many elderly individuals have difficulty with aerobic activity as a form of exercise. For those who are housebound or who have difficulty walking for any distance due to presence of spinal stenosis, peripheral neuropathy, claudication or other medical problems, stationary bicycling, arm lifts with weights, or leg lifts can be encouraged. Progressive resistance training has been proposed as a more reasonable and beneficial form of exercise in these patients.

B. Pharmacologic therapy  TLI is rarely adequate at achieving and maintaining glycemic control without pharmacologic therapy in the majority of patients with type 2 diabetes, including the elderly. This means that some form of pharmacologic therapy will almost always be required. While there is no absolute contraindication to use of any of the oral or injectable agents available for treating diabetes, there are special considerations for prescribing and monitoring of these agents in older adults. As a general rule, medications should be started at the lowest dose and gradually titrated upward as tolerated until glycemic targets are reached. In some cases, it becomes necessary to add on a second agent before maximal doses are reached with one agent as a way of minimizing adverse reactions. For example, the incidence of gastrointestinal side-effects increases with increasing doses of the biguanide, metformin. There are many patients who may be unable to tolerate the maximal dose of 2 g of metformin each day, but who are able to tolerate 1 to 1.5 g/d. In these instances, it may be desirable to continue metformin at a lower dose and add an insulin secretagogue to achieve the desired level of glycemic

---
control. A discussion of pharmacologic therapy in this review is presented with consideration of this strategy in an elderly population (see Table 23–4).

Initiation of metformin together with TLI is recommended at the time of diagnosis of type 2 diabetes. Side-effects with use of metformin that have particular relevance to elderly patients include anorexia, nausea, abdominal cramping, and diarrhea that preclude the use of this drug in approximately 5% of all individuals. Reductions in vitamin B₁₂ levels have also been observed. Given the high prevalence of vitamin B₁₂ deficiency in the elderly population, it is reasonable to monitor its levels and/ or recommend vitamin B₁₂ supplementation at a dose of 50 µg/d or more.

The most feared complication of therapy with metformin is lactic acidosis. This can be avoided by following prescribing guidelines that recommend against use of metformin in those with renal insufficiency, defined as a serum creatinine ≥1.5 mg/dL in men, ≥1.4 mg/dL in women; or a creatinine clearance of <60 mL/min. The observed age-related decline in glomerular filtration rate (GFR), as a measure of creatinine clearance, raises concerns for using metformin in the elderly; however, the formulas used to estimate GFR (eGFR) do not always provide accurate results in this population. When there is doubt as to whether metformin can be initiated or continued in a patient with a normal serum creatinine but a reduced eGFR, measurement of a creatinine clearance with 24-hour urine collections can provide a more accurate measure of renal function. In patients assessed as having normal renal function at the time metformin is started, renal function needs to be reassessed with changes in clinical status. Caution is suggested in patients >80 years of age, although there are no data demonstrating a higher incidence of lactic acidosis in this population, provided that renal function is normal.

There may in fact be advantages to metformin therapy. In a study of patients age 72 years with type 2 diabetes and congestive heart failure (CHF), those treated with metformin experienced lower morbidity and mortality when compared to those treated with sulfonylurea monotherapy. There are also epidemiologic data that suggest that treatment with metformin is associated with a lower incidence of cancer and cancer-related deaths.

Alternative or additional pharmacologic therapy is required for patients for whom metformin therapy is contraindicated, who do not tolerate the medication, or who do not achieve the desired level of glycemic control. Insulin secretagogues include long-acting sulfonylureas and shorter-acting meglitinides, which have similar efficacy in lowering A1c levels by 1.5%. The sulfonylureas reduce both fasting and postprandial glucose levels while the shorter-acting meglitinides reduce postprandial glucose excursions. Both renal insufficiency and increasing age are risk factors for hypoglycemia with use of these agents in the elderly when used as either monotherapy or combination therapy. Glipizide and glimepiride are less likely to cause prolonged hypoglycemia in the elderly than glyburide, which has active metabolites. The shorter-acting meglitinides administered immediately prior to a meal can be useful in reducing the risk for hypoglycemia in the elderly who experience variability in appetite or the timing of meals.

When insulin secretagogues are prescribed, it is important that patients and their family members be educated in how to both recognize and treat a low-BG reaction (Table 23–5). Many individuals are unaware of what these symptoms are and can mistake this for simple fatigue or a cardiac event, resulting in potentially dangerous delays in therapy. It is important that patients be instructed to carry a glucose source with them at all times. This can be in the form of hard candy or glucose tablets.

The two thiazolidinediones available for clinical use are pioglitazone and rosiglitazone. Both agents reduce HA1c levels by 0.8% to 1.5%, with pioglitazone having more favorable effects on circulating triglycerides. Caution is warranted when using this class of medications in elderly individuals due to their potential to cause weight gain, edema, CHF, and reductions in bone mineral density (BMD) with increased fracture risk. In one report investigating outcomes with glitazones in individuals age >65, treatment with rosiglitazone was associated with a 60% increased risk of new-onset CHF, a 40% increased risk for MI, and a 29% increase in mortality. As both the incidence and prevalence CHF increase with age in those with diabetes, caution is required when using these agents in elderly patients. If a decision is made to use these agents, close monitoring for onset of edema, weight gain, and shortness of breath is important. Regular monitoring of 25-hydroxyvitamin D levels and BMD measurements is also indicated to address fracture risk.

The alpha-glucosidase inhibitors, acarbose and miglitol, delay absorption of carbohydrate from the small intestine by inhibiting the enzymes that convert carbohydrates into monosaccharides. This results in a reduction in postprandial glucose excursions, with reductions in A1c of 0.5% to 0.8% when used alone or in combination with other oral agents or insulin. The main limitation to the use of these agents is the high incidence of GI side effects that are directly related to their mechanism of action. Abdominal bloating and distension, diarrhea, and cramping occur in approximately
50% of patients. Initiating therapy at a low dose of 25 mg once a day given with the main meal and allowing gradual upward titration can improve compliance with this group of medications. It is important that patients be instructed to use glucose tablets to treat hypoglycemia that may occur when taking this class of medications with sulfonylureas or insulin, as there can be delayed absorption of glucose from food sources.

There are now two relatively new classes of medications that address the role of the incretin hormone, GLP1, in glucose homeostasis: injectable GLP1 analogs and orally administered dipeptidyl peptidase IV inhibitors (DPP IV). GLP1 is a hormone that is normally secreted by L cells in the distal ileum in response to a meal (Figure 23–7). GLP1 acts directly on beta cells to enhance endogenous insulin secretion, and on alpha cells to reduce glucagon levels. Endogenously secreted GLP1 is degraded by the DPP IV, which contributes to its short circulating half-life. Exenatide is the first GLP1 mimetic approved for clinical use. Liraglutide is another agent in this class that has recently been approved for use. Sustained reductions in A1c of approximately 1% have been observed with use of these agents. The major side-effects include anorexia, nausea and vomiting, abdominal pain, diarrhea, and weight loss. However, these side-effects often abate over time and with exenatide are minimized by starting with doses of 5 μg administered twice a day for a month before increasing to 10 μg twice a day. Hypoglycemia is possible when used in combination with a sulfonylurea. There are at least 36 postmarketing reports of acute pancreatitis with use of exenatide, but the incidence of this disorder does not appear to be greater than in the general population with type 2 diabetes. Nevertheless, a high index of suspicion is recommended in patients who report abdominal pain with use of these agents. It is anticipated that a once-weekly preparation of exenatide will become available for clinical use in the next 1 to 2 years.

There are two DPP IV inhibitors available for clinical use, sitagliptin and saxagliptin. By prolonging the duration of action of endogenously secreted GLP1, these agents reduce A1c by 0.6% to 0.9%. The DPP IV inhibitors are weight neutral and do not cause hypoglycemia when used as monotherapy. The major side-effects of these agents are an increase in upper respiratory and lower urinary tract infections, headache, skin rash, sinusitis, and back pain. The higher incidence of infectious complications may have significance in the elderly population who are more likely to have asymptomatic bacteriuria. However, there is no absolute contraindication to use of these agents in the elderly. Dose adjustments are required in the presence of renal insufficiency with each of the available agents. The relatively benign side-effect profile can make them attractive for use; however, these agents are expensive and may have effects that are currently unknown. DPP IV is a ubiquitous enzyme that is also expressed in lymphocytes, raising concern for alterations in immune function.

When glycemic targets cannot be achieved with the agents discussed earlier, insulin therapy becomes necessary. In patients with isolated morning hyperglycemia, the addition of a bedtime dose of neutral protamine Hagedorn (NPH) can be effective in controlling fasting glucose levels. When both fasting and daytime BG levels are elevated, a long-acting insulin administered once daily can be more effective in lowering glucose levels throughout the day (Table 23–6). When BG levels remain elevated despite the use of basal insulin alone, premeal doses of a short- or rapid-acting insulin can be added.

When adding NPH insulin at bedtime to oral agents, a low starting dose of 5 to 10 U allows an elderly patient to become accustomed to insulin injections with a low risk for hypoglycemia.

The dose can then be titrated gradually over a period of several weeks until glucose levels are in the desired range. A commonly used strategy is to advise patients to increase by 1 or 2 U every 4 days until they achieve a fasting glucose of less than 140 mg/dL.

When initiating basal/bolus insulin, the starting dose of insulin can be calculated as 0.2 to 0.3 U/kg/d, with 50% of the dose administered as basal insulin and 50% as premeal insulin in divided doses prior to meals. For patients already receiving basal insulin who require the addition of premeal insulin, the dose of premeal insulin can be calculated as follows:

- If the BG is mildly elevated with the majority of readings below 200 mg/dL, the dose of basal insulin can be reduced by 50% with distribution of the remaining 50% into three premeal insulin doses.
- If the majority of BG levels are >200 mg/dL, premeal insulin doses can be started as approximately 25% to 30% of the current basal dose given before each meal. For example, if a patient is receiving 24 U of glargine or NPH each day, the starting dose of regular or humalog before each meal would be 6 to 8 U.

Many elderly individuals can be given instructions in how to advance their insulin doses or how to adjust the dose of insulin according to results of BG measurements. Correction insulin refers to the administration of supplemental doses of short or rapid-acting insulin when BG exceeds glycemic targets. A reasonable glycemic target may be to maintain all BG between 100 and 150 mg/dL. In these cases, the individual patient can be instructed to reduce their premeal insulin dose by 1 to 2 U if their BG is <100 mg/dL, and to increase by 1 U for every 50 mg/dL above 150 mg/dL.

There will be a minority of elderly patients who are unable to achieve adequate control of postprandial glucose excursions with insulin alone. Pramlintide, a synthetic analog of the beta cell hormone amylin, is effective at reducing postprandial BG levels when used in combination with insulin. This injectable medication is approved for use in combination with insulin for patients with both type 1 and type 2 diabetes. Side-effects of pramlintide include nausea and vomiting, which are more common in people with type 1 diabetes, and hypoglycemia. Nausea and vomiting can be minimized by starting at doses of 15 μg before each meal with gradual upward titration to 60 for people with type 1 diabetes. Those with type 2 diabetes can be started at a dose of 60 μg and titrated to 120 μg before meals. The risk for hypoglycemia can be reduced by reducing prandial insulin doses by 50% when pramlintide is initiated.

In summary, there are five classes of oral agents and two noninsulin injectable therapies, in addition to insulin, that are effective at achieving glycemic control as monotherapy or as part of combination therapy. The side-effect profile, risk for hypoglycemia, and cost need to be considered when choosing a regimen for an individual patient.

**Screening for Diabetes-Related Complications in the Elderly**

The care of older adults with diabetes is complicated by their clinical and functional heterogeneity. Some older individuals developed diabetes years earlier and may have significant complications. Others may be newly diagnosed but may already have complications related to the disease. Some older adults with diabetes are frail with limited physical or cognitive abilities due to the presence of other underlying chronic conditions. Life expectancies are highly variable for this population, but often longer than clinicians realize. Providers caring for older adults with diabetes must take this heterogeneity into consideration when setting and prioritizing treatment goals.

Screening for microvascular diabetes-related complications is as important in older adults as it is in younger individuals, with attention directed to complications that can result in functional impairments if these remain untreated. While the natural history of diabetic retinopathy is different in those above age 70, recommendations for periodic eye examinations to detect not only changes related to diabetic retinopathy, but also for cataracts, macular degeneration, or glaucoma are important in allowing for early detection of disorders that can progress to cause visual impairment.

Annual measurement of serum creatinine and urine microalbumin allow for identification of nephropathy and chronic kidney disease due to other causes that can have their progression modified by dietary interventions and use of medications to lower blood pressure. Annual measurement of a lipid profile with interventions to treat those identified as having dyslipidemia can modify risk for cardiovascular events, which are associated with morbidity, decreased quality of life, and mortality.

Regular foot examinations with identification of anatomic abnormalities and sensory deficits that can reduce mobility are recommended. Medicare will cover the cost of special shoe wear for individuals with diabetes complicated by neuropathy or foot deformity. Pedorthic shoe wear is characterized by increased depth with a wider toe box that reduces pressure points that predispose to ulcer formation. Many prescriptions for shoe wear also include orthotics that allow for more even pressure distribution, thus improving the ability to walk without concern for foot injury.

**A. Acute hyperglycemic complications**

Hyperglycemic hyperosmolar nonketotic syndrome (HHNS) is more common in elderly patients than diabetic ketoacidosis (DKA). HHNS can occur in patients with and without a history of type 2 diabetes. It is characterized by severe elevations in BG (>600-800 mg/dL), plasma hyperosmolarity (>320 mOsm/L), severe dehydration, and absent to mild acidosis. The development of HHNS in the elderly population can be attributed, in part, to an impaired thirst mechanism and an age-related increase in the renal threshold for reabsorption of glucose leading to an osmotic diuresis and intravascular volume contraction. Predisposing factors include myocardial infarction, pneumonia, infections, use of certain medications (eg, diuretics, phenytoin, glucocorticoids), or any acute medical illnesses. Patients often present with an altered mental status (lethargy, coma), marked volume depletion, orthostatic hypotension, and prerenal azotemia. Urine and serum ketones can be mildly elevated but usually not to the degree observed with diabetic ketoacidosis.

HHNS is a life-threatening disorder that requires prompt therapy with intravenous fluids and close monitoring of cardiac status. In addition to therapy directed toward treatment of the precipitating event (if known), extracellular fluid volume deficits,
which can be profound, are replaced initially with normal saline followed by half-normal (0.45%) saline. Half of the fluid and electrolyte deficits can be replaced in the first 24 hours and the remainder over the next 48 hours.

Once volume replacement is addressed, low-dose intravenous infusions of insulin (5 U bolus followed by 1-5 U/h) can be initiated. The administration of insulin prior to volume correction can exacerbate intravascular fluid depletion and further compromise renal function as glucose shifts to the intracellular compartment. Potassium deficits can be addressed once urine output is established. Following resolution of the hyperglycemia, patients require careful evaluation of the cause of the deterioration as well as attention to the need for ongoing management of hyperglycemia with insulin or oral agents.

Care of the Elderly Patient with Diabetes in the Hospital

Hyperglycemia frequently accompanies acute illnesses that prompt hospitalization in patients with and without a history of diabetes. Newly recognized hyperglycemia adversely affects patient outcomes to a greater extent than established diabetes, with longer hospital length of stay, higher mortality, and increased likelihood of discharge to an extended care or rehabilitation facility. For these reasons, attention to glycemic control is as important during periods of hospitalization as it is in the outpatient setting.

The ability to achieve tight glycemic control in the hospital is hampered by rapid changes in clinical status, as well as by hospital routines that can increase risk for undetected hypoglycemic events that are associated with adverse patient outcomes. Current guidelines suggest glycemic targets of 140 to 180 mg/dL in both critically ill and non-critically ill-hospitalized patients. In critical care settings, this can be achieved with validated IV insulin infusion protocols. In non-critically ill patients, scheduled subcutaneous basal-bolus insulin is preferred. Less stringent glycemic targets may be appropriate for patients who have multiple comorbidities and reduced life expectancy, but in general, glucose levels should be maintained at values below 200 mg/dL to minimize fluid and electrolyte abnormalities, reduce renal complications, and avoid infections.

The practice of using sliding scale insulin as the only glycemic management strategy in hospitalized patients is discouraged. These regimens are associated with both hypoglycemia and hyperglycemia as they encourage reaction to a single BG value rather than a rational management strategy. Oral and injectable non-insulin glucose-lowering agents have a limited role for hospital use but may be appropriate for selected non-critically ill patients.

Osteoporosis and Calcium Homeostasis

Osteoporosis

Despite the high prevalence, severe morbidity, and expense of osteoporosis, until recently most of our knowledge was derived from studies of younger postmenopausal women. Yet it is the older woman who typically experiences the ravages of the disease. Twenty-five percent of women have vertebral fractures by age 70; by age 80, the figure is closer to 50%. More than 90% of hip fractures occur in patients over age 70, and by age 90, one woman in three will have sustained such a fracture. Hip fractures are associated with significant morbidity, an increased risk of institutionalization, and an up to 20% increase in mortality rates. Despite the significant differences between perimenopausal and older women, diagnostic and therapeutic approaches for older women are derived largely from studies of newly postmenopausal women. The relevance of such studies for older women has only recently been questioned.

Definition and Risk of Fracture

The definition of osteoporosis has changed over the years. In 1991, a consensus development conference defined osteoporosis as "a disease characterized by low bone mass and microarchitectural deterioration of bone tissue, leading to enhanced bone fragility and a consequent increase in fracture risk." The World Health Organization issued classification criteria for postmenopausal women based on measurements of BMD or bone mineral content. Osteoporosis is defined as a BMD T-score of $-2.5$ standard deviations below the young adult mean value (Table 23–7). This permits numerical standardization of the definition. In 2008 the World Health Organization developed the FRAX algorithm that estimates the likelihood for a patient to sustain a hip or a major osteoporotic fracture (clinical spine, forearm, hip, or shoulder) over the next 10 years. The model is designed to include men and women, age 40 to 90, who have not previously been treated with medications for osteoporosis. FRAX uses population-based cohorts for Europe, North America, Asia, and Australia, and for the United States risk assessments are available for Caucasian, African American, Hispanic, and Asian groups. In addition to specific risk factors (Table 23–8), the model uses age, gender, height, weight, and femoral neck BMD or T-scores.

### Risk Factors for Osteoporosis and Fractures

Multiple factors contributed to the risk of low bone mass, osteoporosis, or fractures. Lifestyle factors include low calcium or vitamin D intake, high caffeine or salt intake, alcohol, smoking, falls, thin/frail habitus, and inactivity. Common endocrine disorders in the elderly include hyperthyroidism, hyperparathyroidism, and diabetes. Multiple myeloma and lymphoma can present with fractures. Emphysema, congestive heart failure, depression, end-stage renal disease, and malabsorption also contribute to it. Medications in the elderly that contribute to bone loss include glucocorticoids (≥5 mg/d of prednisone or equivalent for ≥3 months), anticonvulsants, aromatase inhibitors, androgen deprivation therapy, excess thyroid hormone, lithium, antirejection drugs, and heparin. By age 70, approximately 80% of women have a hip BMD that is osteopenic or osteoporotic, compared with 40% of women in their fifties (Figure 23–8).

Falling is often cited as a major risk factor for hip fracture in older women. Although more than one-third of elderly women fall annually, however, fewer than 5% of falls result in fracture. A fall to the side, a low hip BMD, low BMI (lean body habitus), and high-fall energy have been shown to be significant independent risk factors for hip fracture in community-dwelling elderly. In nursing home subjects, a fall to the side, low hip BMD, and impaired mobility were independent risk factors. Other factors, including a maternal history of hip fracture, previous hyperthyroidism, inability to rise from a chair, poor depth perception, poor contrast vision, and use of anticonvulsants or long-acting benzodiazepines are also associated with hip fractures in elderly women. Furthermore, with multiple risk factors, the risk of hip fracture increases significantly.

### Factors Affecting Bone Physiology

There are significant physiologic differences between newly postmenopausal and older women with respect to maintenance of skeletal integrity. Although calcium intake is often inadequate in both age groups, calcium absorption declines with age despite an age-related increase in serum levels of parathyroid hormone (PTH). This increase is not due solely to a decrease in renal reabsorption of calcium but may represent secondary hyperparathyroidism from vitamin D insufficiency. When PTH levels are assessed in elderly community dwelling women, PTH levels increase as vitamin D levels fall below roughly 30 ng/mL (75 nmol/L) (Figure 23–9), similar to what has been observed in younger cohorts.

#### A. Vitamin D

Vitamin D deficiency is common in the elderly, and vitamin D metabolism changes with age. Up to 15% of healthy elderly residents of communities in the sunny southwestern United States have frank vitamin D deficiency; still more have subclinical vitamin D deficiency; and up to 50% of elderly nursing home residents are deficient in vitamin D. This occurs because elderly individuals have decreased sun exposure and an impaired ability to form vitamin D precursors in the skin, a decreased dietary intake of vitamin D, and (possibly) an age-related decline in vitamin D receptors in the duodenum. In addition, the ability to convert vitamin D to its active moiety (1,25(OH)2-D3) is impaired with age. Certain vitamin D receptor polymorphisms have been associated with lower BMD and bone loss in some populations, although further investigations of vitamin D metabolism are needed in the elderly in the United States. Finally optimal vitamin D levels of ≥30 ng/mL (75 nmol/L) have been associated with higher BMD, decreased fracture risk, improved

lower extremity function, and decreased risk of colon cancer (Figure 23–10).

**A. Bone loss and architectural changes**

The rate of bone loss also differs between newly postmenopausal and older women. Cortical and trabecular bone are lost rapidly at menopause. Older longitudinal studies suggested that bone loss ceased or slowed in older women. However, longitudinal studies suggest that older women lose an average of 0.7% to 1% per year at the hip, and femoral bone loss increases with age. Vertebral BMD changes assessed by anteroposterior measurements can give a misleading assessment of bone mass as a consequence of nonspecific calcifications from osteoarthritis, sclerosis, aortic calcifications, and osteophytes that interfere with and falsely elevate the measurement. Therefore, measurement of femoral BMD is more reliable in the elderly.

In addition, there are changes in bone geometry; cortical bone remodeling in older women is insufficient to compensate for the loss of bone mineral content (Figure 23–11). There are also qualitative changes in trabecular bone, because an age-related reduction in trabecular bone jeopardizes plate integrity or connectivity; trabecular plates not only become perforated and disconnected, but with aging they continue to thin, causing further loss of bone strength and compromising the bone's ability to regain structural integrity with conventional therapy. The loss of trabecular connectivity in the elderly can be visualized by high resolution MicroMRI technology of the wrist (Figure 23–12).

**FIGURE 23–9** Baseline parathyroid hormone (PTH) and 25-hydroxyvitamin D levels in 553 community-dwelling elderly women. The line shown is a locally smoothed regression line (LOESS) of PTH given 25-hydroxyvitamin D. Twenty-six observations with PTH above 80 pg/mL are not shown (mean vitamin D level 13.1 ng/mL) to allow details of the LOESS curve to be visible. (Reproduced, with permission, from Greenspan SL, et al. Vitamin D supplementation in older women. J Gerontol A Biol Sci Med Sci. 2005;60:754-759. [PMID: 15983179])

**FIGURE 23–10** Relative risks (RRs) of fracture and colon cancer. Solid lines relate to the left axis, and dashed lines relate to the right axis. 25(OH)D, 25-hydroxyvitamin D. For bone mineral density (BMD), the example of older whites was chosen, and the unit is shown in the upper part of the right y axis. For lower extremity, the 8-ft walk test was chosen; the unit is seconds, as shown on the lower half of the right y axis. Alveolar attachment loss (measure of periodontal disease) is given in millimeters for older men, as shown in the lower part of the right y axis. This summary of all outcomes indicates that a desirable serum 25(OH)D concentration for optimal health begins at 75 nmol/L, and the best concentration is 90 to 100 nmol/L. (Reproduced, with permission, from Bischoff-Ferrari HA, et al. Estimation of optimal serum concentrations of 25-hydroxyvitamin D for multiple health outcomes. Am J Clin Nutr. 2006;84:18. [PMID: 16825677])
FIGURE 23–11 Schematic representation of cortical bone remodeling with age in males and females. Note that with age-related bone loss, bone is remodeled in men to increase its diameter and partially offset the loss of strength. In women, bone diameter changes little with age, so that bone strength decreases proportionately more than in men. (Reproduced, with permission, from Ruff CB, Hayes WC. Sex differences in age-related remodeling of the femur and tibia. J Orthop Res. 1988;6:886.)

Evaluation
Screening older patients by obtaining a BMD measurement is a comfortable, painless, noninvasive, rapid technique for determining an individual’s bone mass and relative fracture risk. In general, the relative risk of spine or hip fracture roughly doubles for every standard deviation decrease in BMD below young, gender-matched mean values. Patients may remain dressed and lie on a padded table. Although several methods are available, currently the best technique uses dual-energy x-ray absorptiometry (DXA) of the hip or spine (Figures 23–13 and 23–14). The National Osteoporosis Foundation suggests obtaining a bone mass assessment in all women age 65 or older and all men age 70 or older regardless of risk factors. In addition, younger postmenopausal women and men age 50 to 69 with risk factors (see Risk Factors for Osteoporosis), adults who fracture after age 50, and those with a condition or medication causing bone loss should receive a bone mass measurement. For most elderly women, the hip is the single most useful measurement because nonspecific calcifications can lead to falsely elevated measurements in the posteroanterior view of spine.

Similar to the evaluation in a younger individual who presents with bone loss or fracture, the workup in an older patient can be designed to exclude secondary causes of osteoporosis. Hyperthyroidism and hyperparathyroidism are both more common in older women, can cause bone loss, and can be clinically silent in older individuals. Because 10% of women over age 65 are receiving thyroid hormone replacement therapy and because thyroid hormone overreplacement results in bone loss in postmenopausal women, true physiologic replacement with a normal serum TSH (if possible) should be the goal of treatment. Osteomalacia, vitamin D deficiency, and insufficiency may present as nonspecific muscle or skeletal discomfort and is more common in the elderly. This can best be assessed by checking a 25 hydroxyvitamin D level that should be ≥30 ng/mL or 75 nmol/L. In addition, metastatic carcinoma, multiple myeloma, hepatic and renal disease, and malabsorption (especially secondary to gastrectomy) should be excluded. Hypogonadism in men can be evaluated with a testosterone level. Medications (listed under Risk Factors) can cause bone loss.

Biochemical markers of bone turnover reflect bone formation and resorption. Although these markers are associated with the rate of bone turnover even in elderly women, they cannot be used in lieu of a BMD measurement to assess bone mass or to make a diagnosis. Because factors outside the skeleton contribute to fracture risk in the elderly, however, the search for correctable factors must extend beyond those that affect BMD. Particular attention should be devoted to the patient’s home environment and medication use.

Patients who have sustained a fragility fracture as an adult have clinical osteoporosis and require evaluation and treatment. Because two-thirds of vertebral fractures are asymptomatic, patients with 1.5 to 2 in of height loss may need a lateral radiograph to look for vertebral deformities or compression fractures. Older patients presenting with skeletal discomfort should be evaluated by radiography to rule out a fracture. Vertebral osteoporosis usually presents with anterior wedging, involvement of more than one vertebra, prominent vertebral trabeculae, and vertebral deformities usually occurring below T6 (Figure 23–15). Worrisome signs suggesting that skeletal involvement is not due to osteoporosis alone include nerve root compression, posterior wedging, isolated vertebral involvement (especially above T4), and pedicle destruction.

FIGURE 23–12 High-resolution MicroMRI images of radial trabecular bone in a young woman at peak bone mass and in 76-year-old and 80-year-old women demonstrating loss of trabecular connectivity (trabecular horizontal struts) with age.
This patient has a total hip bone mineral density (BMD) of 0.330 g/cm² (black circle on the reference database graph) as measured by dual-energy x-ray absorptiometry, a femoral neck T-score of −4.69 and a total hip T-score of −5.02. The reference database graph displays age- and sex-matched mean BMD levels ±2 SD (shaded areas) derived from the third National Health and Nutrition Examination Survey. T-score indicates the difference in SD between the subject’s BMD and the predicted sex-matched mean peak young adult BMD; Z-score, the difference in SD between the subject’s BMD and the sex- and age-matched mean BMD; and % of mean, the subject’s BMD as a percentage of the mean peak young adult BMD- or age-matched BMD level. (Adapted from bone densitometry report, QDR-4500C bone densitometer, Hologic Inc, Bedford, Massachusetts.)

This patient has a lumbar spine (L1-L4) bone mineral density (BMD) of 0.410 g/cm² (cross on the reference database graph) measured by dual-energy x-ray absorptiometry and a T-score of −5.79. The reference database graph displays age- and sex-matched mean BMD levels ±2 SDs (shaded areas) derived from a normative database from the manufacturer, Hologic Inc, Bedford, Massachusetts. T-score indicates the difference in SD between the subject’s BMD and the predicted sex-matched mean peak young adult BMD; Z-score, the difference in SD between the subject’s BMD and the sex- and age-matched BMD level; and percentage of mean, the subject’s BMD as a percentage of the mean peak young adult BMD- or age-matched BMD level. (Adapted from bone densitometry report, QDR-4500C bone densitometer; Hologic Inc, Bedford, Massachusetts.)
Treatme nt

Clinical Crossroads. A 73-year-old woman with osteoporosis. (Reproduced, with permission, from Clinical Crossroads. A 73-year-old woman with osteoporosis. JAMA. 1999;281:1531.)

Furthermore, older individuals may complain of persistent groin pain with weight-bearing, while plain radiographs of the hip reveal no fracture. A bone scan may be necessary to confirm the diagnosis of hip fracture. Vertebral fractures can also be assessed with DXA technology by Vertebral Fracture Assessment. Because this can be done at the same point of care when a patient is having a DXA scan, this is convenient for older patients.

Treatment

Because the factors that affect bone physiology—the rate of bone loss, the structure of remaining bone, and the risk of fracture—are substantially different in newly postmenopausal and elderly women, interventions appropriate for younger women may be inappropriate for elderly women. Studies of older individuals that use BMD—or preferably fracture—as an end-point provide the best data.

A. Calcium  Controversy surrounds the use of calcium supplementation by itself in postmenopausal women, and few data are available regarding its use in older women. Theoretically, calcium supplementation seems appropriate because calcium intake in the elderly is low, and the ability to adapt to a low calcium diet declines with age. Calcium supplementation reduces the rate of bone loss. A meta-analysis of prospective cohort studies and randomized controlled trials concluded that calcium intake by itself was not associated with hip fracture risk and was neutral for non-vertebral fractures. However, a reduction in hip fractures and improvement in BMD has been demonstrated in very elderly women (mean age 84) treated with vitamin D (800 IU daily) and calcium (1200 mg daily). The National Academy of Sciences recommends 1200 mg/d of elemental calcium in divided doses. In addition to dairy products, many foods (eg, orange juice, cereals, and nutritional bars) are now fortified with calcium. Calcium carbonate supplements should be given in divided doses with meals to improve absorption in the elderly, who may suffer from achlorhydria. Calcium citrate can be used as an alternative in such patients. A potential problem with prescribing high doses of calcium in the elderly includes inducing or exacerbating constipation. In addition, because compliance with other drug regimens decreases as the number of drugs increases, calcium tablets may be taken at the therapeutic expense of more important medications. Finally, because supplementary calcium does interfere with absorption of zinc, elderly patients receiving calcium supplementation should be encouraged to take a multivitamin containing zinc. Calcium absorption is not impaired by psyllium.

B. Vitamin D  Vitamin D deficiency is common in the elderly, and vitamin D is needed for calcium absorption, mineralization of bone, and improvement in muscle strength. The current recommendation from the National Osteoporosis Foundation is 800 to 1000 IU/d. Vitamin D can be administered as a pure supplement of cholecalciferol (available as 400-2000 U tablets), in a daily multivitamin (400-800 IU) or calcium supplement (200-500 IU/tablet). A Cochrane review of 45 trials involving 84,585 participants comparing vitamin D alone or with calcium versus placebo reported vitamin D alone was not effective, but when combined with calcium, did result in hip fracture reduction in institutionalized elderly. Another meta-analysis of randomized controlled trials concluded that 700 to 800 IU/d of vitamin D, but not 400 IU/d of vitamin D, reduced the risk of hip and nonvertebral fractures in elderly patients. Clinical trials utilizing calcitriol (1,25-dihydroxy vitamin D₃) as a therapeutic option for osteoporosis have reported conflicting results. Given that the complications of hypercalcemia are increased, this form of vitamin D should probably be avoided.

C. Exercise  Although the rationale for exercise therapy is sound, few data are available on results of exercise in elderly women. One study prescribed exercise for older women and found that forearm bone mineral content increased in those who continued exercising during a 3-year trial. Middle-aged women (mean age 60) participating in high-intensity strength training for 1 year had improvements in femoral bone mass, muscle strength, balance, and activity level compared with controls. A Cochrane review of 111 trials (55,303 participants in the community) reported that multiple component group exercise reduced the rate of falls and risk of falling, as did TaiChi. Walking—generally 30 minutes three times a week—is often suggested for frail individuals.

D. Bisphosphonates  Bisphosphonates—nonhormonal agents that inhibit bone resorption—effectively prevent and treat osteoporosis. Bisphosphonates are the mainstay of therapy in the elderly. The aminobisphosphonates, alendronate, risedronate, ibandronate, and zoledronic acid have been shown to increase BMD at the spine (5%-8%) and hip (3%-6%) over 3 years in prospective clinical trials in postmenopausal women. Fractures of...
the spine were reduced by approximately 40% to 70%. Alendronate, risedronate, and zoledronic acid have reduced nonvertebral fractures (25%-40%), including hip fractures (40%-60%), in women with osteoporosis. Improvements following treatment with alendronate and risedronate have also been demonstrated in older women residing in long-term care facilities. Furthermore zoledronic acid has been shown to reduce clinical fracture 35% and reduce all-cause mortality by 28% in patients following a hip fracture. When taken properly, the oral medications are well-tolerated—an important factor in choosing therapeutic alternatives for the elderly. Moreover the oral medications are available as a daily, weekly (alendronate, risedronate), and monthly (risedronate, ibandronate) medication and the IV therapies can be given every 3 or 12 months (ibandronate and zoledronic acid respectively). The oral medications have been associated with nausea, heartburn, and epigastric distress. Both the IV and oral bisphosphonates have been associated with arthralgias and myalgias which is an important clinical consideration in this age group. Theses agents should not be used in elderly patients with an estimated GFR ≤ 35 mL/min. Osteonecrosis of the jaw is a rare event in patients using these agents at a dose for osteoporosis. For men, alendronate, risedronate, and zoledronic acid are approved. For glucocorticoid-induced bone loss, alendronate, risedronate, and zoledronic acid are approved for treatment, risedronate is approved for prevention.

E. Estrogen and selective estrogen receptor modulators

There is considerable evidence that estrogen therapy, if initiated at menopause, slows bone loss, temporarily increases bone mass, and may prevent osteoporotic vertebral and hip fractures. If therapy is continued, its efficacy is sustained at least until age 70. In addition, some studies have shown that estrogen increases vertebral and femoral bone mass. However, the Women’s Health Initiative found an increased risk of cardiovascular disease, breast cancer, and thromboembolic events along with a significant reduction in hip fractures and other osteoporotic fractures in women receiving conjugated estrogen plus medroxyprogesterone. Because of the increased risks, hormone therapy is currently not recommended as a treatment for osteoporosis because there are other available and effective therapies.

Selective estrogen receptor modulators (SERMs) have estrogen agonist and antagonist actions. Raloxifene has been approved for the prevention and treatment of postmenopausal osteoporosis. Although improvements in BMD are less with raloxifene than estrogen therapy, studies demonstrate a reduction of approximately 50% in vertebral fractures with no mastalgia, vaginal bleeding, or increased endometrial thickness. Studies demonstrated a reduction in cholesterol and raloxifene is also approved for the reduction in the risk of invasive breast cancer in postmenopausal women with osteoporosis. Because there is an increase in venous thromboembolic events, raloxifene should not be used in immobilized elderly or those with clotting abnormalities. Raloxifene has not been shown to reduce nonvertebral or hip fractures.

F. Other therapeutic options

Although calcitonin is an approved therapy for osteoporosis in postmenopausal women, few data are available about its effect on the incidence of fractures. It is expensive and when given by injection is poorly tolerated by the elderly. Nasal calcitonin has been shown to reduce fractures of the spine—but not of the hip—with no improvement in hip bone density. Calcitonin may reduce acute pain associated with vertebral fractures.

Teriparatide, PTH (1-34), the first anabolic agent, has been shown to significantly increase bone density (9.7% for spine bone density in 18 months) and reduce vertebral and nonvertebral fractures in postmenopausal osteoporotic women. Teriparatide is approved for postmenopausal women and men at high risk for fracture and for patients with glucocorticoid-induced osteoporosis. There are little data in the frail elderly. This is given as a subcutaneous daily injection for 2 years only.

Denosumab, an antiresorptive agent, that is a fully monoclonal antibody to receptor activator of nuclear factor kappa B ligand (RANK-L) inhibits binding to RANK and the formation and activation of osteoclasts. Denosumab has been shown to increase BMD at the spine by 9.2% and at the hip by 6.0% over 3 years compared to placebo in a clinical trial in women with an average age of 72 years. Denosumab reduced vertebral fractures by 68%, hip fractures by 40%, and nonvertebral fractures by 20% (all p<0.05). This is given as a subcutaneous injection every 6 months and is still under evaluation by the FDA. There are little data in the elderly.

Although results regarding the efficacy of hip protectors for hip fracture reduction in elderly patients have been mixed, hip protectors represent a relatively inexpensive option in frail elders. Poor compliance has been a key component in the lack of efficacy. Furthermore the type and design of the hip pad may also play a role in its efficacy.

Vertebroplasty and kyphoplasty are interventions in which polymethylmethacrylate (vertebroplasty) or polymethylmethacrylate in a balloon (kyphoplasty) are placed in compressed vertebrae for patients with intractable pain from vertebral fractures. There are few trials with these interventions, and it is not known whether the procedures strengthen or weaken adjacent vertebrae. Recent randomized trials with sham-operated controls suggest that vertebroplasty was similar to the control group for pain and pain-related disability associated with an osteoporotic compression fracture.

Summary of Management Recommendations

In summary, there is ample reason to question the validity of extrapolating data from studies of newly postmenopausal women when formulating a treatment plan for older women. However, given the prevalence of the problem, it is reasonable to recommend an adequate daily intake of vitamin D (800-1000 IU), an adequate daily intake of calcium (totaling 1200 mg), and judicious participation in an individually tailored exercise program. The use of bisphosphonates, SERMs, teriparatide (PTH) (1-34), or other treatments needs to be individually considered in elderly women. For elderly men, the use of alendronate, risedronate, zoledronic acid, and teriparatide are available for treatment.
Perhaps more importantly, the risk of falls should be addressed. The risk can be reduced by reviewing medications (including nonprescription agents) and discontinuing (when possible) those with adverse effects on cognition, balance, or blood pressure. Common offenders include long-acting benzodiazepines, tricyclic antidepressants, antipsychotics, antihypertensives, and agents with anticholinergic side-effects. It is also important to correct reversible sensory losses and medical conditions and to educate patients about hazards in their environment, such as throw rugs, extension cords, and poorly illuminated stairways, which could lead to falls and fractures. For patients with gait disorders, physical therapy should be considered.

Patients who have recently sustained a hip fracture should receive the same evaluation and consideration as those without a fracture. Because a hip fracture places the patient at a more than double the risk for a future fracture, and bisphosphonate therapy will reduce that risk, a hip fracture should not serve as a reason to omit evaluation or treatment (see also Chapter 8).

**HYPERPARATHYROIDISM**

**Clinical Features**

The prevalence of hyperparathyroidism increases with age. Although its incidence is less than 10 per 100,000 in women under age 40, the incidence increases to 190 per 100,000 in women over age 60. As a result, more than half of all cases of conventional approach of visualization of all glands. This not only monly seen; renal, gastrointestinal, and skeletal complications tion, and confusion. Failure to thrive and constipation are com­

Although irs incidence is less than 10 per 10 0,000 in women

**Treatment**

For symptomatic patients and those with serum calcium levels 1 mg/dL above the upper limit of normal, parathyroidectomy may be recommended according to current guidelines (see Chapters 8 and 26). Parathyroidectomy is well tolerated in the elderly and is the treatment of choice. Minimally invasive parathyroidectomy uses preoperative localization by neck ultrasound and sestamibi scan and intraoperative measurement of PTH rather than the conventional approach of visualization of all glands. This not only improves the success rate but simplifies the surgical procedure as well. Parathyroidectomy procedures in elderly patients have similar outcomes compared with younger patients with respect to cure rate, morbidity, mortality, and patient satisfaction. For those with more modest elevations, treatment recommendations are less simply stated because it is difficult to differentiate symptoms and signs due to the disease from those seen in older individuals without hyperparathyroidism. Moreover, asymptomatic individuals—especially those with levels of serum calcium under 11 mg/dL (2.8 mmol/L)—have been known to remain asymptomatic for more than a decade. An observational study of 116 patients followed up to 15 years, reported that one-third of subjects had disease progression meeting surgical criteria. Until more data become available, the decision to treat asymptomatic individuals surgically should be made on an individual basis.

In older patients who are not surgical candidates, cinacalcet (a calcimimetic that binds to the calcium-sensing receptor on the cells of the parathyroid gland) can rapidly normalize serum calcium and reduce PTH in patients with primary hyperparathyroidism. Short-term studies demonstrate normalization of serum calcium, a small decrease in serum PTH without a significant impact on BMD. In women, a course of estrogen may be effective. Ethinyl estradiol (30-50 µg/d) or conjugated estrogens (0.6-25-1.25 mg/d) reduce serum calcium by an average of 0.8 mg/dL (0.2 mmol/L), diminish urinary calcium excretion, and antagonize the skeletal effects of PTH. However, the risks of estrogen (discussed earlier) make this an undesirable choice. In men and women with higher elevations of serum calcium, oral phosphates can be used, but they are less well tolerated in the elderly because of their gastrointestinal side-effects and the potential for ectopic calcification. Furosemide is a less satisfactory alternative in frail elderly patients because it increases the risk of dehydration and resultant hypercalcemia.

**CHANGES IN WATER BALANCE**

With age, major changes in renal function and homeostatic mechanisms result in significant changes in water balance. Renal blood flow, cortical mass, the number of glomeruli, and tubular function all decline with age, though medullary mass is preserved. On average, the glomerular filtration rate decreases at a rate of 10 mL/min per decade from age 30 onward. Clinically, however, the most relevant change is the age-related decline in creatinine clearance, which is largely due to relative hypertension in the elderly. Because of the decrease in muscle mass associated with aging, however, serum creatinine levels are unchanged and may not accurately reflect the extent of renal functional impairment.

Extrarenal modulators of water balance also change significantly with age. Although there are no changes in the basal level, half-life, volume of distribution, or metabolic clearance of vasopressin, the stimulated responses of vasopressin are significantly altered. Hyperosmolar stimuli increase serum vasopressin levels in older subjects to five times those achieved in younger subjects. This exaggerated antidiuretic hormone response makes elderly patients more susceptible to hyponatremia. On the other hand, the normal vasopressin increase observed in response to overnight dehydration and postural change is impaired in the elderly.
Additionally, basal and stimulated levels of serum renin and aldosterone decline with age. In contrast, basal levels of atrial natriuretic peptide are three times higher in healthy elderly individuals than in young controls. These elevated levels of atrial natriuretic peptide may help identify patients at risk for the development of CHF. Finally, the thirst sensation appears to be somewhat impaired in healthy elderly individuals and is more impaired in those who are frail.

In addition to physiologic changes, many diseases and drugs further increase the vulnerability of the elderly to changes in water balance. These include kidney disease, hypertension, and congestive heart failure as well as medications that alter water balance (eg, narcotics, diuretics, lithium, carbamazepine, amphotericin B, intravenous hypotonic fluids, and hypertonic contrast agents).

**HYPERNATREMIA**

**Clinical Features**

The incidence of hypernatremia in elderly patients admitted to the hospital ranges from 1% to 3% and is higher for institutionalized elderly patients. Signs and symptoms are usually nonspecific (eg, lethargy, weakness, confusion, depression, failure to thrive). The cause is usually multifactorial, including impaired thirst mechanism, renal disease, sedative-induced confusion, use of restraints, reduced access to free water intake, excess water loss due to fever, and decreased response to vasopressin. Medications can cause nephrogenic diabetes insipidus; these include lithium, foscarnet, diuretics, amphotericin B, and demeclocycline. Central diabetes insipidus can result from CNS trauma, malignancy, infection, or it may be idiopathic.

**Treatment**

As in younger patients, initial therapy involves correcting the volume deficit with isotonic saline and then correcting the water deficit with half-normal (0.45%) saline. Roughly 30% of the deficit should be corrected within 24 hours and the remainder within the next 24 to 48 hours (see also Chapter 5).

**HYPONATREMIA**

**Clinical Features**

The prevalence of hyponatremia is approximately 2.5% in the general hospital setting—higher in geriatric units—and rises to 25% in nursing home settings. Hyponatremia can be classified by the total body sodium as hypovolemic hyponatremia (decrease in total body sodium, eg, after diarrhea, vomiting, diuretic use), euvoletic hyponatremia (normal total body sodium, as seen with syndrome of inappropriate antidiuretic hormone [SIADH]), hypothyroidism, adrenal insufficiency, and medications) or hypervolemic hyponatremia (excess total body sodium, as seen with CHF or cirrhosis). Presenting symptoms and signs of euvolemic hyponatremia are often nonspecific and include lethargy, weakness, and confusion. The mechanisms predisposing to hyponatremia include the exuberant response of vasopressin to osmolar stimuli, a decreased ability to excrete a water load, and the sodium-wasting tendency of the older kidney. Furthermore, elderly patients often use medications and have diseases that impair free water excretion. Drugs that can cause hyponatremia include tricyclic antidepressants, phenothiazines, serotonin reuptake inhibitors, angiotensin-converting enzyme inhibitors, morphine, antiseizure medications, nonsteroidal anti-inflammatory drugs (NSAIDs), and acetaminophen. Common hyponatremic syndromes in the elderly include SIADH and thiazide-induced hyponatremia. In the geriatric rehabilitation hospital, approximately half of patients with hyponatremia have SIADH (see Chapters 5 and 21).

**Treatment**

The treatment of hyponatremia in the elderly depends on the type of hyponatremia. The treatment of euvolemic hyponatremia does not differ from that in younger patients (Chapters 5 and 24). Vasopressin receptor antagonists lead to an increase in electrolyte-free water diuresis, and an increase in serum sodium levels in patients with SIADH and hypervolemic hyponatremia from CHF or cirrhosis. Additional studies are needed, but these agents may become the mainstay of treatment.

**HYPORENINEMIC HYPOALDOSTERONISM**

Hyporeninemic hypoaldosteronism usually occurs in elderly patients with diabetes and mild renal insufficiency. Patients are usually asymptomatic. Hyperkalemia and metabolic acidosis are found on routine screening. Symptoms of hyperkalemia (eg, heart block) may be provoked by administration of a beta-adrenergic blocking agent, which further compromises extrarenal regulation of potassium homeostasis. After other causes of persistent hyperkalemia are ruled out, patients respond well to administration of small doses of fludrocortisone (0.05 mg/d) or furosemide combined with restriction of dietary potassium.

**GLUCOCORTICOIDS AND STRESS**

Cortisol levels increase 20% to 50% with age. There is an increase in the nocturnal level of cortisol, an age-related morning increase in cortisol in women (not men), and an advancement in the circadian rhythm (Figure 23–16). Aging is associated with an increase in the cortisol production rate, independent of weight, and this accounts for the increased daily urinary free cortisol levels in older individuals. Dehydroepiandrosterone (DHEA) secretion declines with age and can be partially restored by mineralocorticoid antagonism, but in healthy elders, trials do not support supplementation with DHEA.

In healthy elderly individuals, dynamic testing of the hypothalamic-pituitary-adrenal axis is normal; expected responses to insulin-induced hypoglycemia, metyrapone, dexamethasone, adrenocorticotropic hormone, and corticotropin-releasing hormone (CRH) are preserved (Figure 23–17).
levels increase to the same extent in young and old patients compared with those in 20- to 29-year-old subjects (the slope of the regression was $r = 0.29$ in men ($p < 0.002$) and $r = 0.50$ in women ($p < 0.0001$). Sex differences in the slope of the regression failed to reach significance. Lower panels: Mean 24-hour cortisol profiles in men and women 50 years of age and older ($n = 25$ and $n = 22$, respectively; blue lines) compared with those in 20- to 29-year-old subjects ($n = 29$ and $n = 20$, respectively; pink lines). The shading at each time point represents the SEM. (Reproduced, with permission, from van Cauter E, Leproult R, Kupfer DJ. Effects of gender and age on the levels and circadian rhythmicity of plasma cortisol. J Clin Endocrinol Metab. 1996;81:2468. Copyright 1996 by The Endocrine Society.)

**DISORDERS OF THE HYPOthalamic-Pituitary-adrenal axis**

1. **Abnormal Response to Stress**

   In contrast to the normal responses in the elderly to dynamic testing of the hypothalamic-pituitary-adrenal axis, increased stress elicits abnormal responses. For example, although serum cortisol levels increase to the same extent in young and old patients undergoing elective surgery, the increase may be protracted in the elderly. Compared to younger, physically fit women, older physically fit women have greater cortisol production in the recovery period after a physical exercise challenge. Patients with diabetes mellitus and hypertension have also been found to have an exaggerated and prolonged response to corticotropin-releasing hormone (CRH) stimulation. Older patients with Alzheimer disease may also have a delayed and prolonged response to CRH stimulation. It is not known if these elevated cortisol levels contribute to the increased hypertension, glucose intolerance, muscle atrophy, and impaired immune function observed in the elderly. However, an elevated urinary free cortisol level is an independent predictor of osteoporotic fractures in the elderly.

2. **Adrenal Hypersecretion**

   Although adrenal hypersecretion (Cushing syndrome) is uncommon in the elderly, it is easily overlooked because it mimics normal aging processes. Signs such as hypertension, glucose intolerance, weight gain, and osteoporosis are less specific in elderly than in younger patients, but as in younger patients the diagnosis is established or excluded using the usual criteria (Chapter 9).

3. **Adrenal Insufficiency**

   Symptoms of adrenal insufficiency in younger patients (eg, failure to thrive, weakness, weight loss, confusion, and arthralgias) are common complaints in adrenally intact elderly patients; the most specific sign of adrenal insufficiency in the elderly is hyperpigmentation. The laboratory findings of adrenal insufficiency are similar to those in younger patients and include azotemia, hypoglycemia, hyponatremia, hyperkalemia, and eosinophilia. Because the metabolic clearance rate of cortisol decreases with age, older patients generally require lower replacement doses of cortisol (Chapter 9). For critically ill patients, the routine use of glucocorticoids should be reserved for patients diagnosed with adrenal insufficiency or...
higher frequency of hypogonadal values (Figures 23–18 and 23–19). Some studies suggest that circulating testosterone and bioavailable testosterone fall with age by 40% to 65% and are even lower in institutionalized elderly. A decrease in the number or responsiveness of testicular Leydig cells is likely because serum follicle-stimulating hormone and luteinizing hormone (LH) increase with age, and the testosterone response to human chorionic gonadotropin decreases. In addition, there is probably an age-related decrease in the ratio of circulating bioactive to immunoreactive LH. Finally, age-related alterations in pituitary function are suggested by a decreased gonadotropin response to luteinizing hormone–releasing hormone (LHRH) stimulation.

Epidemiologic studies suggest that the declining levels of testosterone are associated with decreased muscle mass and strength, decreased bone mass, increased fat, and insulin resistance. The benefit of testosterone replacement in older hypogonadal men is less clear. Potential adverse events of testosterone replacement include disordered sleep and polycythemia. The clinical impact on the cardiovascular system and prostate disease are also concerns.

CHANGES IN REPRODUCTIVE FUNCTION IN MEN

Overall, while sexual activity decreases with age, there are conflicting reports about the physiologic changes in the hypothalamic-pituitary-testicular axis. Longitudinal studies demonstrate an age-related decrease in testosterone and free testosterone and a

FIGURE 23–17 Mean values for groups A, B, and C of plasma ACTH (upper panel), F or cortisol (middle panel), and DHEA (lower panel) before and up to 120 minutes after bolus intravenous injection of ovine CRH (1 μg/kg). Group A, 21-49 years, mean age 35.2 years, n = 19. Group B, 50-69 years, mean age 60.7 years, n = 15. Group C, 70-86 years, mean age 77.1 years, n = 15. CHANGES IN REPRODUCTIVE FUNCTION IN MEN

Overall, while sexual activity decreases with age, there are conflicting reports about the physiologic changes in the hypothalamic-pituitary-testicular axis. Longitudinal studies demonstrate an age-related decrease in testosterone and free testosterone and a higher frequency of hypogonadal values (Figures 23–18 and 23–19). Some studies suggest that circulating testosterone and bioavailable testosterone fall with age by 40% to 65% and are even lower in institutionalized elderly. A decrease in the number or responsiveness of testicular Leydig cells is likely because serum follicle-stimulating hormone and luteinizing hormone (LH) increase with age, and the testosterone response to human chorionic gonadotropin decreases. In addition, there is probably an age-related decrease in the ratio of circulating bioactive to immunoreactive LH. Finally, age-related alterations in pituitary function are suggested by a decreased gonadotropin response to luteinizing hormone–releasing hormone (LHRH) stimulation.

Epidemiologic studies suggest that the declining levels of testosterone are associated with decreased muscle mass and strength, decreased bone mass, increased fat, and insulin resistance. The benefit of testosterone replacement in older hypogonadal men is less clear. Potential adverse events of testosterone replacement include disordered sleep and polycythemia. The clinical impact on the cardiovascular system and prostate disease are also concerns.
Androgen supplementation is currently not recommended in healthy older men. Clinical trials are needed to establish a clear benefit and document the safety of testosterone supplementation in elderly men.

The correlation between sexual activity and the age-related hormonal changes described is weak. There are decreased concentrations of spermatozoa in the ejaculate of older men, sperm motility and the volume of ejaculate decrease with age, and the proportion of abnormal spermatozoa also increases. DHEA and DHEA sulfate are steroids of adrenal origin that decrease with age.

Levels do not correlate with cognitive function or decline, and motility and the volume of ejaculate decrease with age, and the evaluation of erectile dysfunction in the elderly is similar to that in younger individuals (Chapter 12), although more emphasis must be placed on the effects of drugs (both prescribed and nonprescribed) and vascular causes, and a search for multiple causative factors should be undertaken. Medications associated with erectile dysfunction include diuretics (thiazides, spironolactone); antihypertensives (calcium channel blockers, beta blockers, clonidine), cardiac and cholesterol-lowering drugs, antidepressants (SSRI, tricyclic antidepressants, lithium), phenothiazines, H₂ blockers, hormones (GnRH agonists, 5 alpha-reductase inhibitors, glucocorticoids), anticholinergic agents, and cytoxic agents. Excess alcohol and smoking also contribute to it. Therapies include phosphodiesterase type 5 inhibitors that relax vascular smooth muscle cells. Because these medications can result in hypotension and increase the risk of myocardial infarction, if used with nitrates, the use must be carefully considered in elderly men with coronary artery disease.

Reproductive Function in Men

Acute or chronic failure of an endocrine gland can occasionally result in catastrophic illness and even death. Thus, it is important to recognize and appropriately manage these endocrine emergencies. This chapter will discuss crises involving the thyroid, anterior pituitary, or adrenal glands; diabetes mellitus; and abnormalities in calcium, sodium, and water balance. Except where indicated, management recommendations are provided for adult patients. Studies in the general area of endocrine emergencies have been limited in size and number. In many instances, recommendations offered in this chapter are based on published expert opinion rather than scientific evidence.

**MYXEDEMA COMA**

**Clinical Setting**

Myxedema coma is the end stage of untreated or inadequately treated hypothyroidism. The clinical picture is often that of an elderly obese female who has become increasingly withdrawn, lethargic, sleepy, and confused. The presentation is one of severe hypothyroidism, with or without coma (the term myxedema coma may, therefore, be a misnomer). The history from the patient may be inadequate, but the family may report that the patient has had thyroid surgery or radiiodine treatment in the past or that the patient has previously been receiving thyroid hormone therapy. Myxedema coma is most frequently associated with discontinuation of thyroid hormone therapy and less frequently as the first manifestation of hypothyroidism. Myxedema coma may be precipitated by an illness such as a cerebrovascular accident, myocardial infarction, or an infection such as a urinary tract infection or pneumonia. Other precipitating factors include gastrointestinal hemorrhage; acute trauma; excessive hydration; or administration of a sedative, narcotic, or potent diuretic drug.

**Diagnosis**

The physical findings are not specific. The patient may be semicomatose or comatose with dry, coarse skin, hoarse voice, thin scalp and eyebrow hair, possibly a scar on the neck, and slow reflex relaxation time. There is marked hypothermia, with body temperature sometimes falling to as low as 24°C (75°F), particularly in the winter months. It is important to be alert to the presence of complicating factors such as pneumonia, urinary tract infection, ileus, anemia, hypoglycemia, or seizures. Fever may be masked by coexistent hypothermia. Often there are pericardial, pleural, or peritoneal effusions. The key laboratory tests are a low free thyroxine (FT₄) and elevated thyroid-stimulating hormone (TSH). Note that in an emergency situation, serum TSH can be done in 1 hour. The TSH elevation may be less than predicted due to the presence of euthyroid sick syndrome or glucocorticoid or dopamine therapy. If the FT₄ is low and the TSH is low-normal, consider central or pituitary hypothyroidism. Pituitary insufficiency can be confirmed with a low serum cortisol, impaired response to the cosynthrotropin stimulation test, and/or low follicle-stimulating hormone and luteinizing hormone. It is essential to check blood gases, electrolytes, creatinine, and an electrocardiogram in evaluating

COMA

**FIGURE 24–1** Pathogenesis of myxedema coma (CNS, central nervous system). (See text for details.)

Myxedema coma is a complex problem involving a number of organ systems. The pathogenesis is presented in Figure 24–1. The decrease in serum T₄ results in a lowering of intracellular T₃. This can directly affect central nervous system function with altered mental status. The decrease in intracellular T₃ causes decreased thermogenesis, resulting in hypothermia, which in turn causes decreased central nervous system sensitivity to hypercapnia and hypoxia. The resulting respiratory insufficiency induces cerebral anoxia and coma. At the same time, the decreased intracellular T₃ results in decreased cardiac inotropism and chronotropism, decreased sensitivity to adrenergic stimuli, decreased cardiac output, and generalized vasoconstriction. This leads to a low-output state which, if untreated, culminates in decreased blood pressure and eventually shock and death. Finally, there is a change in fluid balance with increased water retention due to impaired renal perfusion as well as increased vascular permeability. These changes result in effusions and hyponatremia, which in turn contribute to the coma.

**Management**

Management of myxedema coma involves much more than simply replacing T₄ (Table 24–1). The patient is severely ill and usually is admitted to the intensive care unit (ICU) for intubation and ventilatory support. Oral medications may be poorly absorbed (due to gastric atony or ileus), and medications should be given intravenously if possible. A loading dose of 300 to 400 µg of T₄ intravenously is given initially to saturate T₄ binding sites in plasma-binding proteins. The patient is then maintained on 50 to 100 µg of T₄ intravenously daily. In addition, small doses of T₃ (eg, 10 µg intravenously every 6-8 hours) may be given over the first 48 hours, but this is usually not necessary, and it may contribute to untoward cardiovascular events. Its use should be restricted to younger patients without history of ischemic heart disease or cardiac arrhythmias. Water restriction is necessary to correct the hyponatremia, and intravenous glucose counteracts the tendency...
to hypoglycemia. It is essential to treat the precipitating illness (eg, pneumonia or urinary tract infection). The use of hydrocortisone is prudent because patients may have hypopituitarism or autoimmune polyglandular failure. Glucocorticoids are generally given in high doses until baseline cortisol or the results of rapid adrenocorticotropic hormone (ACTH) testing are available. If the initial serum cortisol is more than 30 µg/dL, steroid support is probably unnecessary. However, if serum cortisol is less than 30 µg/dL, hydrocortisone should be given intravenously in a dosage of 50 to 100 mg every 6 hours for the first 48 hours and the dose then tapered over the next 5 to 7 days while the pituitary-adrenal axis undergoes formal testing. Once myxedema coma is suspected in a hypothermic patient, external rewarming should be avoided, because this may cause redistribution of blood flow to subcutaneous tissues and cardiovascular collapse.

Prior to the recognition of the need for intravenous T₄, and for respiratory support, the mortality from myxedema coma was about 80%. Currently, the mortality is about 20% and is mostly due to the underlying or precipitating illness. Predictors of acute mortality include level of consciousness, lower Glasgow scores, and higher (acute physiology and chronic health evaluation) APACHE II scores, all indicative of the severity of the illness at presentation. Higher mortality is also associated with increased age, cardiac complications, and high-dose thyroid hormone replacement (≥2500 µg/d of L-T₄ or ≥75 µg/d of L-T₃). The latter presumably reflects the increased metabolic demand attendant to high dose replacement in the setting of limited physiologic reserve. Persistent hypothermia and bradycardia, despite therapy, are associated with a poor prognosis.

THYROID STORM

Clinical Setting
Thyroid storm, or thyrotoxic crisis, is an acute life-threatening exacerbation of thyrotoxicosis. It accounts for 1% to 2% of hospital admissions for thyrotoxicosis. It may occur in a patient with a history of Graves disease who has discontinued antithyroid medication or in a patient with previously undiagnosed hyperthyroidism. The clinical picture is that of an acute onset of hyperpyrexia (with temperature >40°C [104°F]), sweating, marked tachycardia often with atrial fibrillation, nausea, vomiting, diarrhea, agitation, tremulousness, and delirium. The presence of jaundice is considered a poor prognostic sign. Occasionally, the presentation is apathetic without the restlessness and agitation, but with symptoms of weakness, confusion, cardiovascular and gastrointestinal dysfunction, and hyperpyrexia. Some of the factors that may precipitate thyroid storm are listed in Table 24–2.

Diagnosis
The diagnosis is largely based on the clinical findings. Serum T₄, free T₄, T₃, and free T₃ are all elevated, and TSH is suppressed. These findings are not different from what is seen in other patients with hyperthyroidism, but the difference is in the setting. It is

thought that thyroid storm represents an exacerbation of thyrotoxicosis associated with a shift of T₄ from the bound to the free compartment with an increase in free T₃ and T₄ as well as an exaggerated response to a surge of catecholamines that results from the stress of the precipitating event. The cause of death is usually cardiac arrhythmia and failure. Liver function abnormalities are often seen, as is leukocytosis, even in the absence of infection.

Management
The management of thyroid storm is summarized in Table 24–3. Patients are typically admitted to an ICU for cardiac monitoring. Initially it is important to block further synthesis and secretion of thyroid hormone, first with antithyroid drugs and then with iodide. One may give propylthiouracil, 150 mg every 6 hours orally or rectally, or methimazole, 20 mg every 8 hours orally or rectally. A few hours after initiation of antithyroid drug therapy, iodides may be started. Traditionally, saturated solution of potassium iodide, five drops twice daily, has been used, but currently iopanoic acid in a dose of 0.5 g twice daily orally or intravenously, or iohexol 0.6 g (2 mL of Omnipaque 300) intravenously twice daily is the treatment of choice. These drugs not only inhibit

| Propranolol, 40–80 mg orally every 6 h |
| Propylthiouracil, 150 mg every 6 h, or methimazole, 20 mg every 8 h; may be administered per rectum if oral route is unavailable |
| Saturated solution of potassium iodide, 5 drops (250 mg) orally twice daily; or iopanoic acid, 0.5 g IV or orally twice daily; or iohexol, 0.6 g (2 mL of Omnipaque 300) IV twice daily |
| Dexamethasone, 2 mg every 6 h |
| Cholestyramine or colestipol, 20–30 g/d |
therapy should be started immediately, even though it takes time to bring the patient into a euthyroid state. Oral potassium, if indicated, should be administered cautiously. It is particularly helpful to block the conversion of T₄ to T₃, lowering the thyroid hormone level in the blood. Additional specific therapy includes β-adrenergic blockade with propranolol, 40 to 80 mg orally every 6 hours or 0.5 to 1 mg intravenously over 10 minutes every 3 hours, with continuous cardiac monitoring. In patients with asthma, the β₁-selective antagonist esmolol can be given as a bolus dose (0.25–0.5 mg/kg over 10 minutes) followed by continuous intravenous infusion (0.05–0.1 mg/kg/min). The half-life of glucocorticoids is markedly reduced in severe thyrotoxicosis, so that adrenal support may be very useful. Dexamethasone also reduces conversion of T₄ to T₃ (as do the β blockers, especially propranolol). For this purpose, dexamethasone is given in a dosage of 2 mg every 6 hours for 48 hours, followed by tapering of the dose. Finally, cholestyramine or colestipol binds T₄ in the gut interfering with its enterohepatic circulation and may help bring the circulating level of T₄ down more quickly. Supportive therapy includes adequate fluids, oxygen, management of atrial fibrillation or heart failure, parenteral water-soluble vitamins, and a cooling blanket and acetaminophen for hyperpyrexia. Aspirin should be avoided, because it will displace T₄ from thyroid hormone-binding globulin, resulting in an increase in FT₄. Plasmapheresis or dialysis to remove FT₄ has been reported to be useful in nonresponders, but this is rarely necessary.

Therapy for thyroid storm has improved markedly, so the mortality has dropped from 100% in the 1920s to about 20% to 30% in recent series. However, because storm is often associated with other underlying medical problems, it still represents a serious medical complication.

**THYROTOXIC PERIODIC PARALYSIS**

**Clinical Setting**

Thyrotoxic periodic paralysis (TPP) is a rare but frightening thyroid emergency. The usual clinical presentation is of an Asian male (male:female ratio approximately 17:1) with symptoms of untreated hyperthyroidism who awakens at night or in the morning with flaccid ascending paralysis. Typically, there is a history of vigorous exercise and/or a large high-carbohydrate meal before retiring. There is usually no family history of periodic paralysis, but there may be a family history of autoimmune thyroid disease. The paralysis initially involves the lower extremities but progresses to the girdle muscles, followed by the upper extremities. Proximal muscle groups are affected to a greater extent than distal. Facial and respiratory muscles are usually spared. Sensory function, bowel and bladder function are not affected. Deep tendon reflexes are depressed or absent. The acute episode may be complicated by cardiac arrhythmias due to the concomitant presence of hypokalemia. The illness has also been reported to occur in Native Americans, African Americans, and in individuals of Mexican or South American descent, but these ethnic groups are affected rarely.

**Diagnosis**

The differential diagnosis of TPP includes familial periodic paralysis, Guillain-Barré syndrome, and acute intermittent porphyria. The diagnosis is based on the absence of a family history, the characteristic presentation, the presence of hyperthyroidism due either to Graves disease or toxic nodular goiter (other types of hyperthyroidism have been implicated as well), and usually a low serum potassium level.

The pathogenesis is summarized in Figure 24–2. Thyrotoxicosis, increased β-adrenergic activity, and an assumed genetic predisposition, perhaps involving the potassium channel Kir2.6, with which together increased Na⁺-K⁺ ATPase activity leads to increased intracellular potassium concentrations. A high-carbohydrate meal with increased insulin secretion and glycogen deposition, vigorous exercise high salt intake, and the normal nocturnal potassium flux serve to drive serum potassium levels even lower, resulting in flaccid neuromuscular paralysis. Note that there is no loss of total body potassium, merely a shift from the extracellular to the intracellular space. Consequently, aggressive potassium repletion, particularly through the parenteral route, is discouraged because this frequently results in significant hyperkalemia as potassium redistributes across cellular compartments following resolution of the attack. Hypophosphatemia and hypomagnesemia may be present. This is also assumed to reflect intracellular sequestration. The electromyogram, performed while the patient is experiencing weakness, shows myopathic changes with reduced amplitude of compound muscle action potentials. These do not change in amplitude after administration of intra-arterial low-dose epinephrine (distinguishes from familial periodic paralysis). Electrocardiograms show changes associated with hypokalemia, tachycardia, increased QRS voltage, first-degree heart block, and, on occasion, serious ventricular arrhythmias.

**Management**

The management of this problem is presented in Table 24–4. Propranolol in doses of 60 mg every 6 hours blocks the β-adrenergic stimulation of Na⁺-K⁺ ATPase. Antithyroid drug therapy should be started immediately, even though it takes time to bring the patient into a euthyroid state. Oral potassium, if indicated, should be administered cautiously. It is particularly
Amiodarone is a benzofuran derivative that is widely used in the treatment of cardiac arrhythmias. It contains two atoms of iodine per molecule, which represents 37.5% iodine by weight. The compound is stored in adipose tissue and has a half-life in the body of 2 to 3 months, with gradual and continuous release of iodide. The usual daily maintenance dose of amiodarone of 200 to 400 mg/d releases 6,000 to 12,000 μg of iodine daily, which when compared to the normal daily requirement of about 150 μg of iodide represents an enormous iodide load.

The structure of amiodarone resembles that of T₃, and it is thought that part of the cardiac depressant effect of amiodarone may be due to binding to and blocking the T₃ receptor in cardiac muscle. However, the effect of amiodarone on the thyroid gland is different and is due in part to a direct effect of iodine on the thyroid cell—to inhibit or stimulate hormone synthesis—and a cytotoxic effect of amiodarone on the follicular cell—inducing destruction of the cell and release of stored hormone. Thus, the drug may induce hypothyroidism, which is easily managed by thyroxine replacement, or hyperthyroidism, which, because of the underlying heart disease, is much more difficult to manage and may represent a true thyroid emergency. Two mechanisms have been suggested to explain the development of hyperthyroidism: (1) the high iodine level in a multinodular gland, or in the gland of a patient with latent Graves disease, or even in a previously normal gland, can induce hyperthyroidism (see Chapter 7), and (2) the toxic effect of amiodarone itself may cause acute and chronic thyrotoxicosis with release of T₄ and T₃ into the circulation and severe hyperthyroidism. Risk factors for amiodarone-induced thyrotoxicosis include the presence of autoimmune thyroiditis and baseline elevation of TSH levels.

The patient with amiodarone-induced thyrotoxicosis may have been on the drug for months. Thyrotoxicosis typically appears 6 to 12 months after the onset of treatment. The underlying heart disease gradually worsens with increasingly frequent episodes of arrhythmia and heart failure. At the same time there may be weight loss, heat intolerance, increased nervousness, and marked muscle weakness. On physical examination, one may find nontender nodular or diffuse thyroid enlargement, tachycardia with or without atrial fibrillation, tremor, hyperreflexia, and, occasionally, lid lag and stare. Laboratory findings are unique because amiodarone inhibits the conversion of T₄ to T₃. Thus, even in the euthyroid patient taking amiodarone, total T₄ may be elevated while FT₄ and TSH are normal. In the hyperthyroid patient, the FT₄ is markedly elevated and TSH is less than 0.01 mU/L (below the detection limit of the assay). Radioiodine uptake in the iodide-loaded patient is low. It has been difficult to distinguish thyrotoxicosis due to follicular cell hyperfunction from that due to follicular cell destruction. Thyroid ultrasound with color Doppler studies may show increased circulation with hyperfunction and decreased blood flow with thyroiditis. Also, the cytokine interleukin (IL)-6 is low in patients with hyperfunction, whereas it is markedly elevated in patients with thyroiditis. However, these tests have not proven sufficiently robust to separate these two disorders.

Management

Management of amiodarone-induced hyperthyroidism is difficult (Table 24–5). Ideally, amiodarone should be discontinued, but often it cannot be stopped because of the underlying heart disease, and even if it is discontinued, the iodine load persists for several months. Further synthesis of T₄ should be blocked with methimazole in a dosage of 40 to 80 mg/d or propylthiouracil in doses of 400 to 800 mg/d. β-Adrenergic blockade, if needed (amiodarone, itself, has some β-blocking activity), should be instituted with propranolol or a comparable drug if cardiac status permits it. Potassium perchlorate in a dosage of 250 mg every 6 hours blocks further iodine uptake and lowers intrathyroidal iodide content. Aplastic anemia has occurred in patients on

### TABLE 24–4 Management of thyrotoxic periodic paralysis.

| (1) Oral potassium supplement (if needed); monitor serum K⁺ |
| (2) Oral propranolol (60 mg every 6 h) |
| (3) Antithyroid drug therapy |

**Avoid:**

- IV potassium
- IV glucose (ie, crystalloid fluid replacement only)
- β-Adrenergic agonists (eg, isoproterenol)

**Important:** It is important to be cautious if administering intravenous potassium, which may raise total body potassium to toxic levels as the episode resolves. One should also avoid intravenous glucose, which stimulates insulin secretion and worsens hypokalemia, and β-adrenergic agonists such as isoproterenol, which promote movement of potassium into the intracellular compartment and exacerbate the problem. There is no role for potassium supplementation in preventing attacks. Acetazolamide, which has been shown to reduce frequency of attacks in familial periodic paralysis, may worsen attacks of thyrotoxic periodic paralysis and should be avoided. With appropriate treatment, recovery is rapid, and once the thyrotoxicosis is controlled, the paralysis will not recur.

### AMIODARONE-INDUCED THYROTOXICOSIS

**Clinical Setting**

Amiodarone is a benzofuran derivative that is widely used in the treatment of cardiac arrhythmias. It contains two atoms of iodine per molecule, which represents 37.5% iodine by weight. The compound is stored in adipose tissue and has a half-life in the body of 2 to 3 months, with gradual and continuous release of iodide. The usual daily maintenance dose of amiodarone of 200 to 400 mg/d releases 6,000 to 12,000 μg of iodine daily, which when compared to the normal daily requirement of about 150 μg of iodide represents an enormous iodide load.

The structure of amiodarone resembles that of T₃, and it is thought that part of the cardiac depressant effect of amiodarone may be due to binding to and blocking the T₃ receptor in cardiac muscle. However, the effect of amiodarone on the thyroid gland is different and is due in part to a direct effect of iodine on the thyroid cell—to inhibit or stimulate hormone synthesis—and a cytotoxic effect of amiodarone on the follicular cell—inducing destruction of the cell and release of stored hormone. Thus, the drug may induce hypothyroidism, which is easily managed by thyroxine replacement, or hyperthyroidism, which, because of the underlying heart disease, is much more difficult to manage and may represent a true thyroid emergency. Two mechanisms have been suggested to explain the development of hyperthyroidism: (1) the high iodine level in a multinodular gland, or in the gland of a patient with latent Graves disease, or even in a previously normal gland, can induce hyperthyroidism (see Chapter 7), and (2) the toxic effect of amiodarone itself may cause acute and chronic thyrotoxicosis with release of T₄ and T₃ into the circulation and severe hyperthyroidism. Risk factors for amiodarone-induced thyrotoxicosis include the presence of autoimmune thyroiditis and baseline elevation of TSH levels.

The patient with amiodarone-induced thyrotoxicosis may have been on the drug for months. Thyrotoxicosis typically appears 6 to 12 months after the onset of treatment. The underlying heart disease gradually worsens with increasingly frequent episodes of arrhythmia and heart failure. At the same time there may be weight loss, heat intolerance, increased nervousness, and marked muscle weakness. On physical examination, one may find nontender nodular or diffuse thyroid enlargement, tachycardia with or without atrial fibrillation, tremor, hyperreflexia, and, occasionally, lid lag and stare. Laboratory findings are unique because amiodarone inhibits the conversion of T₄ to T₃. Thus, even in the euthyroid patient taking amiodarone, total T₄ may be elevated while FT₄ and TSH are normal. In the hyperthyroid patient, the FT₄ is markedly elevated and TSH is less than 0.01 mU/L (below the detection limit of the assay). Radioiodine uptake in the iodide-loaded patient is low. It has been difficult to distinguish thyrotoxicosis due to follicular cell hyperfunction from that due to follicular cell destruction. Thyroid ultrasound with color Doppler studies may show increased circulation with hyperfunction and decreased blood flow with thyroiditis. Also, the cytokine interleukin (IL)-6 is low in patients with hyperfunction, whereas it is markedly elevated in patients with thyroiditis. However, these tests have not proven sufficiently robust to separate these two disorders.

**Management**

Management of amiodarone-induced hyperthyroidism is difficult (Table 24–5). Ideally, amiodarone should be discontinued, but often it cannot be stopped because of the underlying heart disease, and even if it is discontinued, the iodine load persists for several months. Further synthesis of T₄ should be blocked with methimazole in a dosage of 40 to 80 mg/d or propylthiouracil in doses of 400 to 800 mg/d. β-Adrenergic blockade, if needed (amiodarone, itself, has some β-blocking activity), should be instituted with propranolol or a comparable drug if cardiac status permits it. Potassium perchlorate in a dosage of 250 mg every 6 hours blocks further iodine uptake and lowers intrathyroidal iodide content. Aplastic anemia has occurred in patients on

| (4) Potassium perchlorate, 200 mg every 6 h |
| (5) Cholestyramine or colestipol, 20-30 g/d |
| (6) Prednisone, 40 mg/d, for acute thyroiditis (consider monitoring IL-6 levels) |
| (7) Thyroidectomy |
high-dose or long-term potassium perchlorate therapy, so that use of this medication has usually been limited to 1 month. Iopanoic acid (0.5 g orally twice daily) can be used to decrease T₄ to T₃ conversion. Cholestyramine or colestipol in a dosage of 20 to 30 g/d binds T₄ and T₃ in the gut and brings blood levels down more quickly. If there is reason to suspect thyroiditis (elevated serum IL-6 or decreased blood flow on ultrasound), corticosteroid therapy often yields dramatic results. Predisone is given in a dosage of 40 mg/d for 1 month, gradually tapering the dose over the following 2 months. In those cases where a mixed etiology is suspected (ie, hyperfunction plus thyroiditis), a combination of steroids, antithyroid drugs, and β blockers can be used. If medical therapy is unable to control the disease, thyroidectomy results in a permanent cure and may be used as a last resort. Iopanoic acid (see above) can be used to prepare the patient for surgery. Perioperative mortality may be as high as 8% to 9% due to the underlying cardiac disease.

**ACUTE ADRENAL INSUFFICIENCY**

**Clinical Setting**

Acute adrenal insufficiency usually occurs as an acute illness in a patient with chronic adrenal insufficiency (see Chapter 9). The chronic adrenal insufficiency may be primary, due to destruction of the adrenal glands associated with autoimmune adrenalitis, adrenal leukodystrophy or, rarely, tuberculosis, fungus, or metastatic malignancy. Chronic adrenal insufficiency may also be secondary to pituitary or hypothalamic disease. Acute adrenal insufficiency may also occur with bilateral adrenal hemorrhage in a previously healthy individual during the course of septicism with disseminated intravascular coagulopathy or in a patient receiving anticoagulant therapy. In the patient with known adrenal insufficiency, an acute crisis may be precipitated by inadvertent omission of steroid medication or by the concurrent development of a precipitating illness such as severe infection, acute myocardial infarction, cerebrovascular hemorrhage or infarction, surgery without adrenal support, or severe acute trauma. Acute adrenal insufficiency may also be precipitated by the sudden withdrawal of steroids in a patient previously on long-term steroid therapy with associated adrenal atrophy (ie, secondary adrenal insufficiency). Finally, administration of drugs impairing adrenal hormone synthesis such as ketoconazole, aminoglutethimide, etomidate, or mitotane—or drugs increasing steroid metabolism such as phenytoin or rifampin—may precipitate an adrenal crisis.

The patient presents with an acute onset of nausea, vomiting, hyperpyrexia, abdominal pain, dehydration, hypotension, and shock. A clue to the diagnosis of primary adrenal insufficiency is the presence of pigmentation in unexposed areas of the skin, particularly in the creases of the palms and in the buccal mucosa. The differential diagnosis includes consideration of other causes of cardiovascular collapse, sepsis, and intra-abdominal abscess. Failure of the hypotension to respond to pressors is suggestive of adrenal insufficiency and is an indication for a trial of glucocorticoid therapy.

**Diagnosis**

Primary adrenal insufficiency is characterized by hyponatremia and hyperkalemia. However, in situations of adrenal crisis, the hyponatremia may be obscured by dehydration. Random serum cortisol determinations are not helpful unless the levels are very low (<5 μg/dL [138 nmol/L]) during a period of great stress. The key diagnostic test is failure of serum cortisol to rise above 20 μg/dL (552 nmol/L) 30 minutes after intravenous injection of 250 μg synthetic ACTH (cosyntropin) (see Chapter 9 for details). This test functions best in the diagnosis of primary versus secondary adrenal insufficiency. At a specificity of 95%, sensitivities are 97% and 57%, respectively (see Chapter 3). Interpretation of the test, particularly in the evaluation of secondary adrenal insufficiency, is complicated in the presence of hypoalbuminemia, a marker for reduced protein-bound cortisol in plasma. In this setting, serum-free cortisol levels provide a more accurate assessment of adrenal function. Random serum-free cortisol of >1.8 μg/dL and a Cortrosyn-stimulated value of >3.1 μg/dL in critically ill patients is considered normal. There has been increased interest in using a more physiologic dose of ACTH to perform this stimulation test (1 μg vs 250 μg); however, a recent comparison suggests no particular advantage in the performance characteristics of the low-dose test. Basal serum ACTH is elevated (>52 pg/mL [>11 pmol/L]) in patients with primary adrenal insufficiency but not in patients with secondary adrenal insufficiency due to pituitary or hypothalamic disease. Computed tomography (CT) or sonography of the abdomen reveals adrenal enlargement in patients with adrenal hemorrhage, active tuberculosis, or metastatic malignancy. Atrophy of the adrenals is associated with chronic adrenal insufficiency.

**Management**

The management of adrenal crisis is outlined in Table 24–6. Hydrocortisone should be administered in a dosage of 100 mg intravenously followed by 50 to 75 mg every 6 hours thereafter. Fluids and Na⁺ should be replaced with several liters of 5% glucose in normal saline. After the first 24 hours, the dose of intravenous hydrocortisone can be slowly reduced, but intravenous doses should be given at least every 6 hours because of the short half-life (1 hour) of hydrocortisone in the circulation. When the

| (1) | Hydrocortisone sodium phosphate or sodium succinate, 100 mg IV stat and then 50-75 mg IV every 6 h for 24 h. Then taper slowly downward over the next 72 h, giving the drug every 4-6 h IV. When patient is tolerating oral feedings, shift to oral replacement therapy, overlapping the first oral and last intravenous doses. |
| (2) | Replace salt and fluid losses with several liters of 5% glucose in normal saline IV. |
| (3) | Patients with primary adrenal insufficiency may require mineralocorticoid (fludrocortisone) when shifted to oral hydrocortisone maintenance therapy. |
| (4) | Diagnose and treat the illness that precipitated the acute crisis. |
A patient can tolerate oral feedings, hydrocortisone can be given orally, but the first oral dose should overlap the last intravenous dose. Alternatively, hydrocortisone can be administered as a continuous infusion at the rate of 10 mg/h for the first 24 hours, followed by a gradual decrease in the dose. Mineralocorticoid is not necessary during the acute replacement period since enough NaCl and glucocorticoid are being administered to treat the mineralocorticoid deficiency. However, in patients with chronic primary adrenal insufficiency, mineralocorticoid supplementation is necessary when shifting to an oral maintenance program (see Chapter 9). After steroid therapy has been instituted, it is extremely important to evaluate and treat the illness that may have precipitated the acute crisis (eg, infection, myocardial infarction).

Prevention of acute adrenal insufficiency in patients with chronic adrenal insufficiency exposed to mild stress can be addressed merely by doubling the daily steroid dose until the condition resolves followed by rapid titration back to prestress doses. More severe stress (eg, severe infection) requires intravenous hydrocortisone in dosages as outlined above or administration of dexamethasone sodium phosphate, 4 mg intramuscularly every 24 hours for two doses. Dexamethasone would replace glucocorticoids but not mineralocorticoid and would not be adequate in the presence of severe dehydration.

**Sepsis**

Studies of patients with septic shock have identified a subgroup that may have relative adrenal insufficiency (ie, decreased adrenal reserve). These patients were identified based on a limited increment (ie, the difference between basal and post-ACTH cortisol levels) rather than the absolute level of post-ACTH cortisol. A recent randomized trial (CORTICUS [Corticosteroid Therapy of Septic Shock] study) demonstrated that hydrocortisone therapy did not improve survival or reversal of shock in patients with septic shock, regardless of their response in the Cortrosyn stimulation test. However, hydrocortisone did hasten reversal of shock in those patients in whom shock was reversed. At the present time, the utility of steroid therapy in the management of vasopressor-dependent septic shock remains controversial.

**Diabetic ketoacidosis**

Diabetic ketoacidosis (DKA) occurs in a setting of absolute or relative insulin deficiency. Estimated annual incidence is 4 to 8 episodes per 1000 patients with diabetes. Specific clinical settings should generate a high index of suspicion for the disorder. Interruptions of normal insulin delivery due to purposeful reduction in insulin dosage or interference with the delivery system (eg, kinking in pump tubing) are frequent precipitating events, as are reduced insulin sensitivity in the setting of systemic infection, myocardial infarction, burns, trauma, or pregnancy. In a significant percentage of patients, DKA is the presenting feature of diabetes. In these instances, clinical suspicion and accurate interpretation of the initial laboratory studies will usually lead to the correct diagnosis.
diagnosis. Measurement of HbA1c (hemoglobin A1c) levels may help in assessing the chronicity of the diabetes. Mortality in DKA is less than 5% in experienced centers. Prognosis worsens at the extremes of age and in the presence of coma or hypotension.

**Diagnosis**

DKA is characterized metabolically by two prominent features: hyperglycemia and ketoadidosis (see Chapter 17). Patients with DKA present with evidence of volume contraction (eg, dry mucous membranes, thirst, orthostatic hypotension) and labored breathing (Kussmaul respiration) related to the underlying acidosis. The breath often has a fruity odor, reflecting the presence of acetone. Patients may have abdominal pain mimicking an acute abdomen, nausea, and vomiting. The latter symptoms may be related to elevated gastrointestinal prostaglandins that accrue in the presence of insulin deficiency. Presentation may be dominated by symptoms of the precipitating illness (eg, urinary tract infection, pneumonia, or myocardial infarction).

Plasma glucose levels are elevated, usually to over 250 mg/dL. This reflects impairment in glucose utilization (see discussed earlier), increased gluconeogenesis and glycogenolysis, and reduced renal clearance of glucose in the setting of decreased glomerular filtration rate (GFR). Osmotic diuresis related to glucose excretion results in reduction in intravascular volume and depletion of total body water, sodium, potassium, phosphate, and magnesium. In general, the relative depletion of water is roughly twice that of the solutes it contains. Hypertonicity in the extracellular fluid compartment, although typically not as severe as that seen in hyperosmotic nonketotic coma (see later), can be significant. Calculated plasma osmolalities greater than 340 mOsm/kg are associated with coma. Plasma osmolality—rather than acidemia—correlates most closely with state of consciousness in DKA (Figure 24-3).

Arterial blood pH is low and, in the absence of coexistent respiratory disease, is partially compensated by a reduction in PCO₂. The acidosis is metabolic in origin and accompanied by an anion gap that is calculated by subtracting the combined concentrations of chloride and bicarbonate from serum sodium concentration. Anion gaps greater than 12 mEq/L are considered abnormal. Keto acids account for most of the unmeasured anions that generate the abnormal gap, although under conditions of extreme volume contraction and hypoperfusion, lactate accumulation may also contribute. Levels of serum and urinary ketones (measured using the nitroprusside reagent) are typically high in DKA. It should be recalled, however, that this reagent reacts strongly only with acetoacetate, less strongly with acetone (which is not a keto acid and does not contribute to the anion gap), and not at all with β-hydroxybutyrate. Thus, paradoxically, the most extreme levels of ketoacidosis may be accompanied by relatively modest levels of ketones measured by this method. As a corollary

![Figure 24-3](image-url)
of this, resolution of severe DKA may be linked to transient increases in measurable ketone levels as β-hydroxybutyrate is converted to the more readily detectable acetoacetate.

Serum sodium levels may be high, normal, or low, but in all instances total body sodium is depressed. Estimates of depletion range from 7 to 10 mEq/kg body weight. As blood glucose levels rise in DKA, they create an osmotic gradient that draws water, as well as intracellular solutes, into the extracellular space. This results in moderate hyponatremia, which can be corrected to account for the dilutional effect of the transmembrane flux of water by adding 1.6 mEq/L (more recent studies suggest that the correction factor is closer to 2.4 mEq/L) to the sodium concentration for every 100 mg/dL increment in plasma glucose above a basal concentration of 100 mg/dL (see below). The decrease in serum sodium partially offsets the increase in tonicity that accompanies the elevation in plasma glucose. This results in a net increase in plasma osmolality of 2 mOsm/kg H₂O per 100 mg/dL elevation in plasma glucose:

\[
\text{Corrected Na}^+ = \frac{\text{Measured Na}^+ + 1.6 \left( \frac{\text{Plasma glucose} - 100}{100} \right)}{}\]

Total body potassium levels are also severely depleted in DKA to an average of 5 to 7 mEq/kg body weight. This results from a number of factors, including exchange of intracellular potassium for extracellular hydrogen ion, impaired movement of K⁺ into cells in the insulinopenic state, increased urinary potassium excretion secondary to the osmotic diuresis and, in those instances where intravascular volume contraction is present, secondary hyperaldosteronism. Serum potassium levels may be high, normal, or low depending on the severity and duration of DKA, the status of extracellular fluid volume, and the adequacy of renal perfusion and excretory function. A low serum potassium at presentation generally indicates severe potassium deficiency and, in the presence of adequate renal function, is an indication for early and aggressive repletion (see below). Potassium depletion can result in muscle weakness and cardiac arrhythmias, including ventricular fibrillation.

The H⁺ excess in DKA titrates endogenous buffer systems including serum bicarbonate, resulting in reduction in concentrations of the latter. Chloride levels may also be low, reflecting the osmotic diuresis alluded to above. Ketone bodies have been estimated to account for one-third to one-half of the osmotic diuresis seen in DKA. Electrolyte depletion is further aggravated by the obligate cation (eg, sodium) excretion required to maintain electrical neutrality. In patients who have maintained adequate hydration during the development of DKA or in those who are aggressively resuscitated with normal saline, chloride levels may be elevated and the anion gap narrowed. This reflects the enhanced clearance of the keto anions in the kidney, converting the system from an anion gap acidosis to a hyperchloremic, nongap acidosis (ie, the hydrogen ion excess persists despite clearance of the anion). Because the excreted keto anions represent a lost source of bicarbonate regeneration, correction of the hyperchloremic acidosis may proceed slowly. The hyperchloremic acidosis is inconsequential from a clinical standpoint.

Total body magnesium and phosphate levels are also depleted by the osmotic diuresis in DKA. Phosphate depletion is amplified by diffusion of the anion from the intracellular to the extracellular compartment in the absence of insulin. Phosphate depletion can result in muscle weakness, rhabdomyolysis, hemolytic anemia, respiratory distress, and altered tissue oxygenation (due to reduction in 2,3-diphosphoglycerate levels in the red blood cell).

**Management**

Treatment of DKA is focused on two major objectives. The first is restoration of normal tonicity, intravascular volume, and solute homeostasis. The second is correction of the insulinopenic state with suppression of counterregulatory hormone secretion, glucose production, and ketogenesis and improved utilization of glucose in target tissues. The steps outlined in Table 24-7 provide a general approach to the management of this disorder.

Because depletion of intracellular and extracellular fluids may be severe in DKA (typically in the range of 5-10 L), early and aggressive resuscitation with fluids is mandatory. This is usually initiated with administration of 1 to 2 L of isotonic normal saline (0.9% NaCl) over the first hour of therapy. As intravascular volume is restored, renal perfusion increases, with a consequent increase in renal clearance of glucose and a fall in plasma glucose levels. If volume contraction is severe, a second liter of normal saline can be administered. If not, half-normal saline (0.45% NaCl) can be initiated at a rate of 250 to 500 mL/h.
depending on intravascular volume status. Because water is typically lost in excess of solute in DKA, half-normal saline addresses both the volume depletion and the hypertonicity. It has been suggested that approximately half of the total fluid deficit should be corrected within the first 5 hours of therapy. Half-normal saline can be continued until intravascular volume has been restored or plasma glucose levels fall to 250 mg/dL, at which point D5W should be started. The latter maneuver reduces the likelihood of insulin-induced hypoglycemia and avoids the theoretical complication of cerebral edema due to osmotically induced fluid shifts from plasma into the central nervous system. This complication is, in fact, seen rarely in adults and uncommonly in children with DKA. It is important to account for ongoing urinary volume and electrolyte losses in assessing fluid requirements.

Once fluid resuscitation has been initiated, insulin should be administered. Only short-acting insulin should be used. A number of different insulin regimens have demonstrated efficacy in the treatment of DKA; however, a commonly used regimen includes a loading dose (10-20 U) of regular insulin intravenously followed by a continuous infusion at a rate of 0.1 U/kg/h. The need for a loading dose is controversial and may not be required in the majority of cases. It is not recommended for children with ketoacidosis. If intravenous access is problematic, maintenance insulin can be given intramuscularly (0.1 U/kg/h). This regimen provides plasma insulin levels in a physiologic range (100-150 mU/mL) with minimal risk of hypoglycemia or hypokalemia. It restores plasma glucose levels at rates equivalent to those obtained with regimens using higher insulin doses. Plasma glucose levels should fall at a rate of 50 to 100 mg/dL/h. Failure to achieve this end point over a 2-hour period should lead to doubling of the infusion rate with reevaluation an hour later. When plasma glucose concentrations reach 250 mg/dL, D5W is begun to prevent hypoglycemia (see above). Some diabetologists recommend a coincident reduction in insulin dose (to 0.05-0.1 U/kg/h) at this point. The insulin infusion is continued to suppress ketogenesis and allow restoration of normal acid-base balance.

As noted above, total body potassium stores are depleted in DKA (−3-4 mEq/kg), and plasma potassium levels fall with treatment. Repetition of K⁺ is almost always indicated in management of DKA (one notable exception being DKA that occurs in the setting of chronic renal insufficiency); however, the timing of repetition varies as a function of the plasma K⁺ level. If the initial K⁺ level is less than 4 mEq/L, K⁺ depletion is severe, and repetition should begin with the first administration of parenteral fluids if renal function is adequate. Twenty milliequivalents of potassium chloride can be added to the first liter of normal saline if the serum K⁺ is in the 3.5 to 4 mEq/L range; 40 mEq should be added for K⁺ levels less than 3.5 mEq/L. Particular attention should be devoted to patients in this latter state, because K⁺ levels may plummet to very low levels with initiation of insulin therapy. To avoid this, insulin therapy should be postponed in this group until K⁺ repetition has begun and serum K⁺ levels are on the rise. The general goal of therapy should be to keep the K⁺ in a near-normal range. This may require several hundred milliequivalents of potassium chloride administered over several days.

The administration of bicarbonate in the setting of DKA has been controversial. Acidosis, in addition to increasing ventilatory work (Kussmaul respiration), may also suppress cardiac contractile function. Therefore, restoration of normal pH would seem to make sense in the setting of DKA. However, there is considerable risk associated with the use of sodium bicarbonate in this setting, including paradoxical acidification of the central nervous system due to the selective diffusion of CO₂ versus HCO₃⁻ across the blood–brain barrier and an increase in intracellular acidosis, which may worsen rather than ameliorate cardiac function. Volume overload related to the high tonicity (44.6-50 mEq/L) of the bicarbonate solution, hypokalemia resulting from overly rapid correction of the acidosis, hypernatremia, and rebound alkalosis are also potential complications of bicarbonate therapy. In general, pH of 7.0 or greater is not life-threatening to the average patient with DKA and will resolve with appropriate volume expansion and insulin therapy. For pH less than 7.0, many clinicians would argue for a limited administration of sodium bicarbonate. If bicarbonate is used, careful patient monitoring looking for alterations in mental status or cardiac decompensation is indicated. The goal of therapy should be to maintain pH greater than 7.0, not to return pH to normal.

Similarly, phosphate administration, once considered a key component in the management of DKA (estimated deficit −5-7 mmol/kg), has come under closer scrutiny. Phosphate depletion definitely occurs in DKA for the reasons outlined above, and in the past repetition of phosphate (much of it as potassium phosphate salts) had been advocated to forestall the development of muscle weakness and hemolysis and to promote tissue oxygenation through generation of 2,3-diphosphoglycerate in erythrocytes. However, the administration of phosphate salts has been associated with the development of hypocalcemia and deposition of calcium phosphate precipitates in soft tissues, including the vasculature. Thus, in general, parental phosphate repetition is not routinely provided for patients with DKA unless plasma phosphate falls to very low levels (<1 mmol/L). In this case, 2 mL of a mixture of KH₂PO₄ and K₂HPO₄ solution, containing 3 mmol of elemental phosphorus and 4 mEq of potassium, may be added to 1 L of fluids and introduced over 6 to 8 hours. In no instance should all K⁺ repetition be in the form of potassium phosphate salts. In general, renewal of food ingestion and insulin therapy complete restoration of total body phosphate stores and return plasma phosphate levels to normal over a period of several days.

In pediatric patients (age <20 years) the need for volume expansion needs to be weighed against the potential risk of cerebral edema secondary to aggressive fluid administration, although this is controversial (see below). A recent recommendation suggests 10 to 20 mL/kg/h of normal saline during the first 2 hours with limitation of total fluid administration to 50 mL/kg over the first 4 hours. The remaining fluid deficit is corrected over the next 48 hours. Normal saline or half-normal saline (depending on serum sodium levels) usually accomplishes this with a rate of 5 mL/kg/h. The decrease in serum osmolality should not exceed 3 mOsm/kg H₂O/h. An insulin bolus prior to initiating the insulin infusion (0.1 U/kg/h) is usually not required in children.
Finally, it is necessary to actively seek out and treat the precipitants of DKA when they are identified. This includes appropriate cultures of urine and blood (and cerebrospinal fluid, if indicated) and empiric antibiotic therapy directed against the most likely pathogenic organisms (pending the results of the cultures). The presence of fever is typically a good marker for infection or other inflammatory process because it is not a feature of DKA per se. Elevated white blood cell counts, on the other hand, are frequently seen with DKA alone. Hyper-amylasemia is common but rarely reflects pancreatitis—the amylase is usually of salivary origin. Other precipitants should also be sought. Myocardial infarction, which is often clinically silent in diabetic patients, is an uncommon but life-threatening precipitant of DKA in patients with established diabetes.

Complications

Aggressive resuscitation with isotonic or hypotonic fluids is a theoretical but uncommon cause of fluid overload during management of DKA. Careful attention to the cardiovascular examination, chest x-ray, and urine output should aid in preventing this complication.

Hypoglycemia is relatively rare in the current era given the low doses of insulin used in management and appropriate initiation of glucose-containing fluids as plasma glucose levels fall below 250 mg/dL.

Cerebral edema due to rapid correction of plasma hypertonicity has usually been reported with plasma glucose levels below 250 mg/dL. Clinically significant cerebral edema is relatively uncommon in adult patients. Milder forms of cerebral edema have been noted in many patients being treated for DKA but have not been strongly correlated with changes in extracellular toxicity. At present, in a symptomatic adult patient, it would appear prudent to treat hypertonicity exceeding 340 mOsm/kg aggressively with hypotonic fluids to avoid complications related to plasma hypertonicity. Further correction from that point to normal plasma osmolality (about 285 mOsm/kg) can probably be accomplished in slower fashion over several days. Cerebral edema occurs in 1% to 2% of children with DKA, frequently with devastating results. Approximately one-third of children with clinically significant cerebral edema die during the acute illness, and another third sustain permanent neurologic impairment. The predilection for young children may reflect, in part, immaturity of the autoregulatory mechanism that governs cerebral blood flow. There is increased risk in children less than 5 years of age, and those with low PCO2 or high blood urea nitrogen at presentation. Cerebral edema in children may be associated with high initial rates of fluid resuscitation (>4 L/m²/d) and rapid falls in plasma sodium (or corrected sodium) concentration, although it can occur in clinical settings without an apparent cause, and mild degrees of cerebral edema have been noted in DKA even prior to initiation of therapy. In the absence of definitive trial data to guide therapy, lower rates of fluid administration (<2.5 L/m²/d) with volume resuscitation spread over a longer time interval would seem appropriate if the clinical situation permits. When signs of cerebral edema appear—deterioration in level of consciousness, focal neurologic signs, hypotension or bradycardia, sudden decline in urine output after an initial period of apparent recovery following treatment for DKA—fluid administration should be reduced and mannitol (0.2-1 g/kg given intravenously over 30 minutes) should be administered with repetition at hourly intervals based on response. CT or MRI scan of the brain can be done once therapy has been initiated to confirm the diagnosis. Hyperventilation has not been shown to alter the course of this complication once it develops.

Patients with DKA are also prone to develop acute respiratory distress syndrome, presumably reflecting the sequelae of a damaged pulmonary endothelium and elevated capillary hydrostatic pressures following fluid resuscitation. Patients who present with rales at the time of initial diagnosis may be at higher risk for the development of this complication. Patients may also be at increased risk for development of pancreatitis as well as systemic infection, including fungal infections (e.g., mucormycosis).

Abdominal pain and gastric stasis seen in DKA may put a semi-soporuous patient at risk for aspiration. Up to 25% of patients with DKA have emesis that may be guaiac positive. The latter finding appears to result from hemorrhagic gastritis. Patients who are believed to be at risk with regard to airway protection should have a nasogastric tube in place for evacuation of stomach contents.

Finally, patients with DKA are at risk for recurrence of the disorder if insulin is withdrawn prematurely. The current infusion protocols, because they raise plasma insulin only to physiologic levels, have a very short half-life for control of blood glucose and ketogenesis. Premature cessation of insulin therapy before depot insulin (e.g., NPH or glargine insulin) can exert its effect may allow the patient to regress into ketoacidosis. To preclude this possibility, subcutaneous regular and intermediate-acting insulin should be provided on the morning when feeding is to be resumed. The insulin drip should be continued for 1 hour following this injection to provide coverage until the depot insulin becomes effective.

NONKETOTIC HYPEROSMOLAR COMA

Clinical Setting

Hyperosmolar nonketotic coma, like DKA, is a consequence of uncontrolled diabetes mellitus; however, a number of features of this disorder clearly distinguish it from DKA. First, plasma glucose levels in ketoacidosis are usually in the 250 to 400 mg/dL rather than the 700 to 1000 mg/dL range that can be seen with hyperosmolar nonketotic coma. Second, the time course for development of hyperosmolar nonketotic coma typically takes a week or longer, whereas ketoacidosis can develop over 1 to 2 days. Third, ketosis is rare in hyperosmolar nonketotic coma. Circulating insulin levels are probably adequate to control ketogenesis in the latter, although they are incapable of establishing euglycemia. Fourth, hyperosmolar nonketotic coma tends to occur more commonly in the elderly population, often in those receiving chronic care who have difficulty reporting symptoms or maintaining adequate hydration. Like DKA, hyperosmolar nonketotic coma may present as the first manifestation of diabetes mellitus. Mortality
remains high in hyperosmolar nonketotic coma (perhaps as high as 20% vs 1%-2% in DKA); in both cases, mortality increases with age.

Precipitants of hyperosmolar nonketotic coma include many of the same complicating illnesses that lead to DKA. Infections (pneumonias are said to be the most common precipitating infection in 40%-60% of cases, with urinary tract infections representing 5%-16% of the total), myocardial infarction, cerebrovascular accident, pancreatitis, burns, heat stroke, and endocrine dysfunction (eg, Cushing syndrome, acromegaly) are frequently associated with hyperosmolar nonketotic coma. Administration of hyperosmolar fluids (eg, tube feedings, total parenteral nutrition, peritoneal dialysis) can precipitate hyperosmolar nonketotic coma, as can medications that impair insulin secretion or action (eg, β-adrenergic blocking agents, phenytoin, corticosteroids, or diazoxide). Diuretics, particularly thiazides, can reduce intravascular volume, reduce the GFR (the dominant mechanism for glucose clearance), and activate counterregulatory hormones (eg, catecholamines), all of which promote development of the hyperosmolar state. Finally, limited access to free water intake, particularly in patients who are dependent on others to provide access to water, is a major determinant in the progression of the hyperosmolar state.

These factors interact in a highly variable fashion to promote the hyperosmolar state associated with hyperosmolar nonketotic coma. In a typical scenario, poorly controlled diabetes— or undiagnosed diabetes presenting for the first time—is aggravated by coincident infection (or other precipitant). This results in significant hyperglycemia as the balance of counterregulatory hormones versus insulin shifts in favor of the former. Hyperglycemia promotes increased insulin resistance and further elevations in blood glucose levels. This leads to an osmotic diuresis in the kidney as plasma glucose levels exceed the threshold for tubular reabsorption. This threshold typically increases with age, leading to even higher plasma glucose levels in the elderly. The osmotic diuresis results in a progressive loss of water and, to a lesser degree, solutes (eg, Na+, Cl−, K+) in the urine. As with DKA, the water loss is buffered initially by an osmotically driven movement of water out of the cells into the extracellular compartment. As the diuresis continues, however, contraction of intravascular volume ensues and glomerular filtration falls, shutting off the body’s primary mechanism for controlling plasma glucose levels in this setting. Glucose levels increase dramatically; often to extraordinarily high levels (normal renal excretory function generally limits elevations in plasma glucose to 500-600 mg/dL). Nausea and vomiting, related to the infection, uremia, or hyperosmolality per se, may further aggravate intravascular volume contraction. Factor into this an elderly patient with age-dependent suppression of the thirst mechanism and difficulty communicating a sense of thirst to caregivers, and the stage is set for severe dehydration and the hyperosmolar state of hyperosmolar nonketotic coma.

**Diagnosis**

The diagnosis is usually based on strong clinical suspicion and laboratory assessments of plasma glucose levels and serum osmolality. The typical patient may be a patient with known type 2 diabetes (often taking an oral hypoglycemic agent), who has shown a subtle but steady deterioration over several days immediately preceding admission. The patient demonstrates significant dehydration, somnolence, stupor, or coma. The course may be marked by a precipitating illness, as described above. Tachycardia and low-grade fever may be present, but blood pressure and respiratory rate are normal. Urine output typically is reduced to low levels as the hyperosmolar state progresses.

The clinical presentation is usually dominated by the central nervous system findings. Patients with hyperosmolar nonketotic coma are lethargic and weak, with an altered sensorium. True coma is less common and usually does not appear until plasma osmolality is significantly elevated (see below). Hallucinations are occasionally present, and seizures, particularly focal seizures, may occur in 25% of patients with hyperosmolar nonketotic coma. Focal findings suggesting cortical ischemia may also be seen. A minority of these reflect true cerebrovascular accidents related to thromboembolic complications (see below). Most represent low-flow states in areas of baseline cerebrovascular ischemia that recover with correction of the metabolic abnormality.

Plasma glucose levels are typically high (occasionally >1000 mg/dL). Measured plasma osmolality is often greater than 350 mOsm/kg. These measurements usually include the contribution of urea, which may accumulate to significant levels in the setting of volume contraction and prerenal azotemia; however, urea does not contribute to the osmotic force that drives fluid movement across cellular membranes because it is freely permeable in these membranes and distributes itself in equivalent concentrations in the intracellular and extracellular compartments. A more accurate measure of the effective osmolality, or toxicity, is obtained from the following formula:

$$\text{Effective osmolality} = 2\text{Na}^+ + \frac{\text{Glucose}}{18}$$

where Na+ and glucose are the concentrations of sodium ion and glucose, respectively. Normal effective osmolalities are in the range of 275 to 295 mOsm/kg. Hyperosmolar nonketotic coma is diagnosed with an effective osmolality greater than 320 mOsm/kg, whereas coma itself is seen with osmolalities greater than 340 mOsm/kg. Coma at effective osmolalities ≤340 mOsm/kg suggests some other cause (eg, meningitis, cerebrovascular accident, or other metabolic abnormality).

Anion gap acidosis is usually not a major component of hyperosmolar nonketotic coma, because ketogenesis is suppressed (see above). If gap acidosis is present, it may suggest lactate accumulation due to tissue hypoperfusion, low-output state, metformin toxicity, or coexistent renal failure or toxic ingestion. Measurement of serum lactate levels, standard renal function tests, or a screen for toxic substances in blood (if a suggestive history is obtained) should help discriminate among these possibilities.

**Management**

Therapy is in some ways similar to that for DKA except that there is less concern about correction of the acidosis, which is mild or
nonexistent with most conventional cases of hyperosmolar nonketotic coma, and greater emphasis is placed on restoration of intravascular volume and serum osmolality. It is also important to address the potentially life-threatening precipitants of nonketotic coma.

Resuscitation of intravascular volume is initiated with parenteral fluids. Over the first hour 1 to 2 L of normal saline are administered. If the patient is profoundly hyperosmolar (>330 mOsm/L), half-normal saline (0.45% NaCl) should be substituted for normal saline. Volume status is reassessed based on blood pressure, urine output, or central venous pressure. If volume contraction persists, normal saline (or half-normal saline if hypotonicity persists) can be continued at a rate of 1 L/h. Once blood pressure and urine output have been restored, hypotonic fluids (eg, half-normal saline) can be substituted for isotonic saline at a rate of 250 to 500 mL/h depending on the need for continued volume resuscitation. The total free water deficit can be approximated using the following formula:

\[
\text{Water deficit} = \frac{\text{Plasma osmolality} - 295}{295} \times 0.6(\text{Body weight})
\]

where plasma osmolality is in milliosmoles per kilogram, body weight in kilograms, and water deficit in liters. Fluid rates should be adjusted to correct half of the free water deficit in the first 12 hours and the remainder over the ensuing 24 to 36 hours. As with DKA, glucose-containing fluids (eg, D5W) should be started when plasma glucose levels fall to 250 mg/dL.

Insulin therapy is of secondary importance in the management of hyperosmolar nonketotic coma. It is imperative that insulin therapy not be initiated until volume resuscitation is well under way (eg, following 1-2 L of crystalloid). Insulin promotes movement of glucose, electrolytes, and water into the intravascular compartment. In the absence of adequate volume resuscitation, this can lead to hypotension and cardiovascular collapse. Therapy should be initiated with a loading dose of 10 to 20 U intravenously followed by a drip delivering 0.1 U/kg/h. Conversion back to the outpatient regimen once the acute event has resolved can be accomplished using a strategy similar to that outlined above for DKA.

Electrolytes (ie, Na⁺, K⁺, Cl⁻, PO₄³⁻, and Mg²⁺) are significantly depleted in hyperosmolar nonketotic coma due to the osmotic diuresis. These should be repleted as needed (beginning with the first liter of fluids if necessary). Once again, parenteral phosphate should be administered with care, keeping serum phosphate above 1 mg/dL until feeding can reestablish phosphate balance.

Complications

A. Thromboembolic events Coagulopathies related to increased platelet aggregation, hyperviscosity of circulating blood, or disseminated intravascular coagulation can develop in hyperosmolar nonketotic coma. The most appropriate therapy is resuscitation of intracellular volume and treatment of systemic infections. Focal neurologic findings that fail to improve with fluid resuscitation should be further investigated with appropriate consultation and imaging studies, if indicated. Some investigators have recommended low-dose heparin anticoagulation in patients with hyperosmolar nonketotic coma to guard against thromboembolic sequelae. If such therapy is initiated, patients should be closely monitored for development of gastrointestinal bleeding.

B. Cerebral edema This is a serious—although fortunately uncommon—complication of fluid resuscitation in hyperosmolar nonketotic coma (and DKA; see above). It occurs more commonly in children than in adults and frequently follows an overly aggressive management strategy involving administration of large amounts of parenteral fluids. The pathogenesis is not completely defined but probably relates to the increase in cortical capillary hydrostatic pressure and the osmotic gradient engendered by the aggressive use of hypotonic fluids in this setting. Cerebral edema rarely appears with serum glucose levels above 250 mg/dL. Appropriate introduction of glucose-containing fluids into the management strategy when plasma glucose approaches this level is an effective way to guard against this complication.

Clinically, brain edema develops after an initial period of improvement. It is often heralded by the development of headache, altered mental status, and seizure activity. If untreated, this can progress to herniation, with respiratory arrest and death. Recognition of the syndrome and appropriate treatment with mannitol, dexamethasone, and furosemide can be life saving in this setting.

HYPERCALCEMIC CRISIS

Clinical Setting

Severe hypercalcemia, defined arbitrarily as a total Ca²⁺ greater than 14 mg/dL., can occur in the setting of a known hypercalcemic illness but may represent the initial manifestation of such a disorder. Patients present initially with polyuria and polydipsia and, with a more protracted course, develop evidence of intravascular volume contraction with decreased urine output. Alterations in the sensorium dominate the clinical picture and range from behavioral changes and drowsiness to stupor and coma. Bradyarrhythmias and heart block are major cardiac sequelae of hypercalcemia. Hypercalcemia also potentiates digoxin activity, increasing the risk of cardiac glycoside toxicity. Gastrointestinal complaints are prominent. Anorexia, nausea, and vomiting, which further aggravate the volume contraction, are frequently present. Abdominal pain may be of sufficient intensity to mimic an acute abdomen.

Most chronic hypercalcemia is caused by primary hyperparathyroidism and is usually detected as a result of routine laboratory screening. Cancer-related hypercalcemia, most of which is caused by parathyroid hormone–related protein (PTHrP), is a less frequent but important cause of chronic hypercalcemia (see Chapter 21). In acute hypercalcemic crises, malignancy emerges as the major cause of the elevations in serum calcium. Other causes of hypercalcemia (eg, vitamin D intoxication, thiazides, or
Addison disease) are either too uncommon or cause such small increments in serum calcium that they rarely need to be considered in the differential diagnosis (see Chapter 8).

Hypercalcemia due to any cause creates a state of nephrogenic diabetes insipidus by uncoupling vasopressin from its receptor-effector system in the kidney (Table 24-8). This results in a water diuresis that eventually promotes intravascular volume contraction and reduced GFR, effectively suppressing the only route of egress for calcium mobilized from bone or transported across the gut lumen. Thus, volume contraction is in large part responsible for the very high levels of serum calcium found in hypercalcemic crisis. By inference, resuscitation of intravascular volume (see below) represents an excellent initial intervention to improve renal perfusion and tubular clearance of $\text{Ca}^{2+}$.

Hypercalcemic crisis should be considered in any patient with disseminated malignancy, particularly squamous carcinomas of the head, neck, and lung. This is especially true when there is a change in the patient’s mental status or general clinical condition that cannot be explained by tumor progression, infection, or other metabolic abnormality (eg, uremia). It should also be considered in patients with known primary hyperparathyroidism, particularly in a clinical setting characterized by vomiting, diarrhea, or dehydration (eg, due to thiazide therapy).

**Diagnosis**

The diagnosis is confirmed by measurement of a total or ionized serum calcium level. The latter may be preferable in the presence of low serum albumin, the predominant $\text{Ca}^{2+}$-binding protein in blood, because hypoalbuminemia may mask an elevation in the free fraction if only total calcium levels are assessed. Albumin-corrected calcium levels can be derived by increasing the total calcium by 0.8 mg/dL for each 1 g/dL decrease in serum albumin, based on a normal albumin level of 4 g/dL. The albumin-adjusted calcium does not always correlate with the measured ionized calcium, however, and should not be relied on for more than a rough estimate of the free calcium fraction, particularly if ionized calcium measurements are available.

**Management**

Intravenous fluids represent the first avenue of approach for management of severe hypercalcemia (Table 24-9). Normalization of intravascular volume improves GFR and increases renal excretion of calcium. Sodium and calcium handling is closely linked in the distal nephron. Fluid resuscitation with normal saline (0.9% NaCl) both restores GFR and promotes natriuresis and calciuresis by regulating transporter mechanisms responsible for sodium and calcium handling in the distal nephron. Over the first hour 500 to 1000 mL of normal saline is given, with rates of 250 to 500 mL/h thereafter depending on the state of volume contraction. The latter can be assessed based on clinical examination, urine output, and assessment of renal function. Several liters of fluid are frequently required before intravascular volume is restored. Continued infusions should be matched with urine outputs to avoid fluid overload. Loop diuretics (eg, furosemide) may be used to accomplish this in patients with an underlying predilection toward fluid retention (eg, congestive heart failure). Saline and loop diuretics can increase urinary calcium excretion by as much as 800 mg/d. This is typically accompanied by a moderate but significant reduction in serum calcium levels (1-3 mg/dL). Careful attention should be devoted to detection of signs of fluid overload. Potassium and magnesium depletion related to the diuresis should be corrected. If loop diuretics are used, it is important that the volume of normal saline administered should at least match urine output. Diuretic-induced volume contraction may lead to reduced GFR and worsening hypercalcemia.

At this point, more definitive and specific therapy should be introduced (see Chapter 8). Severe hypercalcemia is almost always
a result of increased mobilization of calcium from bone. Therefore, most effective therapies for hypercalcemia have been directed against the osteoclasts of bone. Bisphosphonates represent the mainstay of therapy. Pamidronate administered at a dose of 60 to 90 mg in 250 mL of saline over 1 to 4 hours (4 hours for outpatients) is effective in reducing serum calcium levels, often into the normal range. A newer generation bisphosphonate, zoledronic acid (4-mg intravenous infusion over 15-30 minutes) has also been used for management of hypercalcemia. In comparison to pamidronate, it is more potent, with a similar safety profile. In addition, it has the advantage of a shorter infusion period and longer duration of antihypercalcemic activity in head-to-head comparisons with pamidronate. The effect of intravenous bisphosphonates can take 2 to 4 days to peak, and the duration of the response is variable, lasting from 1 week to several months. Retreatment for recurrent hypercalcemia is usually successful. Side effects of therapy include inflammation at the infusion site; low-grade fever with flu-like syndrome; osteonecrosis of the mandible and maxilla with long-term or frequent infusions; renal insufficiency; and transient depression of serum calcium, phosphate, and magnesium. Bisphosphonates are also attractive because of their efficacy in controlling pain and fracture in myeloma and osteolytic metastases from breast cancer and other solid tumors. The mechanism here is thought to involve suppression of tumor-induced osteoclastic activity in the neighborhood of the metastases.

Calcitonin has a long history of use in the management of hypercalcemia. It has a direct effect on the osteoclast to suppress bone resorption. It is given either subcutaneously or intramuscularly at a dose of 2 to 4 U/kg body weight every 6 to 12 hours after administration of a test dose to exclude hypersensitivity to the drug. In general, the response to calcitonin, which should be noted after 6 to 12 hours, is modest in magnitude (decrease in serum calcium levels of 1-2 mg/dL) and declines with increasing duration of therapy (tachyphylaxis). Co-administration of glucocorticoids with calcitonin may limit this latter effect and extend the duration of the hypocalcemic effect. Calcitonin is useful largely as adjunctive therapy in controlling hypercalcemia in the acute setting until the effects of more powerful but slower acting agents (eg, bisphosphonates) become available.

Cinacalcet, a calcium receptor agonist, can be useful in the management of PTH-dependent hypercalcemia such as that seen with parathyroid carcinoma. Doses are typically in the range of 30 to 60 mg bid or higher.

Plicamycin is a tumoricidal antibiotic with pronounced hypocalcemic properties at nontumoricidal doses. It presumably targets the osteoclast and its bone-resorptive activity. It is administered as an infusion at a dosage of 15 to 25 μg/kg body weight over 4 to 24 hours. Calcium levels fall, often into the normal range, within 24 to 48 hours in a majority of patients treated. Plicamycin has significant renal and hepatic toxicity, and it induces platelet abnormalities that may result in clinically significant hemorrhage. Toxicity tends to increase with repeated administration, limiting chronic use of the drug. Given the ready availability of less toxic treatment modalities, plicamycin is rarely used in the management of severe hypercalcemia.

Gallium nitrate has shown efficacy in the management of tumoral hypercalcemia in clinical trials. Like the bisphosphonates and plicamycin, gallium is apparently targeted at the osteoclast. Patients are infused with gallium nitrate at a dosage of 200 mg/m² over a 5-day period. Gallium's major limitations are the duration of the infusion (often requiring hospitalization) and the potential for significant nephrotoxicity, particularly if it is used in the setting of other nephrotoxic agents.

Other nonselective treatment modalities that are available for management of hypercalcemic crisis include steroids, phosphate, and dialysis. Aside from their potentiation of calcitonin's effects, as described above, steroids are usually effective only in the management of hypercalcemia due to lymphoproliferative disease (eg, multiple myeloma) or vitamin D toxicity (eg, due to ingestion of vitamin D or disseminated granulomatous disease). They are best suited for chronic management of hypercalcemia associated with these disorders. Parenteral phosphate effectively reduces serum calcium levels, although often at the expense of deposition of calcium phosphate salts in parenchymal tissues, and cannot be recommended. Peritoneal or hemodialysis against a low-calcium bath is also very effective in reducing serum calcium levels and is the treatment of choice for severe hypercalcemia in renal failure patients incapable of tolerating or responding to saline diuresis. In clinically tenuous patients not in renal failure undergoing maximal saline diuresis, persistent hypercalcemia may be an indication for hemodialysis as a tool to bridge the interval until more definitive therapy (eg, bisphosphonates) can achieve its maximal effect.

Finally, some effort should be taken to addressing the primary cause of the hypercalcemia. In some instances (eg, disseminated malignancy), therapeutic options may be limited and ineffective in controlling serum calcium levels. In other instances (eg, primary hyperparathyroidism), a definitive surgical approach can be curative and limit further morbidity. Thus, careful investigation of the source of the hypercalcemia is warranted. Such investigation—even in patients with an obvious potential source of hypercalcemia (eg, malignancy)—may identify correctable problems and, at the very least, assist in the development of long-term management strategies once the acute crisis has resolved.

**ACUTE HYPOCALCEMIA**

**Clinical Setting**

Hypocalcemia may be seen in a number of disorders affecting the synthesis or action of PTH or vitamin D or following sequestration of calcium into a functionally inaccessible compartment (see Chapter 8). Many of these represent chronic illnesses where hypocalcemic symptoms develop insidiously or where the complication of hypocalcemia is anticipated early and appropriate treatment initiated prior to acute decompensation. However, in selected situations, acute hypocalcemia may dominate the clinical presentation. Appropriate recognition of the high-risk clinical setting should lead to earlier diagnosis and therapeutic intervention with reduced morbidity and mortality.
Probably the most important cause of PTH-deficient hypocalcemia occurs in the postoperative setting following neck surgery for treatment of malignancy or resection of adenomatous or hyperplastic parathyroid glands. This may reflect accidental or purposeful (eg, radical neck dissection) removal of all functioning parathyroid tissue or inadvertent vascular compromise of tissue left in the neck. Residual normal parathyroid tissue can also be functionally atrophied in a patient undergoing surgery for hyperparathyroidism. It can take 1 to 2 days for PTH secretion and calcium levels to return to normal following resection of the adenoma.

Magnesium deficiency can compromise both PTH secretion from the parathyroid gland and PTH action at target tissues in the periphery. Magnesium repletion in patients with low serum magnesium and calcium should be undertaken before launching an exhaustive workup of the hypocalcemia.

Hypocalcemia can be seen in chronic renal insufficiency. Hyperphosphatemia and reduced 1-α-hydroxylase activity result in deficient 1,25-dihydroxyvitamin D₃ generation and consequent hypocalcemia. Aggressive management of the hyperphosphatemia (eg, with phosphate binders) and calcitriol are generally useful in promoting normal calcium balance.

Acute sequestration of calcium into bone or nonphysiologic compartments can lead to severe hypocalcemia. Hypocalcemia following removal of a parathyroid adenoma may reflect a hypoparathyroid or parathyroid state, as discussed above. Alternatively, in patients with severe osteitis fibrosa cystica, the bones, in the absence of PTH-driven bone resorption, serve as a sink for extracellular calcium deposition, as previously unmineralized osteoid becomes calcified. This results in the syndrome termed hungry bones or recalcification tetany. It is usually distinguished from PTH deficiency by measurements of the hormone (PTH is typically elevated in the hungry bones syndrome). A similar sequestration phenomenon is seen in osteoblastic metastases (eg, in breast or prostatic carcinoma). Typically, osteoclastic activity in these metastases is abrogated through some specific therapeutic intervention, leaving unmineralized matrix to calcify at the expense of extracellular calcium levels.

Sequestration may also occur in nonphysiologic settings such as the peritoneal cavity in acute pancreatitis, where deposition of calcium soaps leads to a subsequent reduction in serum calcium levels. A similar phenomenon occurs in damaged muscle following rhabdomyolysis. Deposition of calcium salts in damaged muscle beds leads to a reduction in serum calcium levels. Interestingly, serum calcium returns to normal or even elevated levels during the recovery phase, reflecting dissolution of the precipitates as the muscle undergoes repair.

Hypocalcemia occurs in the setting of acute systemic illness with a prevalence of nearly 80% in the ICU setting. It has been linked to the cytokine-mediated inflammatory response that frequently dominates this clinical setting. Other potential contributors include increased calcium binding to albumin (eg, as seen with alkalosis), relative PTH deficiency, and decreased renal 1-α-hydroxylase activity. It has also been associated with specific drugs, including antineoplastic agents such as doxorubicin and cytarabine and other agents such as ketoconazole, pentamidine, and foscarinet.

**Diagnosis**

Symptomatic hypocalcemia presents with a predictable constellation of signs and symptoms. Most of these findings are related to the increased neuroexcitability that is seen with reductions of extracellular calcium levels (see Table 24–10). Symptoms frequently begin as circumoral paresthesias or paresthesias of the fingers or toes. This is followed by increased muscle cramping and spasm (particularly carpopedal spasm) (see Figure 8–18) and diffuse hyperreflexia. The increased propensity for muscle spasm can provoke generalized tetany which if extended to the laryngeal muscles can lead to laryngospasm and respiratory arrest. Increased excitability in the central nervous system can result in seizures, particularly in patients with a history of seizure disorder.

Physical examination looking for evidence of neuromuscular hyperexcitability is often revealing (see Table 24–10). Chvostek sign is evoked by repetitive tapping of the area overlying the facial nerve approximately 2 cm anterior to the ear lobe below the zygomatic arch. A positive test is contraction of musculature innervated by the facial nerve. The extent of the contraction is roughly proportionate to the severity of the hypocalcemia. Trousseau sign is triggered by inflating a blood pressure cuff on an upper extremity to a level that roughly equates with the systolic blood pressure for 3 to 5 minutes. Spasm of the hand musculature (see carpopedal spasm, above) due to transient ischemia of hyperexcitable nerves innervating the hand is regarded as a positive test. Of the two, a positive Trousseau sign is regarded as more specific for hypocalcemia than is the positive Chvostek sign.

Hypocalcemia can also have significant effects on cardiovascular function, including decreased blood pressure, impaired cardiac contractility, and conduction disturbances. On the electrocardiogram, significant hypocalcemia can manifest as prolongation of the QT interval. In extreme cases this can lead to ventricular arrhythmias, including torsades de pointes. Evidence of sequelae of chronic hypocalcemia may also identify individuals who are at risk for acute hypocalcemia. Subcapsular cataracts and
basal ganglia calcification are features associated with long-standing hypocalcemia.

Measurement of total serum calcium, albumin, or ionized calcium, if available, leads quickly to the correct diagnosis. Measurement of plasma PTH, 25-hydroxyvitamin D, and 1,25-dihydroxyvitamin D assists in identifying deficiency of PTH secretion, adequacy of vitamin D stores, or impaired synthesis of bioactive vitamin D, respectively. Mg²⁺ levels should be obtained to exclude hypomagnesemia. Magnesium depletion can present with the same symptoms as hypocalcemia. If present, magnesium repletion should be initiated before additional diagnostic tests are undertaken.

Examination of the medication list looking for drugs with hypocalcemic properties (eg, bisphosphonates, calcitonin, asparaginase, cisplatin, foscarnet) should be performed.

Measurement of serum amylase and lipase should aid in identifying pancreatitis as a source of the hypocalcemia. Creatine kinase and aldolase levels exclude the presence of rhabdomyolysis.

One area of potential confusion is the evaluation of patients in the immediate postparathyroidectomy period. Differentiating a hypoparathyroid or parathyroid state from hungry bones syndrome can be difficult acutely. As pointed out above, measurement of plasma PTH levels (high in hungry bones syndrome and low in hypoparathyroidism) provides the most definitive separation of the two, but outside of referral centers this typically takes several days and thus is usually not helpful in the acute setting. Measurement of serum phosphate (elevated in hypoparathyroidism and low-normal to low in hungry bones syndrome) or urinary phosphate (often low or absent in hypoparathyroidism) may be useful in identifying the source of hypocalcemia. Fortunately, the treatment of hypocalcemia in these two conditions is largely the same. Thus, establishment of a definitive diagnosis is important mainly for planning the subacute and long-term management of the patient's disease.

Management

In a life-threatening situation (eg, cardiovascular collapse) or in the setting of frank generalized tetany, 10 mL of elemental calcium (93 mg of elemental calcium) can be administered intravenously over a 5- to 10-minute period and repeated if necessary. Less acute but recurrent hypocalcemic episodes can be managed with continuous calcium infusions. Nine hundred and thirty milligrams (10 ampules) of calcium gluconate can be mixed in 500 mL of D₅W. Infusion rates are established empirically. The initial infusion rate is typically 0.3 mg/kg/h but may be increased to as much as 2 mg/kg/h in patients with high demands for calcium (eg, hungry bones syndrome). Intravenous calcium should be given through a central vein since extravasation of the infusate can lead to tissue sloughing. Caution should also be exercised in infusing calcium in patients with hyperphosphatemia (precipitation of calcium phosphate salts in soft tissues), hypokalemia, or those on digoxin therapy (increased risk of cardiac arrhythmias).

As the acute situation resolves, selected patients become candidates for chronic replacement therapy. Those with minor hypocalcemia may be treated with calcium supplements alone. Administration of 1 to 3 g of elemental calcium (calcium carbonate contains about 40% elemental calcium by weight) may suffice to restore calcium to the low-normal range and eliminate hypocalcemic symptoms. In those with more refractory hypocalcemia—a category that includes most patients with hypoparathyroidism—the addition of some form of vitamin D or a derivative is required. If ergocalciferol (vitamin D₃) is employed to manage patients with hypoparathyroidism, supraphysiologic doses (50,000 U/d or higher) may be required, reflecting the limited capacity for 1-α hydroxylation of the vitamin D hormone in the hypoparathyroid state. 1,25-Dihydroxycholecalciferol (calcitriol) works faster than vitamin D₃ and circumvents the 1-α hydroxylase blockade, but it is more expensive and the risk of acute hypercalcemia may be higher. It is given in a dose of 0.25 to 1 µg daily.

In all cases the goal of therapy should be to alleviate hypocalcemic symptoms and restore serum calcium levels to the low-normal range. This can usually be accomplished with some combination of vitamin D and supplemental calcium. The latter allows the practitioner additional flexibility in controlling serum calcium levels without requiring frequent dose modification of the longer-acting vitamin D. Efforts to push calcium levels higher may come at the expense of significant hypercalcuria and increased risk of renal stone formation. Difficulty in maintaining calcium even in the low-normal range without unacceptable hypercalcuria may be managed by addition of a thiazide diuretic (hydrochlorothiazide, 25-100 mg/d) to the regimen. These agents reduce hypercalcuria and, secondarily, raise serum calcium levels. If thiazides are used, careful follow-up is required to guard against the possibility of iatrogenic hypercalcemia. Efforts should be made to restore calcium to the target range and maintain it at this level indefinitely. Chronic hypocalcemia is associated with development of subcapsular cataracts and basal ganglia calcification which, in some cases, leads to the development of a parkinsonism-like syndrome.

HYponATREMIA

Clinical Setting

Hyponatremia is the most frequent electrolyte problem observed in hospitalized patients (see Chapter 5). It is often asymptomatic when mild to moderate in severity and subacute to chronic in its time course of development. However, significant hyponatremia (<120 mEq/dL) of rapid onset is frequently symptomatic and can be life-threatening.

Hyponatremia typically occurs in one of three clinical settings, each of which is linked to a specific pathophysiologic paradigm (Table 24-11). Hypovolemic hyponatremia is associated with volume contraction. As intravascular volume is reduced by more than about 9%, there is a nonsomotic stimulation of antidiuretic hormone (ADH; vasopressin) release as the body attempts to retain water to support intravascular volume. Hyponatremia of this type is seen with protracted vomiting, diarrhea, or excessive sweating, particularly when fluid losses are replenished with water or hypotonic fluids alone. Volume contraction and hyponatremia...

Diagnosis

Acute hyponatremia, developing over the course of 24 hours or less, presents with headache, nausea, vomiting, lethargy, restlessness, hyporeflexia, seizures, and altered sensorium, which may progress to stupor and coma. Hyponatremic encephalopathy is responsible for 30% of new-onset seizures in the ICU. These findings are thought to result from cerebral edema as the hypotonic extracellular compartment shifts water into the cerebral cortical cells. Such fluid shifts are opposed early through a reduction in intracellular electrolyte concentration and later by depletion of intracellular solutes (eg, amino acids). This acts to reduce the osmotic gradient and limit the net movement of fluid into brain. With chronicity, such solute shifts can reduce brain water content to near-normal. Thus, the acuteness of the reduction in serum Na⁺ concentration and the magnitude of the reduction are important markers of potential morbidity in this disorder. Young menstruating women are particularly susceptible to the deleterious effects of cerebral edema in the postoperative setting. They are 25 times more likely than postmenopausal women or men to die or have permanent brain damage. This increased susceptibility may reflect the effects of estrogen and progesterone to promote solute accumulation in the cells of the central nervous system. Such accumulation would be predicted to increase the osmotic drive that leads to cerebral edema in these patients. Other patient groups at particular risk include children and patients with hypoxia or hepatic disease.

The first step in making the diagnosis is to exclude the presence of pseudohyponatremia. The latter results from high circulating concentrations of triglycerides or osmotically active solutes (eg, glucose or proteins) in circulating plasma. Hypertriglyceridemia artifically lowers serum sodium by physically excluding it from the sizable nonaqueous phase of the sample being measured. This is usually readily detected in the laboratory (eg, by noting the presence of lactescent serum) and is corrected by centrifuging the sample prior to measuring Na⁺ concentration in the aqueous phase. Osmotically active solutes, like glucose, draw water from the intracellular to the extracellular compartment, where it may transiently lower existing electrolyte (eg, Na⁺) concentrations (see Diabetic Ketoacidosis, above).

Assuming that the presence of hyponatremia is confirmed, an attempt to examine the different diagnostic possibilities listed above should be initiated. Evidence of congestive heart failure, cirrhosis, or nephrotic syndrome is usually apparent on physical examination and confirmable with standard laboratory or imaging studies. Similarly, renal dysfunction should be excluded using conventional renal function tests. Thiazide diuretic use is a frequent cause of hyponatremia and should be investigated early in the evaluation. A careful history of water consumption should be obtained and measurements of water intake in a monitored setting made to exclude psychogenic polydipsia or dipsogenic diabetes insipidus. Hypothyroidism can be excluded with measurement of plasma TSH and free thyroxine levels and glucocorticoid deficiency through an ACTH stimulation test (see Chapters 7 and 9).

Nonosmotic, non-volume-driven ADH secretion is found in SIADH. This is typically a diagnosis of exclusion in non-volume-contracted individuals without evidence of edema, renal
insufficiency, hypothyroidism, or adrenal insufficiency. Serum Na⁺ and osmolality are low in the face of a concentrated urine. Urine Na⁺ may be modestly elevated (>20 mEq/L), reflecting activation of natriuretic pathways responding to the increase in total body fluid volume. If findings are equivocal, an abnormal water load test (inability to excrete at least 90% of a 20 mL/kg water load in 4 hours or failure to dilute urine osmolality to below 100 mOsm/kg) can be used to confirm the diagnosis. SIADH is seen with a variety of disorders affecting the central nervous system (eg, encephalitis, multiple sclerosis, meningitis, psychosis), the pulmonary system (eg, tuberculosis, pneumonia, aspergillosis), or as a paraneoplastic process associated with a number of solid tumors (eg, small cell carcinoma of the lung, carcinoma of the pancreas, bladder, or prostate). It may also be seen with certain types of drugs (eg, cyclophosphamide, vinca alkaloids, opioids, prostaglandin synthesis inhibitors, tricyclic antidepressants, carbamazepine, clofibrate, and serotonin reuptake inhibitors).

Some difficulty may be encountered in differentiating SIADH from a second hyponatremic syndrome called cerebral salt wasting. The latter is also associated with central nervous system disease, particularly subarachnoid hemorrhage. It is thought to be due to a centrally mediated renal wasting of sodium with consequent volume contraction, volume-dependent activation of ADH secretion, and hyponatremia. It has been suggested that atrial natriuretic peptide or brain natriuretic peptide may play a central role in mediating the natriuresis associated with this disorder. Comparison of the features of these two disorders (Table 24–12) suggests that clinical or biochemical evidence of volume contraction is the major way to differentiate cerebral salt wasting from the euvolemic hyponatremia of SIADH. This is an important distinction, because therapy in cerebral salt wasting involves intravascular volume repletion, whereas in SIADH fluid restriction may represent first-line therapy.

### Management

When the primary stimulus provoking water retention (eg, diuretic use) or consumption (eg, psychogenic polydipsia) can be identified, specific therapy represents the most rational approach for long-term management.

When the cause of hyponatremia is unclear or unaddressable (eg, SIADH), a more generic approach may be adopted. Patients with asymptomatic (eg, mild or chronic) hyponatremia can be managed with water restriction. Calculations of daily water intake should incorporate that included in nonliquid foods consumed by the patient. For patients who are symptomatic, non-acute but unable to adhere to water restriction, treatment with an oral vasopressin antagonist, tolvaptan (15-60 mg/day), or demeclocycline (600-1200 mg/d in divided doses), an antibiotic that uncouples ADH from activation of its receptor, may be sufficient to control serum Na⁺ levels. Water restriction is not required with demeclocycline therapy and may even be deleterious. Such therapy should be carefully monitored to guard against precipitous dehydration and renal insufficiency. Alternatively, patients can be managed with regular administration of a loop diuretic (eg, furosemide), which leads to excretion of urine approximately half the tonicity of plasma (loop diuretics disrupt the osmotic gradient required for urine concentration). Loop diuretics should be used concomitantly with NaCl supplementation (2-3 g/d) to increase urinary solute excretion and in that way amplify urinary water loss.

Symptomatic acute hyponatremia is an indication for hypertonic saline (3% NaCl) administration. Estimates of excess total body water can be made using the following equation:

\[
\text{Excess water} = \frac{295 - \text{Plasma osmolality}}{295} \times 0.6(\text{Body weight})
\]

with plasma osmolality in milliosmoles per kilogram, excess water in liters, and body weight in kilograms.

The rise in serum sodium effected by 1 L of 3% saline infusate can be calculated by the following formula from Adrogue and Madias:

\[
\Delta \text{Na}^+ = \frac{\text{Infusate Na}^+ - \text{Serum Na}^+}{\text{Total body water} + 1}
\]

where \(\Delta \text{Na}^+\) is the change in sodium concentration effected by administration of 1 L of infusate; infusate Na⁺ is the concentration of Na⁺ in the infusion (eg, 513 mmol/L for 3% NaCl); and total body water is body weight (kg) \(\times 0.6\) (children or nonelderly men), \(\times 0.5\) (nonelderly women and elderly men), or \(\times 0.45\) (elderly women). The +1 in the denominator accounts for the volume of the infusate. Based on the calculated \(\Delta \text{Na}^+\), one can adjust the infusion rate to provide the desired increase in serum Na⁺ over a fixed time interval. An alternative guide to initial therapy estimates that 1 mL/kg of 3% NaCl will increase serum Na⁺ by approximately 1 mEq/L. Infusion rate algorithms are intended only as a guide and should be adjusted, based on actual Na⁺ measurements, to raise serum Na⁺ levels by no more than 0.5 mEq/h (total <8-12 mEq/d) to diminish the risk of central demyelination (see next). If necessary, infusion rates can be adjusted.
to increase serum sodium by 1 to 2 mEq/h for short periods of time in symptomatic patients; however, the limitation to 8-12 mEq/d should be adhered to, if possible. Furosemide can be administered, if necessary, to avoid intravascular fluid overload; however, given the ability of this drug to promote excretion of a hypotonic urine, the clinician should be aware that the plasma osmolality may increase faster than predicted by the formula set forth above. Once serum Na⁺ reaches 130 mEq/L, hypertonic saline infusion should be terminated and fluid restriction or normal saline (0.9% NaCl) plus furosemide used for the final correction of serum osmolality.

For moderately symptomatic hyponatremia in a patient requiring parenteral medication, the vasopressin receptor antagonist conivaptan may be used (20 mg IV initially followed by infusion of 20 mg/d for 1-3 days; infusion rate may be increased to 40 mg/d if serum sodium fails to increase appropriately). Moderate fluid restriction is recommended to facilitate reaching serum sodium goal.

It is important to mention that interventions directed at the cause of the hyponatremia (vs treatment of the hyponatremia itself) also require close monitoring. Rapid correction of hyponatremia through administration of glucocorticoids in adrenal insufficiency or volume repletion in thiazide-induced hyponatremia, for example, may be associated with central myelinolysis. Careful monitoring of serum Na⁺ levels in the posttreatment period is mandatory. If Na⁺ appears to be rising too rapidly (>1 mEq/h), administration of hypertonic fluids or a small dose of desmopressin acetate (0.25-1 µg parenterally) may be indicated.

### Complications

Central pontine myelinolysis was first described in alcoholics and malnourished patients. In the original descriptions it was characterized by demyelination confined to the pons, resulting in quadriplegia and, not infrequently, death. Subsequent observational studies linked it to the treatment of hyponatremia. The classic presentation is of a patient who is aggressively treated for hyponatremia with resolution of the presenting findings (ie, those of cerebral edema), only to develop symptoms of mutism, dysphasia, spastic quadriaparesis, pseudobulbar palsy, delirium, and, in many cases, death. Surviving patients often have severe neurologic sequelae. More recent studies using CT and MRI indicate that myelinolysis is not confined to the pons but present in many extrapontine locations as well. Lesions are typically symmetrically distributed and clustered in areas where there is close juxtaposition of gray and white matter.

There has been considerable controversy about the prevalence of this particular syndrome and its relationship to the treatment of hyponatremia. However, both animal and human studies are strongly suggestive of a link between this syndrome and rapid, aggressive correction of hyponatremia. Given the imperfect state of our understanding of this disorder, it would seem prudent to approach the correction of chronic hyponatremia, where solute distribution and water content in the brain are undoubtedly altered because of the chronicity of the disorder, cautiously, with rates of correction no greater than 0.5 mEq/h, as indicated above. The risk of solute redistribution in documented acute hyponatremia (ie, duration <24 hours) is substantially reduced. Clinical signs of cerebral edema in this setting may be approached more aggressively, although repletion rates greater than 1 mEq/h with a maximal correction of 12 mEq over the first 24 hours should be avoided if possible.

### DIABETES INSIPIDUS

#### Clinical Setting

Diabetes insipidus is a disorder due to absolute or relative deficiency in the circulating levels or bioactivity of ADH (vasopressin) (see Chapter 5).

ADH release is normally suppressed at plasma osmolalities below 285 mOsm/kg, leading to generation of a maximally dilute urine (<100 mOsm/kg). Above 285 mOsm/kg, ADH secretion increases linearly with plasma osmolality. At a plasma ADH level of 5 pg/mL, which corresponds to a plasma osmolality of about 295 mOsm/kg, the urine is maximally concentrated. Despite the fact that plasma ADH levels continue to rise beyond this point, there is no further concentration of the urine. At 295 mOsm/kg, the osmotic threshold for the thirst mechanism is activated. Thirst also rises linearly with increasing plasma osmolality. It provides the body’s main defense against hypertonicity, much as suppression of ADH secretion guards against hypotonicity. Provided that the patient remains awake and able to drink and provided that the thirst mechanism remains intact, even complete deficiency of ADH secretion can be adequately compensated by increased water intake.

Defects in ADH secretion (central diabetes insipidus) may occur on a heritable basis, occasionally in association with diabetes mellitus, optic atrophy, and sensorineural deafness (DIDMOAD, or Wolfram syndrome). It may also be seen as a component of a polyendocrine autoimmune syndrome (see Chapter 2). Secondary causes of central diabetes insipidus include head injury (often with stalk section), pituitary surgery, granulomatous disease (sarcoidosis, tuberculosis, histiocytosis X), infections, vascular aneurysms and thrombosis, and tumors (craniopharyngioma; dyggerminoma, meningioma; metastatic disease from breast, lung, or gastrointestinal tumors).

Osmoreceptors for ADH release are believed to reside in the organum vasculosum of the lamina terminalis, whereas those controlling thirst are believed to lie in an independent but neighboring location. Thus, those patients with an isolated defect in ADH secretion (either in the osmoreceptors or the secretory nuclei) are protected from severe dehydration by activation of the thirst mechanism. In those with combined involvement of both ADH secretion and the osmoreceptors controlling thirst (hypodipsic or adipsic diabetes insipidus), the risk of volume contraction and severe dehydration is extreme (see below).

Adequacy of the renal response to ADH requires adequate delivery of glomerular filtrate to distal tubular segments, adequacy of tubular function in the ascending limb of the loop of Henle (to establish and maintain the gradient of medullary tonicity and to generate free water for excretion), and a normal response to vasopressin (ie, intact signal transduction mechanism) in the collecting duct. Unresponsiveness to ADH is due to genetic lesions
in the V₂ receptor (X-linked recessive diabetes insipidus) or the functionally linked aquaporin-2 water channel (autosomal recessive diabetes insipidus). It may also be seen in an acquired form with hypokalemia or hypercalcemia, in various forms of intrinsic renal disease (eg, medullary cystic disease) and following therapy with demeclocycline or lithium.

**Diagnosis**

The presentation of diabetes insipidus in an alert, conscious patient is typically an abrupt onset of polyuria and polydipsia. Hypertonicity is avoided as long as the thirst mechanism remains intact and water intake is able to keep up with urinary losses. In a patient who is unconscious or otherwise incapable of communicating the need for fluids or in patients with coexistent adipsia, polyuria is transient and quickly followed by evidence of severe dehydration and hyperosmolality. Urine volumes in this setting may be normal or even reduced. The clinical findings in hypernatremia associated with diabetes insipidus are dominated by the effects of cellular dehydration and contraction of intravascular volume. In the brain, this can lead to increased traction on dural veins and venous sinuses. This may result in avulsion of vessels from their cranial attachments and intracranial hemorrhage. Other findings include irritability, lethargy, weakness, muscle twitching, hyperreflexia, seizures, and coma.

The diagnosis of polyuria is usually reserved for urine outputs greater than 2.5 L/d. A careful history should be taken to document oral fluid intake (particularly beer or other hypotonic fluids) or parenteral fluid administration (eg, in a postoperative setting). Neurologic or endocrine symptoms that might suggest either a hypothalamic or intrasellar mass, use of medications that could impair water reabsorption (eg, furosemide, demeclocycline, or lithium) or intercurrent conditions that might mimic diabetes insipidus (eg, osmotic diuresis associated with diabetes mellitus or resolving obstructive uropathy) should also be investigated.

Initial evaluation should include measurement of serum sodium, plasma osmolality, and urine osmolality. Diabetes insipidus is typically associated with a high-normal or elevated serum sodium and osmolality in the face of submaximally concentrated urine. Plasma glucose measurement and standard renal function tests should help exclude osmotic diuresis as contributing to the polyuria. Measurement of serum K⁺ and Ca²⁺ assists in excluding polyuria resulting from hypokalemia and hypercalcemia, respectively.

In patients with equivocal initial tests, a water deprivation test may be performed. This involves serial measurements of serum Na⁺, urine volume, and osmolality in the absence of fluid intake until serum Na⁺ is greater than 146 mmol/L or urine osmolality plateaus (<10% change with three successive determinations), and the patient has lost more than 2% of body weight. The test should be stopped if the decrease in body weight reaches 3% or the patient demonstrates orthostatic hypotension. Patients with diabetes insipidus become progressively more hypertonic with water deprivation but fail to increase urine osmolality. Administration of desmopressin promotes water retention and an increase in urine osmolality in patients with central but not nephrogenic diabetes insipidus. Increases in osmolality of more than 50% indicate central diabetes insipidus, whereas responses of less than 10% suggest nephrogenic diabetes insipidus. Responses between 10% and 50% are equivocal. Plasma ADH levels may be of assistance in defining the nature of the diabetes insipidus in the latter setting. In the presence of high plasma but low urine osmolality, increased plasma ADH levels are associated with nephrogenic diabetes insipidus, whereas subnormal levels are found with central diabetes insipidus. It may be difficult to establish the diagnosis of mild partial central diabetes insipidus. These patients can often achieve maximally concentrated urine during extreme dehydration, reflecting reduced GFR and stimulated vasopressin secretion; however, as plasma osmolality is corrected and intravascular volume is restored, they typically begin to dilute their urine at a plasma osmolality that is well above normal.

Coexistence of glucocorticoid deficiency may mask the presence of central diabetes insipidus. The development of polyuria with the initiation of glucocorticoid replacement should alert the clinician to the possible presence of diabetes insipidus.

In the 48 hours following pituitary surgery or head trauma, transient diabetes insipidus with polyuria is not uncommon. Over the ensuing 2 to 14 days, a period of antidiuresis and hyponatremia may dominate the clinical course. This in turn may be followed by persistent polyuria. The first phase is thought to result from transient dysfunction or stunning of the ADH-producing neurons of the hypothalamus, the second from leakage of ADH from damaged or dying neurons, and the third from permanent loss of ADH-secreting neurons. Not all patients progress through the entire series of events. It is important to recognize the existence of this syndrome and the natural progression of the disorder in evaluating the need for chronic therapeutic intervention.

In pregnancy, there is a resetting of the osmostat controlling both ADH and thirst, resulting in a state of physiologic hypo-osmolality (about 10 mOsm/kg below that seen in the nonpregnant state). In addition, elevations in placental vasopressinase may rarely promote polyuria in patients with otherwise compensated partial central diabetes insipidus. The appropriate treatment for this disorder is desmopressin acetate, an ADH analog that is resistant to degradation by vasopressinase.

Virtually anything that increases the rate of tubular flow (eg, primary polydipsia or central diabetes insipidus) may create a state of functional nephrogenic diabetes insipidus. This is due to washout of the medullary tonicity responsible for generating the osmotic gradient that promotes movement of water from the tubular lumen into the medullary interstitium as well as down regulation of aquaporin-2 water channels as a result of vasopressin deficiency. A therapeutic trial of 1-deamino-8-D arginine vasopressin (DDAVP) for 1 to 2 days often restores medullary tonicity and facilitates the diagnostic workup. Primary polydipsia (eg, psychogenic polydipsia or dipsogenic diabetes insipidus) presents with a dilute urine, but plasma osmolality and serum Na⁺ levels are typically low or low-normal and ADH levels are low. Moreover, due to the elevation in tubular flow rates, the response to desmopressin may be limited in magnitude (<10%, which is less than that predicted for central diabetes insipidus). This may make it difficult to differentiate primary polydipsia from partial forms of
Management

Acute diabetes insipidus is characterized by polyuria in the presence or absence of plasma hyperosmolality. As noted above, the presence of hyperosmolality is determined by the adequacy of the patient’s thirst mechanism. When a hyperosmolar state with clinical evidence of severe dehydration is present, it is necessary to correct intravascular volume. This is accomplished by administering hypotonic fluids (eg, D2W), which restore intravascular volume and move plasma osmolality back toward normal. The rate at which the hyperosmolality is corrected is dictated in part by the severity of the clinical symptoms and by the chronicity of the disorder. Chronic hyperosmolality (>24 hours) leads to the accumulation of idiogenic osmoles (eg, taurine and myoinositol) in the central nervous system that serve to offset the osmotically driven movement of water out of that compartment. Aggressive correction of the hyperosmolar state can lead to cerebral edema if the rate of hypotonic fluid administration greatly exceeds the rate at which the neurons in the central nervous system eliminate these idiogenic osmoles. If severe volume contraction is present and blood pressure is reduced, intravascular volume should be repleted initially with normal saline (0.9% NaCl). Following expansion of intravascular volume with normal saline, correction of plasma osmolality with D5W at a rate of 0.5 to 1 mOsm/h—not to exceed 15 mOsm within the first 24-hour period—appears to be reasonably effective in reducing plasma tonicity without incurring an increased risk of cerebral edema. Typically, higher infusion rates are used early in the course when serum osmolalities are highest and reduced as osmolality decreases into the range of 330 mOsm/kg. Correction of the total free water deficit should be spread over about 48 hours. Total water deficit is defined above in the section dealing with DKA. Calculation of hypotonic fluid infusion rates can be made using the formula for change in serum sodium set out in the preceding section, substituting 0 mmol/L for D2W, 77 mmol/L for 0.45% NaCl, or 154 mmol/L for 0.9% NaCl into the equation, as needed, to calculate the net reduction in serum Na+. Again, based on the calculated ΔNa+, one can adjust the rate of delivery of the infusate to provide a specific increment in serum Na+ concentration over a defined time interval. If signs of cerebral edema (see Hyponatremia, above) appear, hypotonic fluids should be discontinued and appropriate administration of hypertonic fluids (eg, mannitol) initiated.

If the diagnosis of central diabetes insipidus has been established, the patient should receive parenteral desmopressin acetate. The initial dose, in the range of 1 to 2 μg every 24 hours (administered intravenously or intramuscularly), should be given in the evening with the aim of controlling nocturia and maintaining daily urine output under 2 L. If polyuria returns well before the end of the 24-hour dosing interval, the single dose can be increased or split doses can be administered every 12 hours. Ideally, one would like to see some degree of breakthrough polyuria at the end of the dosing interval. This serves to guard against the development of iatrogenic hyponatremia. If this proves difficult to achieve, a dose can be skipped every 48 to 72 hours. Once the patient has been stabilized on a fixed dose of parenteral desmopressin, conversion to a formulation more suitable for the outpatient setting is indicated. Desmopressin acetate is available in liquid form for insufflation through a nasal cannula or as a fixed-dose (10 μg) nasal spray. The former has the advantage of greater flexibility in adjusting the nasal dose, whereas the latter offers greater convenience for some patients. Parenteral desmopressin is generally about 10 times more potent than the nasally administered drug; however, intranasal doses should be titrated for each individual patient. Desmopressin is also available in an oral form. Effective doses can range widely (50-1200 μg/d in divided doses) and should be adjusted for the individual patient.

Treatment of nephrogenic diabetes insipidus is more complex because the problem is one of resistance to—rather than deficiency of—the endogenous hormone. If possible, one should attempt to address the underlying cause of ADH resistance. This can be accomplished by correcting electrolyte abnormalities (eg, hypokalemia or hypercalcemia) or discontinuing medications (eg, demeclocycline, lithium) that are likely to contribute to ADH insensitivity. Failing this, administration of a thiazide diuretic together with salt restriction often reduces the polyuria. This is assumed to result from contraction of intravascular volume with increased proximal reabsorption of fluids and solutes and, consequently, limited availability of fluid in distal nephron segments for free water generation and excretion; however, there may be a second, ADH-independent effect on the aquaporin-2 channels in the collecting duct. Prostaglandins are endogenous antagonists of ADH activity in the collecting duct. Administration of cyclooxygenase inhibitors (eg, indomethacin, 100 mg/d in divided doses) may improve sensitivity to endogenous ADH and reduce polyuria. If the impairment in ADH responsiveness is mild, higher doses of synthetic desmopressin (DDAVP) occasionally prove effective in promoting water retention. Aminorexide is the preferred treatment for lithium toxicity. It is thought to prevent the uptake of lithium in collecting duct cells. However, lithium-induced diabetes insipidus may not abate following discontinuation of the drug.

Disorders of thirst in the setting of central diabetes insipidus deserve special mention with regard to therapy. Excessive thirst due to altered osmoreceptor function or behavioral conditioning (eg, before desmopressin treatment) may result in severe hyponatremia once desmopressin treatment is initiated. The patient should be cautioned about excessive consumption of water, and fluid must be restricted if necessary.

Adipsic diabetes insipidus is probably one of the most difficult therapeutic problems faced by endocrinologists. Affected patients have essentially lost all ability to regulate water metabolism on their own. This function must be taken over by the medical team providing care. Desmopressin is administered in a fixed parenteral dose that is sufficient to reduce urine output to 1.5 to 2 L/d with a fluid intake of 2 to 2.5 L. The difference here is intended to cover the daily insensible losses (about 500-1000 mL) and may need to be adjusted empirically to maintain normal fluid homeostasis. After plasma osmolality and sodium are in the normal range, fluid intake is balanced against urine output. Any net change in urine output over an 8-hour period (this may be extended as the patient's fluid requirements become more predictable) is accommodated by
modifying the fluid orders for the ensuing 8 hours. The patient should also be weighed daily. Any alteration in weight is usually reflective of net changes in water retention and can be corrected through modification of fluid intake. Plasma osmolality and serum sodium should be monitored once or twice weekly and appropriate changes in fluid administration made depending on the direction and magnitude of the shift in osmolality. With this system of redundant monitoring, urine volumes and plasma osmolality can be reasonably well controlled for protracted periods of time.

Complications

If left untreated, polyuria secondary to diabetes insipidus can lead to dilution of the collecting system, hydrenephrosis, and renal dysfunction. This is the dominant reason for treating polyuria even in patients with an intact thirst mechanism who are capable of controlling plasma osmolality through water ingestion.

Overly rapid correction of the hyperosmolality can result in cerebral edema. The relative risk of this complication should be minimized by careful attention to the rate at which the water deficit is corrected (see earlier).

Sympcoms consistent with endocrine disorders and alterations in endocrine laboratory values are not unusual in individuals infected with the human immunodeficiency virus (HIV). Some of these changes are common to any significant systemic illness; others appear to be more specific to HIV infection or its therapies. Alterations can be found in HIV infection even before clinically significant immunocompromise occurs. As the infected individual becomes immunocompromised, opportunistic infections and neoplasms—as well as the agents used in the treatment of these disorders—can give rise to further changes in endocrine function. Herein we discuss alterations in endocrine function that can accompany HIV infection and acquired immunodeficiency syndrome (AIDS), focusing on evaluation and interpretation of clinical and laboratory findings.

In the era of highly active antiretroviral therapy (HAART), clinical thyroid dysfunction is relatively uncommon in stable HIV-infected patients. In several large studies, the prevalence of hypothyroidism was 1% to 2.5% and hyperthyroidism was 0.5% to 1%. The prevalence of subclinical disease was higher, with subclinical hypothyroidism between 3.5% and 20% and subclinical hyperthyroidism <1%, although definitions varied between studies. These data do not support screening for thyroid disease above the standard guidelines. With advanced HIV disease, alterations in thyroid function tests do occur but generally do not result in clinical dysfunction. In patients with AIDS, the effects of opportunistic infections and neoplastic involvement of the thyroid, as
well as the effects of some medications used to treat HIV-infected patients, should be considered.

### Alterations in Thyroid Function Tests

HIV-infected patients can show alterations in thyroid function tests that are largely asymptomatic. Some of the changes are similar to those seen in the classic euthyroid-sick syndrome, whereas others are unique to the HIV disease state. Advanced HIV is associated with a decrease in thyroid hormone levels, triiodothyronine (T₃) and thyroxine (T₄), similar to that seen in the euthyroid-sick syndrome. When HIV-infected patients were stratified by weight loss and the presence of secondary infection, a decline in T₃ levels corresponded to the severity of disease, consistent with the euthyroid-sick syndrome. Deterioration in nutritional status can also contribute to the decrease in T₃ and T₄ because there is a strong correlation between albumin levels and both free T₄ and total T₃ levels. In the euthyroid-sick syndrome, decreased levels of serum thyroid hormones are due to impaired peripheral T₄ to T₃ conversion by 5' deiodinase. In HIV-infected patients, decreases in serum free T₄ and free T₃ may be due to decreased extrathyroidal conversion of T₄ to T₃, an increase in serum binding proteins, and/or decreased secretion of TSH.

Despite the similarities in serum thyroid hormone levels between HIV and the euthyroid sick syndrome, significantly ill HIV-infected patients often do not demonstrate the elevated reverse T₃ levels characteristic of the euthyroid sick syndrome. The significance of this difference is unknown.

Another characteristic finding in HIV-infected patients is an elevation in thyroxine-binding globulin (TBG), which rises progressively with advancing immunosuppression. TBG levels correlate inversely with the CD4 lymphocyte count, and in the past were used as a surrogate marker for disease progression. The increase in TBG does not appear to be due to generalized changes in protein synthesis, increases in sialylation and altered clearance of TBG, or changes in estrogen levels. The cause and clinical significance of the increased TBG found in HIV-infected patients are unknown. However, increases in TBG affect total T₄ and T₃ measurements, and this should be considered when interpreting these tests in HIV-infected patients.

Subtle alterations in TSH dynamics have been reported in stable HIV-infected patients. Although their TSH and free T₄ levels remain within the normal range, these individuals demonstrate significantly higher TSH values and lower free T₄ values than uninfected controls. In circadian studies, HIV-infected individuals have higher TSH pulse amplitudes with unchanged pulse frequency as well as a higher peak TSH in response to thyrotropin-releasing hormone (TRH) stimulation. These studies are consistent with a subtle state of compensated hypothyroidism in HIV infection; the mechanisms underlying these alterations have not been elucidated.

The typical pattern of alterations in thyroid function tests in HIV-infected patients is outlined in Table 25–1.

### Opportunistic Infections and Neoplasms

Opportunistic pathogens and neoplasms can invade the thyroid in HIV-infected individuals but generally do not cause clinical thyroid dysfunction. Although the prevalence of thyroid involvement is unknown, autopsy of 100 AIDS patients prior to the era of HAART showed the presence of *Mycobacterium tuberculosis* in 23% of patients’ thyroids, followed by cytomegalovirus (CMV) (17%), *Cryptococcus neoformans* (5%), *Mycobacterium avium* (5%), *Pneumocystis carinii* (4%), and other bacteria or fungi (7%). A few of these pathogens are noteworthy because they have been associated on occasion with both hyper- and hypothyroidism. *Pneumocystis carinii* has been associated with inflammatory thyroiditis accompanied by hypothyroidism in seven cases, hyperthyroidism in three cases, and normal thyroid function in one case. Antithyroid antibodies were negative in all six cases in which they were measured. Radionuclide scanning in seven cases revealed poor visualization of the entire thyroid gland in patients with bilateral disease and nonvisualization of the affected lobe in patients with unilateral disease. Two patients with hyperthyroidism had normalization of thyroid function after treatment of the *P. carinii* infection. Kaposi sarcoma has also been reported to infiltrate the thyroid gland and resulted in significant destruction and hypothyroidism in at least one case. In two cases, lymphoma was associated with thyroid infiltration, causing thyroidal enlargement.

### Medication Effects

Several medications used to treat HIV-infected patients can alter the clearance of thyroid hormone by inducing hepatic microsomal enzymes. These medications include rifampin, phenytoin, ketoconazole, and ritonavir. Patients with normal thyroid function should not be clinically affected, although decreases in T₄ may be observed. However, patients receiving L-thyroxine may require increased doses, and patients with decreased pituitary or thyroid reserve may develop clinically apparent hypothyroidism. Isolated, but well-documented reports of need for increased thyroxine doses after starting ritonavir and decreased doses after indinavir have been published; these medications affect glucuronidation, but given the common use of high doses of these drugs in the past, it is surprising how rarely problems present. Interferon-alpha, a therapy used for Kaposi sarcoma and hepatitis C (an increasing coinfection with HIV), has been associated with autoimmune diseases of the thyroid, including hyperthyroidism and hypothyroidism. Medications used in HIV-infected patients that can affect the endocrine system are listed in Table 25–2.

With the advent of HAART, there have been case report series of newly diagnosed autoimmune diseases such as Graves disease, Hashimoto thyroiditis, and alopecia areata. Immune reconstitution with HAART raises the possibility of subsequent induction of autoimmune diseases. The cases appeared late after immune reconstitution (8-32 months). Possible theories include thymic regeneration or peripheral T lymphocyte expansion causing irregularities in tolerance, leading to autoimmune dysfunction. Other studies, however, could not link autoimmune thyroid disease to HAART, and the low prevalence in the large published studies suggests that increased screening above standard guidelines may not be warranted.

ADRENAL DISORDERS

Opportunistic infections commonly involve the adrenal glands but rarely occupy enough of the gland to cause adrenal insufficiency. Impaired adrenal reserve without overt symptoms of adrenal insufficiency has been described in patients with HIV. Those patients with a subnormal response to dynamic testing represent a group for which there is controversy over when to give baseline replacement glucocorticoids (or mineralocorticoids) or increased doses in stressful situations, especially when baseline levels are normal or elevated. With restoration to health by treatment of opportunistic infections or HIV itself, many of these patients no longer have adrenal insufficiency.

Opportunistic Infections and Neoplasms

Opportunistic organisms are found commonly in the adrenal glands of patients dying of AIDS although they rarely cause clinical adrenal insufficiency. CMV has been associated with significant necrosis of the adrenal gland, although the amount of tissue affected rarely reaches 90%, thought necessary to cause clinical adrenal insufficiency. In one preliminary study, however, the presence of CMV retinitis was associated with an increased rate of adrenal insufficiency compared with AIDS patients without that disorder. Less common opportunistic infections involving the adrenals include Mycobacterium tuberculosis, Mycobacterium avium-intracellulare, Cryptococcus neoformans, Histoplasma capsulatum, P. carinii, and Toxoplasma gondii. In addition, Kaposi sarcoma and lymphoma can involve the adrenals, but rarely to the extent of inducing adrenal insufficiency.

Glucocorticoids

Classic clinical symptoms of adrenal insufficiency are seldom seen, but some clinicians view the weakness and weight loss observed in patients with AIDS as an indicator of adrenal insufficiency. HIV-infected patients usually have normal or, even more commonly, elevated basal cortisol levels. The elevated levels occur most commonly in advanced disease, which may be a stress response, but is confounded by an increase in cortisol-binding globulin. Adrenocorticotropic hormone (ACTH) levels have mostly been found to be normal or elevated in patients with elevated basal cortisol levels, although some reports of low levels exist. Some of these alterations may be mediated by multiple cytokines; both interleukin (IL)-1 and tumor necrosis factor (TNF) can directly stimulate cortisol secretion, while IL-1 and IL-6 can stimulate ACTH and corticotropin-releasing hormone (CRH) release. On the other hand, IL-2 and IL-4 increase sensitivity to cortisol. An increase in cortisol levels may also be a direct response to HIV infection itself. The HIV envelope protein gp120 increases cortisol levels. HIV-1 virus encodes several proteins such as Vpr and Tat that may increase cortisol sensitivity. An increased cortisol to dehydroepiandrosterone (DHEA) ratio correlates with body weight loss and HIV-associated malnutrition.

Subclinical abnormalities in hypothalamic pituitary axis dynamics are often present. Nearly all HIV-infected patients have a normal cortisol response to the standard high-dose (250 µg) ACTH stimulation testing. Other studies have shown that stimulation with low-dose cosyntrphin (1 µg) resulted in a diagnosis of glucocorticoid insufficiency in roughly 10% to 20% of outpatients with HIV and up to 50% of critically ill HIV-infected patients. During CRH stimulation testing, a reduced ACTH or cortisol response was seen in up to 50% of stable HIV-infected patients with CD4 counts less than 500/µL. The abnormalities of decreased reserve either at the pituitary or at the adrenal level in HIV infection are similar to those that occur in other infections or serious illnesses.

Although clinically significant abnormalities in glucocorticoid secretion appear to be uncommon, subtle alterations in adrenal biosynthesis may be more common. HIV-infected patients have
reduced products of the 17-deoxysteroid pathway (corticosterone, deoxycorticosterone, and 18-hydroxydeoxycorticosterone) with normal or elevated products of the 17-hydroxy pathway (cortisol) before and after ACTH stimulation. It is not known whether this alteration represents an early indication of evolving adrenal insufficiency or is an adaptive response that shifts adrenal synthetic activity to steroids that are crucially needed under conditions such as HIV infection that impose physical stress. Twenty-four-hour urine-free cortisol levels do not predict the subtle adrenal alterations in HIV-infected patients, but may indicate adequate adrenal function.

Glucocorticoid resistance has been described in HIV-infected patients. This syndrome is characterized by symptoms of weakness, fatigue, weight loss, and hyperpigmentation, with elevated cortisol levels and mildly increased ACTH levels. Decreased lymphocyte glucocorticoid receptor affinity for glucocorticoids has been described in these patients. A similar state is seen in glucocorticoid-resistant asthma patients. Increased expression of the beta form of the glucocorticoid receptor, which inhibits the alpha form, has also been reported. Partial glucocorticoid resistance could explain the finding of increased basal cortisol in some HIV-infected patients, but the prevalence and clinical significance of this syndrome are uncertain.

**Adrenal Androgens**

HIV-infected patients have decreased basal adrenal androgen levels and impaired adrenal androgen responses to ACTH stimulation. Decreased adrenal androgens have been seen at all stages of HIV infection, as well as in HIV-negative intensive care unit patients. Thus, this change may not be specific to HIV infection but may instead be a feature of the physiologic response to illness, which is often accompanied by increased cortisol. In two studies, a fall in DHEA levels predicted progression to AIDS independent of CD4 cell counts. DHEA has been shown in vitro to inhibit HIV replication, which raised the possibility that the decreased DHEA levels observed in HIV-infected patients might influence the effects of the HIV infection. However, the efficacy of DHEA replacement in HIV-infected patients has never been demonstrated. Adrenal androgens may be decreased in women with HIV infection; low-dose testosterone replacement has been shown to induce small improvements in lean mass, depression, and sexual function.

**Mineralocorticoids**

Although electrolyte disturbances are not uncommon in HIV-infected patients, provocative testing of the mineralocorticoid axis has revealed few abnormalities. In contrast to glucocorticoid levels, basal and ACTH-stimulated aldosterone levels have been found to be normal in almost all HIV-infected patients studied, including both outpatients and inpatients. Nevertheless case reports of hypo- and hyperaldosteronism appear in the literature, including both outpatients and inpatients. The usual pattern of alterations in adrenal hormones is shown in Table 25-3.

**Medication Effects**

Several medications used in the treatment of HIV-related disorders can alter glucocorticoid metabolism. Ketoconazole inhibits the cytochrome P450 enzymes P450scc and P450c11, decreasing cortisol synthesis and leading to adrenal insufficiency in patients with decreased adrenal reserve. Rifampin increases hepatic metabolism of steroids and may lead to adrenal insufficiency in patients with marginal adrenal reserve.

Megestrol acetate has intrinsic cortisol-like activity, decreasing serum cortisol and ACTH levels through suppression of the hypothalamic-pituitary-adrenal axis centrally. Patients taking megestrol have decreased cortisol and ACTH levels in response to metyrapone testing. They may become frankly Cushingoid and may show signs of adrenal insufficiency upon its rapid discontinuation. Some HIV protease inhibitors (PIs) block the metabolism of the inhaled steroid fluticasone by CYP3A4 and can lead to Cushing syndrome even in the absence of systemic steroid use. PIs do not seem to have an effect on plasma cortisol levels. However, there is debate in the literature about whether these agents increase or decrease urinary free cortisol or 17-hydroxycorticosteroid excretion.

Medications used to treat HIV-related illnesses can lead to electrolyte disturbances mimicking disorders of mineralocorticoids. Trimethoprim impairs sodium channels in the distal nephron, decreasing potassium secretion, which can result in hyperkalemia. Pentamidine has also been associated with hyperkalemia in rare instances, perhaps through nephrotoxicity. Sulfonamides are associated with interstitial nephritis and hyporeninemic hypoaldosteronism. Finally, amphotericin B causes renal potassium and magnesium wasting.

Medications used in HIV-infected patients that can affect the endocrine system are listed in Table 25–2.

**Summary of Adrenal Disorders**

In summary, there is little evidence for clinically significant impairment of adrenal steroid excretion in HIV infection. The subtle alterations in the glucocorticoid and androgen synthesis pathways...
may be an adaptive response to physiologic stress and may occur with other illnesses. Patients with HIV infection who exhibit symptoms consistent with adrenal hormone deficiency should undergo provocative testing in the same manner as uninfected individuals. Patients with both low baseline and abnormal glucocorticoid or mineralocorticoid responses to provocative testing should be treated with physiologic replacement doses of oral glucocorticoids or mineralocorticoids. Patients on replacement should be covered with high doses of glucocorticoids (usually 150–300 mg of hydrocortisone per day or equivalent) during episodes of severe illness. Electrolyte abnormalities should prompt evaluation for medication effects and the presence of renal disease.

The HIV-infected patient with a minimally elevated or frankly high basal cortisol who does not increase significantly after ACTH stimulation poses a difficult problem. Most of these individuals have normal responses to prolonged ACTH stimulation, and seronegative patients with significant illness can have similar patterns that revert to normal after treatment of the illness. Chronic glucocorticoid therapy may have significant adverse consequences in these individuals, who are already immunocompromised. Most HIV-infected patients with this pattern and even many with baseline low levels during acute illness do not appear to require long-term glucocorticoid replacement. Consideration could be given to administering short courses of steroid therapy during significant illness for individuals with indeterminate stimulation results based on clinical judgment and individual patient circumstances.

**BONE AND MINERAL DISORDERS**

**Osteopenia and Osteoporosis**

There is evidence of low bone mass and, less commonly, osteoporosis in HIV-infected patients either without therapy or while receiving HAART, but the etiology remains controversial. The incidence of fractures may be increased, but there are too few studies of fracture rate to know with certainty. Therapy with bisphosphonates is effective at increasing bone mineral density (BMD) in HIV-infected patients, but there are no convincing data on fracture prevention.

Prior to the introduction of HIV PIs, low BMD was not commonly observed in HIV-infected patients. The few clinical studies on the effects of HIV on bone mineralization suggested that HIV had relatively little effect on BMD. One study followed 45 HIV-infected men for 15 months and found no change in lumbar spine and hip BMD. However, histomorphometric analysis of bone biopsies from AIDS patients showed some evidence of decreased bone formation and bone turnover; these changes were more marked in more severely affected patients. HIV itself may have an indirect effect on BMD by activating the receptor activator of nuclear factor kappa B ligand (RANK-L), which activates osteoclasts and their precursors. Activated T cells express the receptor for RANK-L—that is, RANK. The cytokines TNF-alpha and IL-1, whose levels may be increased in HIV infection, also have been shown to activate RANK-L.

After the introduction of PI-based HAART, reports of osteoporosis began to emerge. Some cross-sectional studies suggested that patients on PIs had a higher prevalence of osteoporosis and osteopenia compared to HIV-infected patients not taking PIs. However, other studies did not find a specific association of PIs with decreased BMD by dual energy x-ray absorptiometry (DXA). To date, most cross-sectional studies have shown that both HIV-infected men and women, on any form of HAART, have lower BMD or a higher prevalence of osteopenia, compared to gender- and ethnicity-matched control subjects. In one meta-analysis of 20 papers, the prevalence of reduced BMD was 67%, and the prevalence of osteoporosis was 15% in HIV-infected patients, which represents a 6.4-fold greater prevalence of reduced BMD and 3.7-fold greater prevalence of osteoporotic T scores compared to controls. Furthermore, those treated with ARV had a 2.5-fold higher prevalence of reduced BMD than those who were ARV-naive. Lactic acidemia associated with nucleoside reverse transcriptase inhibitor (NRTI) use has been hypothesized to contribute to bone demineralization. However, the role of specific ARV drugs as a cause of bone demineralization remains debated, as many recent studies fail to show an association between osteopenia and individual drugs. Thus, ARV use per se is associated with lower BMD. Divergent effects of PIs on bone cells in vitro have been reported.

Another meta-analysis found that the effect of HIV infection was mostly accounted for by decreased weight. Other studies have found associations of low albumin and past steroid use with low BMD. A randomized longitudinal study showed that continuous ARV therapy, used to suppress HIV, was associated with greater loss of bone mass and perhaps more fractures than intermittent ARV therapy designed to reduce drug exposure. However, the absolute rate of BMD loss by DXA was actually quite small in those on continuous ARV therapy (−0.5%/year at the hip and −0.7%/year at the spine). In a large database analysis, the fracture rate was increased 1.7-fold in HIV-infected Caucasian men and 1.4-fold in HIV-infected Caucasian and African American women compared to their respective controls.

Treatment for HIV-associated osteoporosis with bisphosphonates has been examined. Multiple studies have shown that the bisphosphonates alendronate and zoledronic acid given either with or without calcium and vitamin D supplementation to HIV-infected patients with osteopenia or osteoporosis improved BMD in the lumbar spine and hip after 1 to 2 years of therapy. The effects of treatments for other HIV-related problems on BMD or bone markers have been assessed. Eugonadal men with AIDS wasting syndrome treated with intramuscular testosterone for 3 months had small increases in lumbar spine BMD; however, high doses of testosterone were associated with decreases in HDL cholesterol levels. Recombinant growth hormone (GH) treatment for 24 weeks in HIV wasting syndrome did not affect BMD. Short-term growth hormone-releasing hormone (GHRH), used to treat HIV-infected men with abdominal fat accumulation, was associated with an increase in bone turnover markers; however the effect of GHRH use on BMD remains to be determined.
Osteonecrosis

Osteonecrosis has been reported both in adults and in children infected with HIV, and there is concern about the rising prevalence of osteonecrosis in this population. The most likely reason for the apparent rise in prevalence of the syndrome is increased awareness among clinicians. A study of 339 HIV-infected patients reported a prevalence of asymptomatic osteonecrosis, diagnosed by magnetic resonance imaging (MRI) at 4.4%. The annual incidence has been reported to be between 0.08% and 1.3%, which is much higher than the annual incidence in the general population (0.01%-0.135%).

The clinical presentation and anatomic distribution are similar to HIV-negative patients. The most common location for osteonecrosis is the hip, but other locations include the humeral heads, femoral condyles, and scaphoid and lunate bones. In HIV infection, the majority of large joint involvement is bilateral. Cases of osteonecrosis of the jaw/oral cavity have also been reported.

Plain film x-rays often underdiagnose osteonecrosis as changes on x-ray are confined to advanced stage (III and IV) disease; MRI is more effective at finding early-stage disease. Some data support treatment with bisphosphonates in early disease involving major joints to reduce pain, but there are inadequate randomized, controlled trials to assess whether such therapy prevents progression. Core decompression with and without bone graft has had some success. Total joint replacement may be the only recourse in later disease (eg, following collapse of the femoral head).

An association between osteonecrosis and PI's was initially reported; however, subsequent studies have failed to show a causal relationship with PI use. Other possible etiologies include those that may be more frequent in patients with HIV infection (corticosteroid use, HIV-associated vasculitis, chemotherapy, and irradiation) and other traditional risk factors (ethanol use, sickle cell disease, hemoglobinopathies, and clotting disorders).

Calcium and Phosphate Homeostasis

Calcium, phosphate, and calcitropic hormone disturbances are associated with several HIV-related illnesses and medications. Hypercalcemia with an elevated 1,25-dihydroxyvitamin D level has been associated with both AIDS-related lymphoma and infections with M. tuberculosis, M. avium-intracellulare, P. jiroveci, C. neoformans, and Coccidioides immitis. This hypercalcemia is likely due to increased extrarenal 1-alpha hydroxylation of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D by inflammatory macrophages or tumor cells. In CMV infection, activated T cells or proinflammatory cytokines may secrete factors that activate osteoclasts, causing hypercalcemia. The syndrome has also been reported after starting antiretroviral therapy, with improvements in lymphocyte function, as part of the immune reconstitution syndrome. Recombinant human GH treatment has been associated with slight increases in serum calcium levels in some studies.

Mild hypocalcemia has been associated with HIV disease. HIV-infected patients have been shown to have low 1,25-hydroxyvitamin D and 25-hydroxyvitamin D levels, but normal vitamin D-binding protein levels, suggesting an impairment in 1-alpha hydroxylation and a compromised nutritional state. Low 1,25-hydroxyvitamin D levels are associated with advanced disease stage and increased TNF-alpha levels.

Inadequate parathyroid hormone (PTH) responses (ie, functional hypoparathyroidism) may also contribute to the hypocalcemia seen with HIV. PTH levels have been shown to be decreased in HIV-infected patients compared to controls. Parathyroid cells may be targeted by HIV infection: they express CD4 receptors which when activated affect PTH secretion. Invasion of the parathyroid gland by neoplasms and infections can also rarely occur.

Severe hypocalcemia is usually due to medications used to treat opportunistic infections. Variations on Fanconi syndrome are reported increasingly. Hypocalcemia and hypophosphatemia have been reported with tenofovir and adefovir (which are used to treat HIV) and cidofovir (which is used to treat CMV). Hypocalcemia has also been seen during therapy for CMV retinitis with foscarnet. Foscarnet can complex ionized calcium and may have mineral wasting effects at the level of the renal tubule, leading to concurrent hypomagnesemia and hypokalemia. Hypocalcemia and hypomagnesemia have also been reported during pentamidine treatment, and the combination of foscarnet and pentamidine can result in severe, even fatal, hypocalcemia. Trimethoprim-sulfamethoxazole, ketoconazole, and aminoglycosides are also associated with hypocalcemia. Ketoconazole and rifampin can alter vitamin D metabolism but usually do not produce clinically significant effects. Ketoconazole can reduce serum levels of 1,25-dihydroxyvitamin D and lower total—but not ionized—calcium levels. Rifampin and rifabutin can decrease 25-hydroxyvitamin D levels, but usually do not appear to significantly change calcium or PTH levels; one case has been reported of severe osteomalacia attributed to rifabutin.

Medications used in HIV-infected patients that can affect the endocrine system are listed in Table 25–2.

GONADAL DISORDERS

Testicular Function

Testicular atrophy is common in AIDS patients. Histopathologic changes include decreased spermatogenesis, thickened basement membrane, and an interstitial infiltrate. Possible causes of testicular atrophy include opportunistic infection by M. avium-intracellulare, Toxoplasma, and CMV, hypogonadism, HIV infection itself, and chemotherapy toxicity. HIV-infected men generally have oligoteratospermia, and as the disease state becomes more severe, the sperm can become grossly abnormal. Hence, male fertility decreases with advancing disease.

Semen washing has been used as a technique for HIV-discordant couples to reduce the risk of viral transmission. The three-step process involves gradient centrifugation, washing, and spontaneous migration to obtain motile sperm. There have been several thousand published cases of semen washing followed by either intrauterine or in vitro fertilization. These observational
reports have shown that semen washing is a relatively safe and effective means of establishing pregnancy in HIV-negative women. Still, there is concern that the risk of infection is not completely eliminated after the procedure.

Hypogonadism is a common finding in men, particularly with advanced HIV disease. Prior to the introduction of HAART, hypogonadism was observed in approximately 40% of HIV-infected men. With the widespread use of HAART, the prevalence of hypogonadism has declined to 20%. Early in HIV infection, testosterone levels are normal or even elevated. Elevated basal luteinizing hormone (LH) levels and an increased LH response to gonadotropin-releasing hormone (GnRH) have been observed in these patients, suggesting pituitary dysfunction. In the later stages of HIV infection, low serum testosterone levels are seen, often accompanied by symptoms of decreased libido or erectile dysfunction. Because hypogonadism is associated with loss of lean body tissue and muscle mass, it is thought to contribute to AIDS wasting syndrome. Hypogonadal men infected with HIV tend to have low or normal LH and follicle-stimulating hormone (FSH) levels, similar to that seen in hypogonadotropic hypogonadism. However, GnRH testing in hypogonadal men with HIV has been normal in most cases. Primary hypogonadism with elevated LH and FSH levels has been observed but is far less common.

Several etiologies of the hypogonadism in men infected with HIV have been proposed, and in many cases, the cause of hypogonadism is multifactorial. Chronic illness and weight loss can alter the hypothalamic-pituitary axis. HIV infection increases the levels of the cytokines IL-1 and TNF, which have been shown to suppress hypothalamic pituitary function. Direct pituitary or hypothalamic invasion by toxoplasmosis or CMV is rare. There are divergent data on the extent to which treatment of HIV with ARV drugs increases testosterone levels.

Medications can also alter testicular function. Ketoconazole inhibits gonadal steroidogenesis, resulting in lower testosterone levels, oligospermia, and gynecomastia. Megestrol acetate, a progestosterone-like agent, can lead to decreases in testosterone in HIV-infected men, perhaps through central feedback on gonadotropins. Medications used in HIV-infected patients that can affect the endocrine system are listed in Table 25–2.

Most of the studies of testosterone replacement have been performed in the context of AIDS wasting syndrome in which muscle and fat mass are decreased. Testosterone therapy in hypogonadal men with HIV increases lean body mass, but only small improvements in strength are seen. Most studies find that testosterone replacement therapy results in improved sexual functioning, mood, and energy. Testosterone therapy does not appear to exacerbate Kaposi sarcoma, although the studies of this relationship have involved limited numbers of patients.

**Ovarian Function**

Women represent one of the fastest growing populations with HIV infection. Two key issues include the effects of reproductive function on the natural history of HIV disease, and conversely, the effects of HIV on reproductive function. Recent studies found that women infected with HIV possess 30% to 50% lower HIV-1 RNA levels than men. Limited data suggests that the ovulatory cycle affects HIV infection in women. Early studies suggested no association between the menstrual cycle and HIV-1 RNA levels but may have included women with anovulatory cycles. In ovulating women, HIV-1 RNA levels have been shown to decline from the early follicular phase to the luteal phase. Menopause does not seem to affect the progression of HIV disease or the response to therapy.

In addition to affecting HIV-1 RNA levels, the menstrual cycle may also affect the pharmacokinetics of drugs used to treat HIV infection. Zidovudine levels have been shown to be negatively correlated with estradiol levels, suggesting that the menstrual cycle may affect zidovudine glucuronidation. Further studies are warranted.

Pregnancy does not seem to have a deleterious effect on maternal progression of HIV disease. However, an increase in HIV-1 RNA levels may occur in the early postpartum period. Several, but not all, studies suggest that pregnancy increases the rate of detection of HIV-1 in the genital tract. When HIV-1 is identified in the genital tract, the risk of perinatal transmission has been consistently shown to increase. Simple ARV regimens at the time of delivery have been shown to significantly reduce transmission of HIV to the child.

It is unclear whether HIV infection itself causes menstrual irregularities and/or amenorrhea. Early studies reported menstrual irregularities in HIV-infected women. However, these studies relied on self-report of menstrual symptoms and cycles, and many studies had enrolled an inadequate number of HIV-negative women as controls. Recent studies suggest that HIV may alter menstrual function only slightly. One large study of 802 HIV-infected and 273 HIV-negative women matched for demographic characteristics, body mass index, and substance abuse found that HIV infection increased the odds of having a very short or long cycle. There were no differences in amenorrhea, length of menses, or variability between the two groups. Another study of 197 HIV-infected women and 189 HIV-negative women found that HIV was not associated with menstrual dysfunction.

It is also uncertain whether HIV has an effect on the onset and symptoms of menopause. The average age at menopause in HIV-infected women has been reported to be between 46 and 50 years. While some studies contrast that to reported average age at menopause in controls being slightly greater than 50, the range in multiple population studies is actually 48 to 51. The diagnosis of menopause is complicated by the occurrence of amenorrhea lasting more than 1 year (which meets the clinical definition of menopause) in HIV-infected women who do not have ovarian failure as indicated by normal FSH and LH levels. Factors associated with such amenorrhea include oocyte use, low body mass index, and low serum albumin levels suggesting hypothalamic dysfunction and malnutrition as causes rather than menopause. There are conflicting data concerning whether HIV is associated with increased or decreased symptoms of menopause.
With HIV infection, fertility rates decline. Quantifying the rate of decrease in fertility in the United States has been difficult due to confounding factors such as sociodemographics, drug use, weight loss, systemic illness, and sexually transmitted diseases. In Africa, where therapy for HIV was rare, there are numerous studies establishing an association between untreated HIV infection and infertility in virtually all age groups. In sub-Saharan Africa, HIV infection has been shown to account for a population-attributable decline in total fertility of 0.37% for each percentage point of HIV prevalence.

Like men, women infected with HIV have a decline in serum testosterone and adrenal androgen levels with progression of HIV disease and development of complications. Approximately 50% of women with AIDS-related wasting have low androgen levels. Androgen-deficient women may have subtle symptoms of decreased energy, libido, mood, strength, and bone mass. Despite the increased prevalence of androgen deficiency in study subjects with advanced disease, clinical laboratory diagnosis remains difficult in the female population. Total testosterone levels may be increased due to elevations in sex hormone-binding globulin in HIV-infected women, whereas free testosterone levels for women are not well-standardized in clinical laboratories.

Hormonal contraception is affected by ARV therapy. The estrogen component is metabolized by CYP3A4 enzyme. Many of the PI’s and some nonnucleoside reverse transcriptase inhibitors (NRTIs) either inhibit or induce CYP3A4, thus altering ethinyl estradiol and norethindrone levels. Other medications used to treat opportunistic infections such as rifabutin and rifampicin can also induce CYP3A4. There are very few studies on the effects of these medications on ovulation in subjects taking oral contraceptives. The Centers for Disease Control and Prevention recommend using barrier methods or condoms in addition to or in place of oral contraception.

**PITUITARY DISORDERS**

**Opportunistic Infections and Neoplasms**

In autopsy series of AIDS patients, nearly 10% of pituitary glands demonstrate some degree of infarction or necrosis; infectious organisms such as CMV, *P. carinii*, *Cryptococcus*, *Toxoplasma*, and *Aspergillus* have been observed. Antemortem pituitary function was not reported in these patients.

**Anterior Pituitary Function**

Hypopituitarism appears to be rare in AIDS patients; stimulation with TRH, GnRH, or CRH results in normal pituitary responses in almost all patients. Likewise, prolactin levels generally have been found to be normal, with a normal response to TRH stimulation. Some patients have shown a higher maximal pituitary response to stimulation testing compared with uninfected subjects, but the clinical significance of this alteration is not known.

The GH axis has received particular attention in children with HIV who can have poor growth velocity, especially when symptomatically ill. Most of these children demonstrate normal GH levels, although low insulin-like growth factor (IGF)-I levels can be seen. Low IGF-I in the setting of relatively normal GH is often seen in states of malnutrition, which may partially explain this finding. In adults, IGF-I levels may be low in malnourished or symptomatic HIV-infected patients but are usually normal in clinically stable individuals. Circadian GH secretion does not appear to be altered in adults with HIV infection, except in the presence of visceral obesity.

**Posterior Pituitary Function**

Posterior pituitary function may be altered in HIV infection. Hyponatremia is common in both inpatients and outpatients with HIV. Inappropriately high serum antidiuretic hormone levels have been seen in euvolemic AIDS patients with hyponatremia; however, many of these patients had pulmonary or cerebral infections, which themselves can cause the syndrome of inappropriate antidiuretic hormone secretion. As with any patient, destruction of the posterior pituitary by infection or tumor can lead to central diabetes insipidus; like anterior pituitary destruction, this appears to be rare in HIV infection.

**AIDS WASTING SYNDROME**

Prior to the introduction of HAART, weight loss and tissue wasting were commonly observed complications of AIDS in up to 30% of patients infected with HIV. A characteristic feature of this syndrome includes wasting of muscle, which is directly associated with increased morbidity and mortality. Muscle is disproportionately lost compared to fat in men. In contrast, women start with higher fat mass, and fat depletion dominates muscle loss until fat reserves are decreased. Weight loss can either be gradual or rapid in nature. Gradual weight loss has been associated with gastrointestinal disease, whereas rapid weight loss is usually seen during opportunistic infections.

The pathogenesis of wasting remains poorly understood. Several etiologies have been proposed including starvation, cachexia, hypermetabolic state, and hypogonadism. Starvation implies solely a limitation of calories, which may occur due to decreased appetite or decreased intake due to gastrointestinal infections with marked diarrhea. Cachexia refers to a state in which muscle is disproportionately lost due to direct effects on muscle. A hypermetabolic state has been proposed as a cause of AIDS wasting syndrome, because resting energy expenditure (REE) has been observed to be increased in HIV infection. However, the increase in REE is also seen in HIV-infected subjects with stable weight. HIV patients with either opportunistic infections or gastrointestinal disease have decreased caloric intake, but do not show the protective decrease in REE that occurs in pure starvation. Hence, the combination of decreased caloric intake and hypermetabolism is the driving force for...
wasting. The persistent metabolic defects make recovery from wasting incomplete, and recurrent events lead to progressive, stepwise wasting.

Hypogonadism is a prominent finding in up to 50% of men and women with AIDS wasting. A direct correlation between testosterone levels and decreased muscle and fat mass exists. Resistance to GH has also been demonstrated in patients with more than a 10% loss in body weight.

Because a 10% loss of weight is associated with increased morbidity and mortality in patients infected with HIV, clinical trials have targeted the restoration of appetite, weight, and lean body mass. The cannabinol derivative dronabinol increased subjective appetite in patients with AIDS wasting syndrome, but had little or no effect to promote weight gain. Megestrol acetate increased appetite and weight, but resulted in mostly gain of fat.

Currently, recombinant GH therapy is the only Food and Drug Administration–approved treatment specifically for AIDS wasting syndrome that increases lean body mass. At high doses (0.1 mg/kg/d), 3 months of GH therapy increased lean body mass by 3 kg and weight by 1 kg. However, patients did experience side-effects including swelling and joint pain. In a lower-dose study (1.4 mg/d), patients had no significant increase in lean body mass after 12 weeks, which suggests that high-dose GH therapy is required. Therapy with recombinant GH is quite costly, especially if given at higher doses.

Androgen therapy has been studied extensively, because almost half of patients with AIDS wasting syndrome exhibit decreased levels of testosterone. In a meta-analysis of six clinical trials, testosterone therapy was shown to increase lean body mass and weight, especially when the therapy was given intramuscularly as opposed to transdermally. However, there have been no studies in which subjects have been randomized to different routes of administration of testosterone. Because testosterone may decrease HDL cholesterol levels, there is some concern about the long-term effects of testosterone therapy on lipid profiles and cardiovascular risk. However, no other side-effects were reported in these small, short-term studies.

Anabolic steroids have similar effects on the AIDS wasting syndrome. Nandrolone decanoate is an injectable testosterone derivative that is approved for treating anemia in patients with chronic renal failure. Two studies of nandrolone decanoate in men found that lean body mass and strength significantly increased. Nandrolone therapy improved lean body mass and weight without evidence of acute toxicity. Therapy using oral anabolic steroids oxandrolone and oxymetholone also increases lean body mass and weight in men and women, but it is associated with significant hepatic transaminis as well as dyslipidemia.

Another approach has been to use anticytokine therapies to treat patients with AIDS wasting syndrome, but the results have been disappointing. Two studies reported small increases in weight after treatment with thalidomide, a TNF inhibitor. However, TNF levels actually increased and the patients experienced significant side effects including rash, fever, and increased viral load.

ABNORMALITIES OF FAT DISTRIBUTION ASSOCIATED WITH HIV

Shortly after the introduction of HAART with PIs, a constellation of symptoms appeared including abdominal obesity, lipoatrophy in the extremities and face, dorsocervical fat pads (buffalo hump), gynecomastia, breast enlargement, increased neck circumference, and lipomas along with insulin resistance and dyslipidemia. These changes were clustered into a single syndrome reminiscent of the metabolic syndrome and named HIV lipodystrophy.

In retrospect, some of these changes are not related to HAART with PIs. The appearance of lipoatrophy, fat accumulation in the dorsocervical fat pad, lipomas, and breast hypertrophy was reported in patients on two NRTIs before the introduction of HAART or PIs. The presence of dorsocervical fat pads and lipomas is striking, but their prevalence is low.

Furthermore, the original description of the HIV lipodystrophy syndrome has been refuted, as it has been shown definitively that the major changes in fat (lipoatrophy and abdominal obesity) are not part of the same syndrome, but have different causes. Unfortunately, there is still no widely accepted definition of HIV lipodystrophy that is used in the literature. Depending on the definition of HIV lipodystrophy, the prevalence of these findings varies widely (11%-83%). Part of the confusion is due to differences in methodology used to report fat loss or gain. Many early studies relied on the patient’s self-report and/or the clinician’s subjective assessment. Later studies quantified fat by anthropometrics or DXA. Neither technique permits the isolation of subcutaneous from visceral fat in the abdomen and trunk; therefore computed tomography and MRI are needed and have been utilized more recently to separately quantify fat in these compartments. Because changes in fat may take years to develop, many studies in the field are cross-sectional rather than prospective in design. In these cross-sectional studies, it is unclear how to match patients to a control group with normal fat distribution, given that most healthy adults are overweight.

Despite these challenges, it has become apparent that peripheral fat loss in the extremities and face does occur with increased frequency in patients taking HAART. In one study, 50% of HIV-infected subjects fell below the lowest decile (10%) of leg fat in controls. However, loss of subcutaneous fat in the abdomen also occurs. In contrast, it is not clear that visceral adipose tissue mass is increased in HIV infection. Furthermore, recent cross-sectional and prospective data showed that increased visceral fat is not linked to loss of subcutaneous fat.

Several etiologies have been proposed for the development of lipodystrophy associated with HIV, but to date no mechanism has been definitively linked to the disorder. The thymidine-based nucleoside analogs, stavudine and zidovudine, have the strongest association with the development of peripheral lipodystrophy. These NRTIs have been proposed to cause lipodystrophy through mitochondrial injury by inhibiting mitochondrial DNA polymerase-γ or depleting mitochondrial DNA. Fortunately, the use of stavudine and zidovudine has decreased. Abacavir is the NRTI with the least
effect on fat. Some PIs (eg, indinavir) and NNRTIs (eg, efavirenz) may contribute secondarily to the lipoatrophy observed with NRTI therapy, but there are not enough trials to understand fully the effects of each ARV drug.

The development of central lipohypertrophy is even less well understood. While central lipohypertrophy has been attributed to PI use, the evidence is controversial. In the first reports of appearance of buffalo hump, half of the patients were not on PI therapy or HAART. Recent data suggest that increased visceral fat may be due to restoration to health and normal aging.

Much research has focused on the treatment of the fat changes associated with HIV. Fat loss, especially in the face, can reveal the HIV status of a patient and lead to social stigmatization. The metabolic sequelae can also predispose the patient to the development of hypertriglyceridemia and atherosclerosis. One proposed strategy is to reverse the peripheral lipoatrophy by switching ARV drugs. Substituting another NRTI for a thymidine NRTI, such as stavudine or zidovudine, causes a minimal, albeit statistically significant increase in subcutaneous fat. Lipoatrophy does not fully resolve. In one study, switching from stavudine or zidovudine to abacavir caused a 0.4-kg increase in total limb fat after 24 weeks and a 1.3-kg increase in total limb fat after 104 weeks. However, that gain is insufficient to reach the levels seen in control populations. Complete cessation of therapy without replacement of NRTI results in virologic failure. Switching from PIs to nevirapine, efavirenz, or abacavir did not improve peripheral lipoatrophy. The newer NRTIs, tenofovir and emtricitabine, have been associated with less peripheral lipoatrophy than stavudine.

Thiazolidinediones are potentially attractive agents for treatment of peripheral lipoatrophy and insulin resistance. As ligands for the transcription factor peroxisome proliferator–activated receptor gamma (PPARγ), thiazolidinediones promote adipocyte differentiation. Unfortunately, two randomized studies found no improvement and a third showed minimal improvement in lipoatrophy after thiazolidine treatment for at least 24 weeks. However, the studies did show the expected improvement in insulin resistance.

Reconstructive therapy is available for peripheral lipoatrophy. Injectable skin fillers for the face include bioabsorbable and permanent fillers. Bioabsorbable fillers such as poly-L-acetic acid stimulate collagen production. In one open-label, single-arm study, 43% of patients had an increase in cutaneous thickness greater than 10 mm in the face after 96 weeks of therapy. The effects on collagen production last for approximately 18 months. Hyaluronic acid has also been used to a lesser extent in the treatment of facial lipoatrophy. Side-effects include easy bruising, redness, and swelling. Permanent fillers are generally not recommended due to the dynamic nature of fat loss in peripheral lipoatrophy. More invasive procedures include autologous fat transplants.

Central lipohypertrophy has been treated with GH and GHRH analogues. At high doses (6 mg/d), GH decreased visceral fat by 21% to 24%. However, a significant number of patients experienced joint swelling, fluid retention, and deterioration in glucose tolerance. A lower dose of GH (3 mg/d) also reduced visceral fat, although to a lesser extent. With further dose reduction, GH (1 mg/d) decreased total fat, but did not significantly alter visceral fat content. A GHRH analogue, tesamorelin, is a recently approved therapy for reduction of visceral obesity in HIV-lipodystrophy that limits the side-effects of excessive GH secretion by increasing the endogenous pulsatility of GH secretion. Tesamorelin (2 mg/d) given for 26 weeks decreased visceral fat by 15%. Unlike GH therapy, tesamorelin did not induce insulin resistance; there were fewer GH-like symptoms of joint and fluid retention. GH therapy is very expensive, and the effects of GH and GHRH reverse when therapy is stopped.

**DISORDERS OF GLUCOSE AND LIPID METABOLISM**

Shortly after the introduction of HAART, reports of impaired fasting glucose, insulin intolerance, diabetes, and hyperlipidemia appeared in the HIV literature. Given the close temporal relationship to the introduction of PIs, studies focused on the association with PIs. However, other factors such as restoration of health, immune reconstitution, and body composition changes (including lipoatrophy and visceral hypertrophy) may also contribute to the disturbances in metabolism. To clarify these issues, several groups have given HIV antiretroviral drugs to healthy, HIV-seronegative volunteers in order to define direct drug effects. In the sections later, the results in HIV-infected subjects will be compared to those in healthy volunteers to understand the effects of drug versus disease. Metabolic effects are specific to certain drugs and not an effect of the PI class as a whole.

**Insulin Resistance, Glucose Intolerance, and Diabetes**

With the reports of rapid onset of diabetes after introduction of HAART with a PI, researchers looked for effects of PI on insulin resistance. Subsequent studies looked at hepatic glucose production and insulin secretion.

Several factors contribute to the development of insulin resistance in the setting of HIV. Unlike other infectious states, in which insulin resistance is common, early in the epidemic, AIDS was found to be associated with an increase in insulin sensitivity (Table 25-4). Compared with 10 healthy controls, insulin sensitivity was higher in 10 stable patients with symptomatic HIV. However, with asymptomatic HIV infection, another early study found that there was no change in insulin sensitivity compared with healthy controls. Insulin resistance is common in healthy subjects. Thus, improvement of HIV infection alone may contribute to an observed decrease in insulin sensitivity. More recent studies have found insulin resistance in ARV-naïve, HIV-infected subjects.

Body composition influences insulin sensitivity. Patients studied early in the epidemic, were thin, if not cachetic. In recent studies body weight was higher even in many ARV-naïve patients. Increased visceral fat in the abdomen has been linked to insulin resistance in subjects with or without HIV disease. Upper trunk fat is also independently, strongly associated with insulin resistance.
Likewise, severe lipoatrophy has been linked to insulin resistance regardless of HIV status. The lesser levels of lipoatrophy seen in most HIV-infected patients may also contribute. It should be recognized that each of these factors may contribute in an additive way to insulin resistance.

Much attention has focused on the role of individual therapies in the induction of insulin resistance. Some PIs have been reported to decrease insulin-mediated glucose disposal per unit insulin level (M/I) during the hyperinsulinemic, euglycemic clamp, a technique during which insulin is infused at a steady rate and glucose infused to maintain euglycemia, which directly measures insulin action. In a double-blind, placebo-controlled study in healthy normal volunteers, a single dose of indinavir has been shown to decrease insulin-mediated glucose disposal by 34% (Table 25–5). Indinavir for 4 weeks has also been shown to cause a 17% decrease in insulin-mediated glucose disposal as well as deterioration in glucose tolerance. A single dose of ritonavir decreased insulin sensitivity by 15%. Lopinavir/ritonavir has less of an effect on insulin sensitivity, but the magnitude of this effect is not clear (see Table 25–5). In two studies, lopinavir/ritonavir given for 4 weeks caused no change in insulin sensitivity, whereas in shorter studies, lopinavir/ritonavir given for 1 to 5 days was associated with a 13% to 24% decrease in insulin sensitivity. The study reporting a 13% decrease compared rates in the same subjects on placebo and lopinavir/ritonavir; the study reporting the 24% decrease presented pooled data from some subjects who received both placebo and drug on different occasions, some drug only and some placebo only.

Of note, not all PIs decrease insulin-mediated glucose disposal. In double-blind, placebo-controlled studies, atazanavir and amprenavir had no effect on insulin sensitivity in healthy normal volunteers (see Table 25–5). NNRTIs have not been associated with insulin resistance. In studies where PIs are replaced with NNRTIs, insulin resistance improved.

The mechanism of insulin resistance with PIs includes the acute blockade of the peripheral insulin-regulated glucose transporter (GLUT4). In vitro studies have shown that PIs (indinavir, ritonavir, and amprenavir) selectively inhibit 2-deoxyglucose transport into 3T3-L1 adipocytes without affecting early insulin-signaling events or the translocation of intracellular GLUT4 to the surface. Indinavir has also been shown to block partially GLUT2, the glucose transporter postulated to be involved in glucose sensing in the pancreas and regulation of insulin secretion. Recently, an analog of the peptidomimetic phenylalanine moiety found in all PIs has been shown to inhibit GLUT4-induced glucose transport in vitro. Because serum levels of PIs vary, some PIs, such as amprenavir, may block GLUT4 in vitro but have no effect in patients.

Increased insulin resistance has also been found in HIV-infected subjects on NRTI therapy. However, it is unclear if the effects of NRTIs are a direct effect of the drug, reactivation of the immune system, restoration of health, or changes in body composition. When stavudine was given to healthy volunteers, there was no decrease in M/I.

In addition to peripheral insulin resistance, impairment in insulin secretion was reported in HIV patients on PI therapy. In HIV-infected subjects treated with either nelfinavir, indinavir, lopinavir/ritonavir, or saquinavir, beta cell function assessed by first-phase insulin secretion showed a 25% decrease. However, insulin secretion in the HIV-infected patients was higher than controls before PI therapy and was reduced only to that of controls after PI therapy. The HIV-infected patients had suppression of HIV RNA levels and increases in CD4 counts. More recently, healthy normal volunteers were given lopinavir/ritonavir for 4 weeks, and no effect was seen on first-phase insulin secretion. Thus, it is not clear whether currently used PIs alter insulin secretion.

Hepatic glucose production is also increased in some patients on PIs. Endogenous glucose production, comprised mostly of hepatic gluconeogenesis and glycogenolysis, is the largest determinant of fasting glucose and can be measured by tracer stable isotope technology. In studies of healthy normal volunteers, indinavir increased endogenous glucose production in the fasting state. During the hyperinsulinemic, euglycemic clamp, indinavir blunted the ability of insulin to suppress endogenous glucose production. Endogenous glucose production was not increased in rats treated with intravenous indinavir during a hyperinsulinemic, euglycemic clamp study. However, the method of stable isotope analysis was different in the rat and human studies, which may explain the discrepancy in results. In humans, full-dose ritonavir has a small detrimental effect on endogenous glucose production, while amprenavir had no effect. The effects of other PIs remain to be determined.

Adipocytokine levels have been explored in HIV infection, and they may explain some of the results in glucose metabolism. Adiponectin, a hormone secreted by adipocytes, has been shown to increase peripheral and hepatic insulin sensitivity. Adiponectin levels inversely correlate with the amount of visceral fat in

In insulin resistance is expressed as M/l from euglycemic hyperinsulinemic clamp data as explained in the text. An increase in insulin resistance is reflected in a negative M/l and an upward arrow.

LDL increases in patients with HIV infection who start with low LDL. There is little effect of PI in HIV-negative subjects.

In HIV-negative subjects given one to five doses. No effect after 4 weeks.

EGP, endogenous glucose production; HDL, high-density lipoprotein; LDL, low-density lipoprotein; NA, not available; TG, triglyceride.

HIV-negative subjects. In patients with HIV-associated peripheral lipoatrophy, adiponectin levels are reduced. Low adiponectin levels have been proposed to mediate some of the insulin resistance observed in peripheral lipoatrophy and visceral lipohypertrophy. The mechanism which reduces adiponectin levels is unknown. Some have attributed the reduction to PI therapy. In vitro studies of cultured fat cells have suggested that PI treatment suppresses adiponectin mRNA and protein expression. However, two studies in healthy normal volunteers found that in fact adiponectin levels were increased during treatment with the PIs indinavir or lopinavir/ritonavir. The discrepancy in the effect of PIs on adiponectin levels in vitro and in humans is not well understood.

Levels of leptin, another hormone secreted by adipocytes, correlate with insulin resistance. However, some diseases with very low leptin levels also have insulin resistance. Leptin levels have been shown to be decreased in HIV patients with peripheral lipoatrophy.

Current guidelines set forth by the International AIDS Society-USA (IAS-USA) suggest measuring fasting glucose levels before and during PI therapy. In patients with risk factors for diabetes or with peripheral lipoatrophy or visceral lipohypertrophy, oral
glucose tolerance testing may be warranted. Patients with preexist-
ing abnormalities in glucose metabolism or with first-degree rela-
tives with diabetes mellitus should consider avoiding the PIs most
associated with insulin resistance; atazanavir and newer PIs may be
better choices.

Treatment of PI-induced diabetes should ideally be tailored to
the specific alteration in glucose metabolism. Although there are
no studies of treatment of PI-induced diabetes per se, there are
studies of therapy of patients who have HIV-associated lipoa-
trophy and lipohypertrophy who also are taking PIs. Thiazolidinediones can ameliorate peripheral insulin resistance
induced by PIs. Thiazolidinediones improve insulin resistance
in patients with HIV-associated lipoatrophy and lipohypertrophy.
Proliferation of lipomas has been reported in one patient with
HIV-associated lipoatrophy. Given the recent findings that thiazo-
lidinediones decrease BMD and may increase fracture risk, cau-
tion is warranted in HIV-infected patients as they may be at
higher risk for bone loss and fracture. Metformin decreases hepatic
insulin (AIDS Endocrinopathies 799)
glucose production and peripheral insulin resistance. Metformin
should be used with caution in combination with NNRTI's stavu-
dine and didanosine, which, like metformin, are associated with
increased lactic acidosis. Sulfonylureas may prove to be useful in
improving insulin secretion. Due to the risk of hypoglycemia,
sulfonylureas should be used with caution in treating mild
PI-induced diabetes.

Other medications used to treat opportunistic infections are
associated with hyperglycemia and hypoglycemia. Pentamidine
causes pancreatic beta cell toxicity, acutely leading to hypoglyce-
mia, and over the long-term, it causes diabetes mellitus. Hypoglycemia during pentamidine treatment is associated with
increased length of treatment, higher cumulative doses, and renal
insufficiency. Patients who develop hypoglycemia in association
with pentamidine therapy are at increased long-term risk of
developing diabetes mellitus. HIV-infected patients who develop
diabetes mellitus following pentamidine therapy have low C pep-
tide levels, suggesting beta cell destruction. Aerosolized pentami-
dine therapy has also been reported to cause hypoglycemia and
diabetes mellitus. Pentamidine, trimethoprim-sulfamethoxazole,
and the nucleoside analogs didanosine and zalcitabine have been
associated with acute pancreatitis. Megestrol acetate, which has
intrinsic glucocorticoid activity, may be associated with diabetes
mellitus in HIV-infected patients, perhaps through its glucocor-
ticoid activity, although the rate of hyperglycemia in controlled
clinical trials appears to be low. GH can also cause insulin resis-
tance, leading to hyperglycemia and diabetes. Medications used
in HIV-infected patients that can affect the endocrine system are
listed in Table 25–2.

### Lipid Disorders

Alterations in lipid and lipoprotein profiles are common in patients
infected with HIV. The observed changes can be due to a number
of interrelated issues, including HIV infection itself, antiviral medi-
cations, body composition changes, and immune reconstitution. A
rational approach to disturbances in lipid metabolism is to assess the
status of the HIV infection, medications used to treat HIV, and
presence of body composition changes (including peripheral lipoa-
trophy and central lipohypertrophy). The following section reviews
the lipid and lipoprotein profiles individually, with an emphasis on
studies prospectively measuring fasting lipid levels.

HIV infection is associated with a mild increase in triglyceride
and very low density (VLDL) cholesterol levels (see Table 25–4).
Triglyceride and VLDL cholesterol levels rise in association with
advancing HIV disease and correlate with HIV RNA levels. The
increased triglycerides are thought to be due to interferon-alpha
induced decreased clearance of triglycerides and, to a lesser extent,
increased VLDL production.

Several antiviral medications can increase triglyceride levels.
Full-dose ritonavir can cause a two- to three-fold increase in tri-
glyceride levels, probably by increased VLDL production
(see Table 25–5). Ritonavir has been shown in vitro to inhibit the
degradation of apolipoprotein B, a protein involved in the forma-
tion of VLDL particles. Other studies have suggested that activ-
ated sterol regulatory-binding proteins (SREBPs) in the liver are
involved in the increase in VLDL production. Because of its abil-
ity to inhibit the hepatic enzyme CYP3A4, ritonavir is used to
increase the pharmacologic doses of other PIs metabolized through
the same cytochrome system. Boosting doses of ritonavir (100 mg
twice daily) have also been shown to increase triglycerides, albeit
to a lesser extent. The combination lopinavir/ritonavir given to
healthy normal volunteers increased triglycerides and VLDL cho-
esterol levels by 83% and 33%, respectively. Tipranavir/ritonavir
produces similar increases to those of lopinavir/ritonavir in HIV-
infected individuals. Not all PIs alter triglyceride levels; in healthy
normal volunteers, administration of indinavir and atazanavir
resulted in no change in triglyceride levels (see Table 25–5). The
data are mixed on amprenavir and nelfinavir, with some studies
showing an increase in triglycerides and others finding no effect.

The NNRTI efavirenz is associated with increased triglycerides.
Again, this is not a class effect as another NNRTI, nevirapine, has
not been associated with alterations in triglyceride metabolism.

The effects of NRTIs on lipid metabolism have not been well
studied. In some, but not all studies, stavudine use was associated
with increased triglyceride levels. The most informative trial com-
pared stavudine with tenofovir and found an increase in triglyc-
erides in the stavudine arm, but not in the tenofovir arm. Given
that all subjects got efavirenz, a likely interpretation is that there
was a lipid-lowering effect of tenofovir; other data support this
interpretation, as adding tenofovir to an effective ARV regimen
lowers lipids.

The original clinical syndrome of HIV lipodystrophy has also
been reported to be associated with increased triglyceride levels.
One study found that 57% of patients with both peripheral lipoa-
trophy and central lipohypertrophy had triglyceride levels above
300 mg/dL. It has long been recognized that visceral obesity in the
general population is associated with high triglycerides. However,
recent data suggest that lower body fat is protective, as increased
levels of lower body fat are associated with lower triglycerides in
both HIV-infected patients and controls. Therefore, the loss of
lower body fat in HIV-associated lipoatrophy is another reason
why triglycerides are high in HIV infection. Hypertriglyceridemia is well known to be multifactorial; genes, diet, alcohol, and physical activity also play a role. In HIV infection, one can add the synergistic effects of the host response to HIV itself, treatment with ritonavir and efavirenz, and HIV-lipoatrophy to the pathogenesis.

After the introduction of HAART, a reported increase in low-density lipoprotein (LDL) cholesterol levels was largely attributed to PI therapy. Recently, it has become increasingly clear that factors other than PIs contribute to this rise in LDL cholesterol levels. In the early stages of HIV infection, LDL cholesterol levels fall (see Table 25-4). With effective therapy, LDL cholesterol levels rise in response to suppression of the infection, independent of the type of therapy. Most, but not all PIs have been associated with increases in LDL cholesterol levels, but average levels are not high. Studies in healthy normal volunteers have provided insight into the direct effects of PIs on cholesterol metabolism apart from those associated with HIV infection. Indinavir, ritonavir, lopinavir/ritonavir, and atazanavir all have no effects on LDL cholesterol levels in healthy normal volunteers (see Table 25-5). In patients with HIV infection, treatment with the NNRTI nevirapine raises LDL cholesterol levels. Studies that involve switching patients from PIs to the NNRTIs nevirapine and efavirenz found that LDL cholesterol levels do not change. Hence, the increase in LDL cholesterol seen in HIV-infected patients is not solely an effect of PI therapy, but likely represents suppression of HIV and restoration to health. Tenofovir may lower LDL levels.

HIV infection and the NNRTIs have significant effects on high-density lipoprotein (HDL) metabolism. Early in the course of HIV infection, prior to the appearance of clinically evident disease, HDL cholesterol levels decline to levels around 25 to 35 mg/dL (see Table 25-4). With advancing HIV disease, HDL cholesterol levels continue to decline to less than 50% of baseline values. The pathogenesis of these changes is not well understood. Shortly after the introduction of PIs, one cross-sectional study reported decreased HDL cholesterol levels in HIV-infected patients. However, subsequent studies have failed to show a decrease in HDL cholesterol levels in either HIV-infected patients or healthy normal volunteers. Indeed, some studies have found modest increases (13%-21%) in HDL cholesterol levels during treatment with indinavir, nelfinavir, amprenavir, and atazanavir therapy in prospective studies of HIV-infected patients. More impressive is the nearly 50% increase in HDL cholesterol seen during treatment with the NNRTI nevirapine. Efavirenz has also been shown to increase HDL cholesterol levels by 15% to 23%. When patients were switched from PIs to the NNRTIs efavirenz and nevirapine, somewhat smaller increases were seen again supporting the concept that HAART with PI induces small increases in HDL. Hence, the increase in HDL cholesterol levels is likely directly due to NNRTI therapy. In some studies, HDL levels have been reported to be lower in patients with HIV-associated lipodystrophy, but the extent to which that decrease is due to HIV is not clear. Visceral obesity and upper trunk fat are associated with lower HDL levels.

A panel of the IAS-USA has suggested guidelines for the diagnosis and treatment of dyslipidemia in HIV-infected subjects. The National Cholesterol Education Program guidelines are recommended for initiating therapy in patients infected with HIV. To monitor for dyslipidemia, a fasting lipid panel should be obtained before initiating or switching therapy. Lipid panels should be repeated 3 to 6 months after starting ARV therapy. In those patients with preexisting cardiovascular disease (CVD) or uncontrolled hyperlipidemia, switching HIV therapy should be considered if the regimen is one linked to the observed dyslipidemia and it is refractory to conventional treatment.

Hypolipidemic therapy should be tailored to the type of dyslipidemia. For patients with triglyceride levels greater than 500 mg/dL, fibrate therapy is recommended. Studies have shown that gemfibrozil and fenofibrate are effective in reducing triglyceride levels in patients infected with HIV, but those who start at high triglyceride levels do not reach normal levels. Fish oil lowers triglycerides, but raises LDL, leading to no net decrease in CVD risk. Niacin is effective and has the advantage of raising HDL levels as well as lowering triglycerides, but niacin-induced insulin resistance may be problematic in HIV-infected patients. HMG-CoA reductase inhibitors may be better second-line agents for lowering triglycerides. As with HIV-negative patients, combination pharmacologic therapy may be required to correct extremely elevated triglyceride levels.

HMG-CoA reductase inhibitors are effective, first-line agents for the treatment of hypercholesterolemia. However, there are multiple drug-drug interactions that are important in HIV-infected patients. Some statins are metabolized by Cyp3A4 which is induced or inhibited by some ARV drugs. In particular, the combination of PI and simvastatin or lovastatin should not be used. PI, especially ritonavir, which is used to boost levels of many HIV ARV drugs to therapeutic levels, inhibit Cyp3A4 which is the major metabolic pathway for simvastatin and lovastatin. Ritonavir-based regimens increase simvastatin levels by 5- to 32-fold and multiple cases of rhabdomyolysis have been reported on such combinations. Atorvastatin activity increases twofold, so 80 mg atorvastatin should be avoided. Lopinavir/ritonavir increases rosuvastatin levels two- to fivefold, and tipranavir/ritonavir increases rosuvastatin levels twofold and atorvastatin levels eightfold by unknown mechanisms. If those PI combinations are used, only low doses of rosuvastatin (5 mg) and atorvastatin (10 mg) should be tried. Thus, pravastatin and fluvastatin XL are recommended as first-line statins for patients on PI- or ritonavir-based HAART.

The effects of HIV protease inhibitors on glucose and lipid metabolism are shown in Table 25-5.

HIV, Antiretroviral Therapy, and Risk of Atherosclerosis

The changes in lipid and glucose metabolism seen in HIV raise the question about whether atherosclerosis increases due to HIV or its therapies. Retrospective studies report an increased prevalence of CVD in HIV-infected patients. Some studies also found an association with ARV therapy, particularly PI therapy, in addition to
traditional risk factors such as age, gender, smoking, and LDL and HDL cholesterol levels. Smoking is more prevalent in those with HIV infection versus uninfected controls. Cross-sectional studies of the intima media thickness (IMT) of the carotid and femoral arteries by ultrasound have also shown that traditional CVD risk factors provide the dominant contribution to increased plaque. However, after adjusting for traditional CVD risk factors, HIV infection is an independent risk factor for increased IMT, similar in magnitude to male sex, diabetes, and smoking.

**CONCLUSION**

Some of the changes in HIV infection are similar to those seen in other serious illnesses (euhormone-sick syndrome). However, many of the endocrine and metabolic changes that occur with HIV infection are unique to HIV and require careful consideration in diagnosis and treatment. In addition to the HIV disease state itself, several factors contribute to the development of these changes such as opportunistic infections, immune reconstitution, and ARV medications. As patients are living longer due to the introduction of effective ARV therapy, there is increased interest in the long-term implications of metabolic alterations such as insulin resistance, dyslipidemia, and body composition changes. Given the increased atherosclerotic disease in HIV-infected patients, more aggressive treatment of dyslipidemia is warranted.

Endocrine Surgery
Geeta Lal, MD and Orlo H. Clark, MD

INTRODUCTION
Many endocrine diseases are appropriately managed surgically. The details of clinical presentation, diagnosis, and medical management are discussed in other sections of this book. This chapter provides an overview of the principles involved in the surgical therapy for these conditions. The indications for surgical intervention, relevant procedures, and the benefits of these procedures are discussed.

THE THYROID GLAND
EMBRYOLOGY AND ANATOMY

The thyroid gland arises in the midline as an endoderm-derived pharyngeal diverticulum around the third week of gestation. The paired median thyroid anlages then descend from their origin at the base of the tongue (foramen cecum) and ultimately form a bilobed thyroid gland anterolateral to the trachea and larynx. The thyroid lobes are connected just below the cricoid cartilage by an isthmus. The connection to the foramen cecum—the thyroglossal duct—separates and is partially resorbed by the sixth week of gestation. Its distal remnant forms the pyramidal lobe. The calcitonin-producing C cells are neuroectodermal in origin, arise from the fourth branchial pouch, and are located in the superoposterior aspect of the gland.

A number of embryologic or developmental abnormalities of the thyroid have been described and are related to the absence or mutations of thyroid differentiation factors, including thyroid transcription factors 1 and 2 (TTF-1 and TTF-2) and transcription factor Pax 8. Thyroglossal duct cysts are usually found in the midline, just inferior to the hyoid bone. A lingual thyroid results from maldescent of the median thyroid anlage and is often accompanied by agenesis of other thyroid tissue. Rests of thyroid tissue may be found anywhere in the central compartment of the neck, including the anterior mediastinum. Tongues of thyroid tissue are often seen to extend off the lower thyroid poles, particularly in large goiters. In contrast to the above, thyroid tissue in the lateral neck lymph nodes (lateral aberrant thyroid) almost always represents metastatic thyroid cancer and is not a developmental abnormality.

The adult thyroid gland is reddish-brown in color and weighs approximately 20 g. The thyroid gland is supplied by paired superior and inferior thyroid arteries. The former arise from the external carotid artery and the latter from the thyrocervical trunk. A thyroid ima artery arises directly from the aorta or innominate artery in approximately 2% of individuals and enters the isthmus, replacing an absent inferior artery.
The thyroid is drained by three sets of veins: the superior, middle, and inferior thyroid veins. The first two drain into the internal jugular vein, whereas the last drains into the innominate veins. Both recurrent laryngeal nerves arise from their respective vagus nerves and enter the larynx at the level of the cricothyroid articulation, posterior to the cricothyroid muscle. The left recurrent laryngeal nerve recurs around the subclavian artery and runs 1 to 2 cm lateral to the tracheoesophageal groove at the level of the clavicle and courses obliquely to the larynx. The superior laryngeal nerves also arise from corresponding vagus nerves and divide into internal and external branches. The former provides sensation to the larynx and the latter innervates the cricothyroid muscles. A description of parathyroid embryology and anatomy is presented in the next section.

Prior to discussing indications for thyroidectomy, it is prudent to clarify the definitions of various thyroid resections. A description of these terms is presented in Table 26–1. Of note, nodulectomies are rarely performed, and most surgeons agree that thyroid lobectomy constitutes a minimum resection.

### Indications for Surgery

#### DEVELOPMENTAL THYROID ABNORMALITIES

Thygoglossal duct remnants may become symptomatic, forming cysts, abscesses, and fistulae. There is also a 1% risk of thyroid cancer development in thyroglossal duct cysts. Most are papillary carcinomas, but very rarely a squamous cell carcinoma may develop. Medullary thyroid cancers do not occur at this site.

Treatment of thyroglossal duct remnants consists of the Sistrunk procedure, which involves removal of the cyst and duct up to the foramen cecum. Because the duct may pass anterior to, posterior to, or through the hyoid bone, it is generally recommended that the midsection of this bone is also resected in order to reduce the risk of recurrence. Surgery may also be needed for enlarged lingual thyroid tissue causing symptoms such as choking, dysphagia, airway obstruction, and hemorrhage. Prior to resection, care must be taken to determine whether the patient has any other functioning thyroid tissue, usually via a thyroid scan or ultrasound.

#### HYPERTHYROIDISM

Hyperthyroidism may result from increased thyroid hormone production or release of stored thyroid hormone following injury to the thyroid gland such as that seen in subacute thyroiditis. This is an important distinction, because the former group of disorders leads to increased RAIU, whereas the latter are associated with low or normal RAIU. The most common causes of hyperthyroidism are diffuse toxic goiter (Graves disease), toxic multinodular goiter (Plummer disease), or a single toxic nodule, all of which cause increased RAIU. Rarer causes of hyperthyroidism with increased radioactive iodine uptake (RAIU) include a TSH–secreting tumor and a hydatidiform mole. Causes of hyperthyroidism without increased RAIU include subacute thyroiditis, excessive ingestion of medicinal thyroid hormone, struma ovarii, and thyroid hormone–secreting metastatic thyroid cancer. These latter conditions present with the usual symptoms and signs of hyperthyroidism but lack the extrathyroidal manifestations of Graves disease such as ophthalmopathy, pretibial myxedema, and thyroid acropachy.

#### Diagnostic Tests

Hyperthyroidism is characterized by a suppressed TSH in the presence of elevated free T4 levels. If free T4 is normal, free T3 levels should be measured because they are often elevated early in the course of disease. RAIU can be used to distinguish the various causes of hyperthyroidism. Approximately 90% of patients with Graves disease have elevated levels of thyroid-stimulating antibodies or immunoglobulins (thyroid-stimulating immunoglobulin).

#### Management of Hyperthyroidism

Hyperthyroidism may be treated medically with antithyroid medications, but relapse is common when the medical treatment is discontinued. Ablation of the thyroid gland with RAI is the mainstay of treatment in North America for patients over 30 years of age. A dose of 8 to 12 mCi of I-131 taken orally is generally required. However, it is associated with a prolonged latency period before effective action, a slightly increased risk of future benign and malignant thyroid tumors, hyperparathyroidism, worsening ophthalmopathy (particularly in smokers), and unavoidable hyperthyroidism (3% per year after the first year, independently of dosage). Furthermore, only about 50% of patients treated with RAI are euthyroid at 6 months. It is contraindicated in pregnant women, of concern in children, and should be avoided in women wishing to become pregnant for up to 1 year after treatment.
Surgery overcomes many of the problems associated with RAI and achieves rapid control of hyperthyroidism with minimal side effects in experienced hands.

Absolute indications for thyroidectomy in patients with Graves disease include biopsy-proven suspicious or cancerous nodules, local compressive symptoms, severe reactions to antithyroid medications, reluctance to undergo RAI ablation, or fear of recurrence after RAI. Women who want to become pregnant after treatment or who develop side effects from antithyroid drugs during pregnancy are also candidates for thyroidectomy, as are children. Relative indications for thyroidectomy include patients in whom rapid control of the disease is desired; poorly compliant patients; and patients with severe ophthalmopathy, very large goiters, or low RAIU.

**Preoperative Preparation**

Patients are usually treated with antithyroid medications to render them euthyroid and to prevent the risk of thyroid storm. Propylthiouracil (100-200 mg 3 times daily) or methimazole (10-20 mg twice daily and then once daily) are the most commonly used medications and are continued up to the day of surgery. In patients who develop agranulocytosis as a complication of these medications, surgery should be deferred until granulocyte counts reach 1000 cells/μL. In addition, patients are also often treated with propranolol (10-40 mg 4 times daily) to control the adrenergic effects of hyperthyroidism. Relatively large doses may be necessary because of increased catabolism of the drug. Lugol solution (iodine and potassium iodide) or saturated solution of potassium iodide is also generally started about 10 days preoperatively to reduce the vascularity of the gland and decrease the risk of precipitating thyroid storm.

**Extent of Surgery**

The extent of surgery is controversial and depends on multiple factors. For those patients who have experienced severe complications with antithyroid drugs, those who want to eliminate the risk of recurrence, and those with coexistent carcinoma or severe ophthalmopathy, total or near-total thyroidectomy is recommended. However, total thyroidectomy results in inevitable hypothyroidism and is potentially associated with higher complication rates when compared to lesser procedures. Thus, the procedure traditionally preferred by most surgeons for treating patients with Graves disease is a subtotal thyroidectomy. This may be accomplished safely by bilateral subtotal excision or by unilateral lobectomy and isthmusectomy with subtotal contralateral resection (Hardy-Dunhill procedure). Provided an adequate remnant is left behind, the procedure provides rapid relief of thyrotoxicosis while maintaining a euthyroid state without the need for thyroid hormone. However, it is difficult to define what constitutes an adequate remnant, although most surgeons consider a 4- to 7-g remnant sufficient in adults. Rates of postoperative hypothyroidism are variable and are primarily determined by remnant size, thyroid antibody titer, and whether hypothyroidism was reported to be subclinical or overt. Remnants <4 g are associated with a >50% risk of hypothyroidism, and those >8 g are associated with recurrence rates of 15%. Subtotal resections are associated with recurrence rates of 1.2% to 16.2%, and recurrence may take place many years after thyroidectomy. Therefore, many surgeons now consider avoidance of recurrence, rather than attainment of euthyroidism, as the goal for thyroidectomy in Graves disease. This is gradually leading to total or near-total thyroidectomy becoming the preferred operation for these patients. Patients who experience recurrence after surgery are usually treated with RAI. Patients with hyperthyroidism secondary to toxic multinodular goiter are managed similar to those with Graves disease. Subtotal thyroidectomy is generally advised, however, if no normal remnant can be left, a near-total or total thyroidectomy is recommended. Patients with a solitary toxic nodule >3 cm in size are best treated by ipsilateral lobectomy. Patients with smaller hot nodules may be managed by tumor enucleation or RAI ablation.

**THYROIDITIS**

Thyroiditis, an inflammatory disorder of the thyroid gland, may be classified as acute, subacute, or chronic. Acute suppurrative thyroiditis is diagnosed by fine-needle aspiration for cytology, smear, Gram stain, and culture and treated by incision and drainage and antibiotics. Acute thyroiditis is usually self-limited. Thyroidectomy, however, is occasionally needed for clinically coexistent suspicious nodules or cancer, local compressive symptoms, or persistent infection. Recurrent acute thyroiditis is often due to a persistent pyriform sinus fistula. Resection of the entire tract is necessary to prevent recurrence. Subacute and chronic thyroiditis is usually managed medically, but surgical resection is occasionally needed for local symptoms or relapse.

**GOITER (NONTOXIC)**

Goiters may be diffuse, uninnodular, or multinodular. Thyroidectomy is indicated for goiters enlarging despite thyroxine suppression, those causing compressive symptoms (chokein, dysphagia, hoarseness, dyspnea, or a positive Pemberton sign—dilation of neck veins and facial erythema on elevation of arms), nodules deemed suspicious by ultrasound, and goiters containing biopsy-proven suspicious or cancerous nodules. Goiters with a significant substernal component (>50%) are considered a relative indication for thyroidectomy. Subtotal thyroidectomy is the preferred treatment for multinodular goiters. A total lobectomy is performed on the side with the dominant nodule, and a subtotal thyroidectomy is performed on the other. A total or near-total thyroidectomy may be performed if there is no normal thyroid tissue present.

**THYROID NODULES**

Approximately 4% of the North American population develops thyroid nodules. However, the incidence of clinical thyroid cancer is much lower (about 40 patients per million), thus making it imperative to determine which nodules require treatment with thyroidectomy. A thyroid nodule is more likely to be malignant if
the patient has a history of therapeutic radiation to the head and neck (6.5-3000 cGy to the thyroid), a family history of thyroid cancer, Cowden syndrome, or MEN 2, and a personal history of thyroid cancer. Other features suggesting cancer include male sex, young (<20) or old (>70) age; a solitary, cold solid (or mixed solid-cystic), hard nodule, a nodule with microcalcifications or irregular edges on ultrasonography; the presence of ipsilateral palpable nodes or vocal cord palsy; and a fine-needle aspiration biopsy (FNAB) suspicious for cancer. Approximately 40% of individuals with a history of therapeutic radiation exposure or a family history of thyroid cancer have a thyroid cancer. The cancer is in the index nodule in 60% and in other nodules in 40% of patients.

**Diagnostic Tests**

Patients with thyroid nodules should be evaluated with TSH measurement and FNAB. If the biopsy suggests a follicular neoplasm, and the TSH level is suppressed or is in the low-normal range, an RAI scan should be performed to rule out a hot nodule.

**Management**

Nodules with any of the worrisome features mentioned above should be removed with—at minimum—an ipsilateral lobectomy and isthmusectomy. If FNAB confirms a malignancy, the patients should undergo thyroidectomy. Patients with benign nodules on FNAB may be treated with exogenous thyroxine. Nodules that continue to enlarge during follow-up may be re-biopsied or removed via a thyroidectomy.

**THYROID CANCER**

Malignant thyroid tumors include differentiated lesions (which arise from follicular cells); MTC; undifferentiated or anaplastic cancers; and other rare tumors such as lymphomas, squamous cell carcinomas, sarcomas, teratomas, plasmacytomas, paragangliomas, and metastatic thyroid cancers (from melanoma or from breast, kidney, lung, and other head and neck tumors).

**1. DIFFERENTIATED THYROID CANCER**

This group includes papillary, follicular variant of papillary, follicular, and Hürthle cell tumors. Hürthle cell carcinoma has been considered a subtype of follicular carcinoma by some investigators and a unique differentiated thyroid cancer of follicular cell origin by others.

The characteristics of these tumors are depicted in Table 26–2. The biologic behavior of the follicular variant of papillary thyroid cancer is similar to that of papillary carcinoma. In follicular and Hürthle cell tumors, the diagnosis of malignancy can only be made by the presence of capsular, blood vessel, or lymphatic invasion or when lymph node or distant metastases are present. Familial non-MTCs, especially if there is a family history of more than two affected relatives, have been shown to be more aggressive than their sporadic counterparts.

**Surgical Treatment**

Occult or minimal papillary carcinomas (<1 cm) have an excellent prognosis and are adequately treated by lobectomy. Lobectomy alone is also considered sufficient treatment for low-risk, unifocal, intrathyroidal cancers in the absence of a history of head and neck irradiation or a family history of thyroid cancer or cervical node metastases. Patients with high-risk cancers (determined by AGES, AMES, or TNM classification; Tables 26–3, 26–4, and 26–5) or bilateral cancers are best treated by total or near-total thyroidectomy. Considerable debate has existed regarding optimal treatment for low-risk differentiated thyroid cancer >1 cm.

Proponents of total thyroidectomy argued that this procedure is advantageous for several reasons: (1) RAI can be used to diagnose and treat recurrent or metastatic disease, (2) serum thyroglobulin becomes a sensitive indicator of recurrent disease, (3) the procedure eliminates the risk of growth of occult cancer in the contralateral lobe and reduces the risk of recurrence, (4) it decreases the 1% risk of progression to undifferentiated cancer, and (5) it decreases the risk of reoperation in case of central neck recurrence. On the other hand, those favoring thyroid lobectomy noted that (1) total thyroidectomy is associated with a higher complication rate and that 50% of local recurrences can be cured with surgery, (2) <5% of recurrences occur in the thyroid bed.

</tbody>
</table>

It is not usually possible to distinguish follicular and Hürthle cell carcinomas from corresponding adenomas preoperatively. If there are no obvious signs of cancer at surgery (lymphadenopathy or extrathyroidal invasion), a lobectomy is performed, because more than 80% of these tumors are benign. If final pathology confirms cancer, a completion thyroidectomy is usually recommended, except in those patients with minimally invasive tumors. Total or near-total thyroidectomy may be performed at the initial operation in individuals with large (>4 cm) tumors, particularly if nodules are present bilaterally. Total or near-total thyroidectomy is also recommended if marked atypia is seen on FNA, if it is read as suspicious for papillary carcinoma or the patient has a family history of thyroid cancer or a personal history of head and neck irradiation.

### Postoperative Treatment

Long-term cohort studies by Mazzaferri and Jhiang and others demonstrate that postoperative RAI therapy reduces recurrence rates and leads to improved survival even in patients with low-risk tumors. Several features place patients at increased risk for local recurrences or metastases. These high-risk features include certain histologic subtypes (such as tall cell, columnar, insular, solid variant, and poorly differentiated thyroid cancer), presence of intrathyroidal vascular invasion, or gross or microscopic multifocal disease. According to recently published guidelines from the American Thyroid Association, RAI is currently recommended for patients with known distant metastases, gross extrathyroidal extension of tumor (regardless of size) or tumors >4 cm even in the absence of other high-risk features. Ablation is also recommended for selected patients with 1 to 4 cm tumors with lymph node metastases or other high-risk features. In contrast, RAI is not recommended for patients with unifocal cancers <1 cm in diameter or patients with multifocal tumors (all <1 cm) without additional high-risk features. Thyroxine therapy is not only important as replacement but is given in higher doses to suppress TSH levels (to 0.1 μU/L in low-risk patients and <0.1 μU/L in high-risk patients), thus decreasing the growth stimulus for thyroid cancer cells. The need for TSH suppression must be balanced with the risks of subclinical thyrotoxicosis, such as exacerbation of angina in patients with ischemic heart disease, increased risk for atrial fibrillation, and osteoporosis in postmenopausal women.

### 2. MEDULLARY THYROID CANCER

This tumor comprises 7% of thyroid malignancies but accounts for approximately 17% of thyroid cancer–related deaths. It arises from the parafollicular (C cells) of the thyroid, which are derived from the neural crest and secrete calcitonin. MTC may be sporadic (75%) or occur in the setting of MEN 2A, MEN 2B, and familial non-MEN MTC. In the hereditary setting, the tumors are often bilateral and multicentric (90%). Approximately 50% of patients with MTC have nodal metastases in the central or lateral neck at presentation. All patients presenting with MTC should be screened for pheochromocytomas, hyperparathyroidism, and mutations of the \( RET \) proto-oncogene.

(3) multicentricity within the thyroid is not clinically significant, and (4) the prognosis is excellent in patients with low-risk tumors undergoing lobectomy.

Retrospective data indicate that the recurrence rate for patients with low-risk differentiated thyroid cancer is 10% and that the overall mortality rate is approximately 4% at 10 to 20 years. However, among patients who have recurrences, 33% to 50% die from thyroid cancer. Recent studies involving >50,000 patients with low-risk differentiated thyroid cancer demonstrated that total thyroidectomy is associated with improved recurrence and survival rates even in patients with low-risk tumors. Furthermore, the most important information regarding risk for recurrence is available only postoperatively. Revised guidelines from the American Thyroid Association also recommend near-total or total thyroidectomy for thyroid cancers >1 cm unless there are contraindications to this procedure.

3. UNDIFFERENTIATED (ANAPLASTIC) THYROID CANCER

This tumor type constitutes approximately 1% of all thyroid cancers and is the most aggressive variant. The peak incidence is in the seventh decade of life. Lymph node involvement is early and common (84%), as is local invasion into the larynx, vocal cords, recurrent laryngeal nerve, esophagus, and major vessels. Distant metastases are present in about 75% of patients. The role of surgery is usually limited to palliation of obstruction by tumor debulking and tracheostomy. In patients without advanced disease, total or near-total thyroidectomy can be performed for cure in a minority of cases. External beam radiation and chemotherapy are usually recommended.

4. THYROID LYMPHOMA AND METASTASES

Most thyroid lymphomas are of the non-Hodgkin B cell type and often develop in patients with long-standing chronic lymphocytic thyroiditis. Chemotherapy and radiotherapy form the mainstay of treatment, with thyroidectomy and node dissection reserved for palliation of airway obstruction or in patients who do not respond to the above therapies. The thyroid gland is a rare site of metastases from tumors of the kidney, lung, breast, and melanoma. In selected patients, thyroidectomy may increase survival.

5. MANAGEMENT OF LYMPH NODES IN THYROID CANCER

Clinically inapparent lymph node metastases may be present in 20% to 90% of papillary thyroid cancers, and a smaller proportion of patients with other tumor subtypes. Several retrospective studies have suggested that lymph node metastases do not have a significant effect on survival in papillary thyroid cancers. Others report that lymph node metastases are associated with poorer survival but only in patients with follicular cancers and papillary cancer >45 years of age. In patients with matted nodes or extranodal invasion, the recurrence rates are higher and the prognosis is worse.

The lymph node regions of the neck are depicted in Figure 26–1. A preoperative neck ultrasound is recommended for patients with malignant findings on FNAB to evaluate the contralateral lobe and lymph node regions. All clinically apparent disease in the central neck should be removed at the time of total thyroidectomy to improve clearance of disease from the central neck. Bilateral central node dissection (level VI) may also improve survival compared to historic controls and decrease the risk of central neck recurrence. Other studies, however, show that central neck dissections are associated with a higher risk of hypoparathyroidism and recurrent nerve injury rates without any reduction in recurrence rates. Given the above, recently published guidelines do not recommend routine prophylactic lymph node dissections but indicate that they may be performed in patients with advanced primary tumors (T3 or T4). Prophylactic central neck clearance should also be considered for Hurthle cell cancers which tend to be less RAI-responsive, provided they can be performed by experienced surgeons without increased rates of hypoparathyroidism and recurrent nerve injury.

Papillary and Hurthle cell cancers can also metastasize to lymph nodes in the lateral and posterior compartments (II, III, IV, and V). In patients with biopsy-proven nodal involvement, either clinically or on preoperative ultrasound examination, an ipsilateral modified radical neck dissection is recommended, particularly if these patients may fail RAI therapy based on lymph node number, size, or aggressive primary tumor histology. This procedure removes all the fibrofatty and lymph node tissue while preserving the internal jugular vein, the spinal accessory nerve, the cervical sensory nerves, and the sternocleidomastoid muscle and may reduce the risk of recurrence and subsequent mortality. Because thyroid cancers rarely metastasize to compartment I, these nodes are not routinely removed during a modified radical neck dissection.

In case of MTC, prophylactic central neck lymph node clearance is recommended because these tumors have a worse prognosis and do not take up RAI. The role of prophylactic lateral neck dissection is controversial. Ipsilateral node removal is recommended for MTCs over 1 cm in diameter (or a palpable tumor) and when the central neck nodes are involved with cancer. If ipsilateral nodes are involved, a contralateral neck dissection will also be needed. Therapeutic modified radical neck dissection is indicated for biopsy-proven metastatic disease in clinically involved nodes or those deemed suspicious by imaging.

6. RECURRENT AND METASTATIC THYROID CANCER

Thyroglobulin levels are generally undetectable in patients following total thyroidectomy and RAI ablation. Thyroglobulin levels >2 ng/mL in the absence of thyroglobulin antibodies indicates recurrent or persistent disease. These patients should be imaged with neck ultrasound, CT, or MRI. In general, surgical extirpation is recommended for patients with macronodular disease (>1 cm in diameter), followed by RAI therapy and TSH suppression. Thyroid cancers may metastasize to the lungs, bone, liver, and brain. Microscopic lung metastases in patients with papillary and follicular thyroid cancer are best treated with RAI and macroscopic disease surgically. External beam radiation is useful for unresectable, locally invasive or recurrent disease and to treat bony metastases with minimal to no RAI uptake.
CONDUCT OF THYROIDECTOMY

A 4- to 5-cm incision is placed in or parallel to a natural skin crease 1 cm below the cricoid cartilage (Figure 26-2A). The subcutaneous tissue and platysma are divided, subplatysmal flaps are raised (Figure 26-2B), and the strap muscles are separated in the midline from the thyroid cartilage to the suprasternal notch. Initial dissection is begun in the midline by identification of delphian nodes and the pyramidal lobe, followed by division of the fascia just cephalad to the isthmus. The trachea is then cleared just caudal to the isthmus. The thyrothymic ligaments and the inferior thyroid veins are ligated and divided. The side with the dominant or suspicious mass is approached first. In case of a proposed lobectomy or the absence of cancer, the isthmus is divided. Tissues are swept lateral to the thyroid by blunt dissection, and the middle thyroid veins are ligated and divided (Figure 26-2C). The superior pole vessels are then individually ligated and divided low on the thyroid gland to decrease the risk of injury to the external branch of the superior laryngeal nerve (Figure 26-2D). The recurrent laryngeal nerve and the superior parathyroid gland are identified at the level of the cricoid cartilage. Once this is accomplished, the ligament of Berry is divided (Figure 26-2E), and the thyroid is sharply dissected off the trachea. The same procedure is repeated on the other side for a total thyroidectomy.

Several approaches to minimally invasive thyroidectomy such as mini-incision procedures, video-assisted thyroidectomy and total endoscopic thyroidectomy via supraclavicular, axillary incisions, chest and breast approaches have been described (Figure 26-3). These methods are clearly feasible; however, they do require further study to determine their advantages over the more traditional open approach.

Complications of Thyroidectomy

General complications after thyroid surgery include bleeding and wound complications such as infection and keloid formation. Specific complications include injury to the recurrent laryngeal nerve (<1%), or external branch of the superior laryngeal nerve,

Endoscopic thyroidectomy: supraclavicular approach and Takami HE, Ikeda Y. Endoscopic thyroidectomy via an axillary or anterior chest approach. In: Gagner M, Inabnet WB, eds. Minimally Invasive Endocrine Surgery. Lippincott, Williams and Wilkins; 2002).

temporary hypocalcemia (1.6%-15%), permanent hypocalcemia (<2% for total thyroidectomy), and injury to surrounding structures such as the esophagus, major vessels (carotid artery, internal jugular vein), and the cervical sympathetic trunk.

THE PARATHYROID GLAND

EMBRYOLOGY AND ANATOMY

Around the fourth week of gestation, the human embryo forms five pairs of endoderm-lined pharyngeal pouches. The inferior parathyroid glands are derived from the third branchial pouch (with the thymus), whereas the superior glands arise from the fourth branchial pouch. Most individuals have four parathyroid glands that are found as paired structures on the posterior aspect of the thyroid gland. Supernumerary glands occur in up to 22% of people. Fewer than four glands have also been reported in 3% to 5% of individuals. Approximately 85% of parathyroid glands are found within 1 cm of the point of intersection of the recurrent laryngeal nerve and the inferior thyroid artery. The superior parathyroid glands are usually dorsal to the nerve, whereas the inferior glands are usually ventral to it. The glands may also be found in several ectopic locations. Because the inferior glands migrate farther, they are more often situated in ectopic locations than the thyrothymic ligament, thymus, carotid sheath, and anterior mediastinum. Ectopically located superior glands can be located in the tracheoesophageal groove, carotid sheath, and posterior mediastinum. Intrathyroidal glands have been reported in 0.5% to 3% of individuals and may be superior or inferior. Normal parathyroid glands are generally embedded in fat, appear golden-yellow to light-brown in color, and weigh approximately 40 to 50 mg. The blood supply to the parathyroid glands is primarily via the inferior thyroid arteries, but the superior thyroid arteries may also supply both the upper and the lower glands.

Indications for Surgery

PRIMARY HYPERPARATHYROIDISM

This disorder occurs in 1:500 women and 1:2000 men. It is the most common cause of hypercalcemia in the outpatient population, and along with malignancy-associated hypercalcemia accounts for the majority (>90%) of cases of hypercalcemia. Although most cases of PHPT are sporadic, the disorder may also be inherited as a component of MEN 1, MEN 2A, isolated familial hyperparathyroidism, and familial hyperparathyroidism with jaw tumor syndrome. PHPT is the earliest and most common manifestation of MEN 1, and 80% to 100% of patients develop hypercalcemia by age 40. MEN 1 is characterized by germline mutations in the MENIN gene located on chromosome 11. In contrast, hyperparathyroidism develops in only 20% of individuals with MEN 2A and is generally less severe. MEN 2A is characterized by inherited mutations in the RET proto-oncogene located on chromosome 10.

In sporadic cases, hyperparathyroidism results from a single enlarged gland (adenoma) in 85%, multiple enlarged glands (hyperplasia) in 11%, double adenomas in 3%, and parathyroid carcinoma in 1% of patients. Parathyroid carcinoma should be suspected if patients present with a short history, profound hypercalcemia, and a palpable parathyroid gland. In heritable disorders, hyperparathyroidism is more frequently associated with multiple abnormal parathyroid glands and a higher risk of persistent or recurrent disease. Familial hyperparathyroidism with jaw tumor syndrome is associated with an increased risk of parathyroid cancer and results from germline mutations in the HRPT2 tumor suppressor gene on chromosome 1.

The classic symptoms of PHPT include painful bones, renal stones, abdominal groans, psychic moans, and fatigue overtones. Other symptoms such as polyuria, nocturia, polydipsia, constipation, and musculoskeletal aches and pains may be present. The disorder may also be associated with hypertension, osteopenia,
osteoporosis, nephrolithiasis, gout, pseudogout, peptic ulcer disease, and pancreatitis.

**Diagnostic Tests**

Other causes of hypercalcemia can generally be excluded by a careful history and physical examination. Laboratory tests that are helpful in making the diagnosis have been discussed in Chapter 8. PHPT is characterized by hypercalcemia (95%), hypophosphatemia (50%), hyperchloremia (30%), serum chloride to phosphate ratio ≥33 (95%), elevated 24-hour urinary calcium, and an increased or inappropriately elevated intact PTH. An elevated alkaline phosphatase level suggests bone disease (osteitis fibrosa cystica). The 24-hour urinary calcium levels may be normal or elevated. Usually, 24-hour urinary studies are obtained unless the patient has previously had documented normocalcemia, to rule out FBHH, a disorder caused by inherited mutations in the CASR gene and characterized by low (often <50 mg) 24-hour urinary calcium excretion. Furthermore, the serum calcium to creatinine clearance ratio is <0.01 in patients with FBHH and generally >0.02 in patients with PHPT (see Chapter 8).

Parathyroid tumors may be localized using noninvasive studies such as Tc-99m sestamibi (Figure 26-4A) and ultrasound scanning (Figure 26-4B). MRI and CT scans and invasive localizing studies, including highly selective venous catheterization for PTH, and FNAB of suspected parathyroid masses and arteriograms are generally only used in cases of recurrent or persistent hyperparathyroidism. The utility of noninvasive studies prior to initial neck exploration is controversial; however, most surgeons agree that they are dispensable for recurrent or persistent hyperparathyroidism and for using a minimally invasive approach. 99m-Tc Technetium-labeled sestamibi has more than 80% sensitivity for the detection of hypercellular parathyroid glands, and when it is used in conjunction with SPECT, it has particular utility in identifying ectopic tumors. Neck ultrasound is often complementary and has a sensitivity of 75% in experienced centers. More recently, 4-D CT scans have shown tremendous utility in localizing parathyroid tumors with excellent anatomic detail, in addition to providing functional information. It is important to note that most localizing studies are less sensitive in the setting of multinodular disease. Since the first use of intraoperative PTH in 1993, it has become widely used to assess the adequacy of parathyroid resection. Although preoperative localization studies and a focused surgical approach are being increasingly used, long-term outcome and cost-effectiveness studies will be necessary before recommending their routine use. However, they should be obtained if a focused parathyroidectomy is planned.

**Surgical Management**

**A. Rationale and guidelines for parathyroidectomy**

Patients with classic symptoms and metabolic complications related to PHPT are generally treated by parathyroidectomy. Whether asymptomatic patients should undergo parathyroidectomy is controversial. One aspect of the controversy is the fact that there is no consensus on what constitutes an asymptomatic patient. At the 1990 NIH Consensus Conference, asymptomatic PHPT was defined as, "the absence of common symptoms and signs of PHPT, including no bone, renal, gastrointestinal or neuromuscular disorders." Nonoperative management was recommended in this group of patients with calcium levels ≤12 mg/dL, based on several observational studies that suggested stability with respect to serum calcium, kidney stones, bone loss, and renal function with time. Parathyroidectomy was recommended for asymptomatic patients <50 years of age and in certain other patients, as outlined in Table 26-6.

**FIGURE 26-4** Parathyroid localization studies. **A.** Sestamibi scan with early (5-10 minute) and delayed (60-90 minute) images showing persistent uptake inferior to the right thyroid lobe (black arrow), suggesting a hypercellular parathyroid gland in this location. **B.** Neck ultrasound (longitudinal view). **C.** Neck ultrasound (transverse view) also showing a probable right inferior parathyroid adenoma (white arrow), which is hypoechoic compared to thyroid tissue.
A second NIH Conference was held in 2002 to reevaluate the criteria for parathyroidectomy in asymptomatic patients. The guidelines issued were similar to the previous recommendations except for the following changes. Parathyroidectomy was recommended in the following cases: for milder elevations in serum calcium (ie, if the serum calcium was 1 mg/dL above reported normal range) and if the bone mineral density at any site (forearm, spine, or hip) was more than 2.5 standard deviations below that of gender-matched peak bone mineral density (T score, rather than Z score of <-2.5). The panel recommended caution in using neuropsychological abnormalities, cardiovascular disease, menopause, gastrointestinal symptoms, and serum or urine indices of increased bone turnover as sole indications for parathyroidectomy. These recommendations were revised again in 2008, with elevated urinary calcium excretion (in the absence of nephrolithiasis) no longer being a criterion for surgery. Recommendations from all these conferences are summarized in Table 26-6. It is critical to emphasize that the level of evidence supporting the recommendations is not that of randomized controlled trials.

B. Conduct of parathyroidectomy

Issues to consider before deciding on the optimal treatment approach are whether one is dealing with sporadic or familial disease and whether it is the initial operation or reexploration. The presence of concurrent thyroid pathology needing surgical treatment must also be considered. The positioning, incision, and dissection are as described previously for thyroidectomy. A bloodless field is crucial to enable identification of parathyroid glands. The middle thyroid veins are ligated and divided to allow medial retraction of the thyroid lobe. The space between the carotid sheath and thyroid is then opened by sharp and blunt dissection, from the level of the cricoid to the thyromental space. Most parathyroid glands are found within 1 cm of the junction of the nerve and inferior thyroid artery—the superior glands lie dorsal and the lower glands more ventral or anterior to the nerve. Because parathyroid glands are often embedded in fat, any fat lobule at typical parathyroid locations should be explored.

C. Bilateral versus unilateral approach

Traditionally, all four parathyroid glands have been explored without preoperative localizing studies, with a 95% success rate in the hands of an experienced surgeon. Investigators in favor of unilateral exploration have suggested decreased recurrent laryngeal nerve injury, less postoperative hypocalcemia, shorter operative time, and early discharge as advantages of this approach. Potential disadvantages of unilateral exploration include the risk of missing multiple abnormal or ectopic parathyroid glands.

More surgeons today are using a unilateral or focal approach directed by localizing studies with or without intraoperative gamma probe or intraoperative PTH measurements. We have found that when two localizing studies—Tc-99m sestamibi and ultrasound—identify the same solitary parathyroid gland in patients with sporadic PHPT, this was the only abnormal parathyroid gland in 95% of patients. In patients with sporadic PHPT and positive preoperative localization studies, our current approach is to recommend focused parathyroidectomy via a 2.5-cm incision with intraoperative PTH measurement. If the PTH level falls more than 50% within 10 minutes after removal of an abnormal parathyroid gland, the procedure is terminated. If the level does

not fall, a PTH measurement is repeated in another 10 minutes, because it may fall slowly in some patients. A bilateral approach is needed in patients with known familial disease, with negative or equivocal localization tests, with secondary or tertiary HPT, or a history of lithium treatment. If parathyroid cancer is suspected intraoperatively, it is resected with the ipsilateral thyroid lobe and regional lymph nodes.

**D. Subtotal parathyroidectomy versus total parathyroidectomy with autotransplantation**  
Either subtotal (generally resection of 3½ glands) or total parathyroidectomy with primary parathyroid autotransplantation may be performed in patients with multiglandular disease. In the latter technique, 12 to 20 small fragments (1 × 1 mm) of parathyroid tissue are placed into multiple pockets in the forearm muscle of the nondominant arm. The site is marked with silk sutures and is easily accessible under local anesthesia should the patient develop recurrent hypercalcemia. The recurrence rates for hyperparathyroidism appear to be similar after subtotal or total parathyroidectomy. However, a 5% failure rate has been reported after autotransplantation of parathyroid tissue. Therefore, subtotal parathyroidectomy is preferred. The most normal gland is biopsied first, leaving a 50-mg remnant (the size of a normal parathyroid gland); if it appears viable, the remaining glands are excised. Patients undergoing either of these procedures should have tissue cryopreserved, if possible. Parathyroid glands should not be routinely biopsied at exploration but rather biopsy should be used to confirm parathyroid tissue or help determine if the gland is normal or abnormal. As with thyroid surgery, video-assisted and endoscopic axillary approaches are feasible, but clear benefits compared with the open approach await long-term multicenter studies.

**PERSISTENT AND RECURRENT PRIMARY HYPERPARATHYROIDISM**

Persistent hypercalcemia occurs after about 5% to 10% of explorations. Recurrent hypercalcemia is rare except in patients with familial disease and occurs after an intervening period (>6 months) of normocalcemia. The most common reasons for persistent or recurrent hyperparathyroidism are a missed gland in normal or ectopic location, unrecognized hyperplasia, supernumerary glands, subtotal tumor resection, parathyroid carcinoma, or parathyromatosis (usually due to implantation of cells due to spillage at the initial procedure). The most common sites of ectopic glands in patients with recurrent or persistent PHPT (Figure 26-5) are paraeosophageal (28%), mediastinal (26%), intrathymic (24%), intrathyroidal (11%), carotid sheath (9%), and undescended (high cervical 2%). The management of these patients involves confirmation of the diagnosis—in particular, exclusion of FBHH; review of original operative notes and pathology reports; and localization studies, which are absolutely essential in this group of patients. Preoperative evaluation of the vocal cords is routinely performed. The issue of reexploration in mildly symptomatic patients is controversial. The neck is usually reexplored first, and median sternotomy may be needed in 1% to 2% of patients. Cryopreservation should be performed routinely and autotransplantation selectively. Reexploration by an experienced surgeon is successful in more than 90% of patients, but reoperative parathyroidectomy is generally associated with more complications than an initial operation.

**SECONDARY HYPERPARATHYROIDISM**

This disorder occurs most often in individuals with end-stage renal failure but may also occur in other conditions resulting in hypocalcemia, such as vitamin D deficiency, idiopathic hypercalcemia, and long-term lithium therapy.

Indications for surgery include serum calcium and phosphate product more than 70, renal osteodystrophy with or without bone pain, severe pruritus, ectopic soft tissue calcifications and tumor calcinosis, serum calcium >11 mg/dL with markedly elevated PTH, and calciphylaxis.

These patients should undergo dialysis the day prior to surgery to correct electrolyte (specifically potassium) abnormalities. Patients with this disorder require bilateral exploration and either subtotal parathyroidectomy, leaving a 50 to 60 mg histologically confirmed, well-vascularized remnant of hyperplastic parathyroid distant from the recurrent laryngeal nerve, or total parathyroidectomy with autotransplantation of a similar amount of tissue.
Upper thymectomy is usually performed in these patients, because up to 15% of patients have a fifth hyperplastic gland.

SPECIAL CONSIDERATION: FAMILIAL HYPERPARATHYROIDISM

Patients from MEN 1 families should have PHPT treated before coexisting gastrinoma. All glands should be identified, ectopic glands should be sought in the neck and upper mediastinum, and bilateral cervical thymectomy should be routinely performed due to the occurrence of thymic carcinoids. A subtotal parathyroidectomy (preferred by authors) or total parathyroidectomy, as described above, can be performed. MEN 2A patients should undergo screening for the presence of a pheochromocytoma and RET mutation prior to thyroid or parathyroid surgery. Because the parathyroids are at risk during thyroidec­tomy and central neck node dissection, and hyperparathyroidism is less virulent in these patients, only obviously enlarged glands should be removed. Normal-appearing glands should be marked and removed abnormal parathyroid tissue cryopreserved.

COMPLICATIONS OF PARATHYROID SURGERY

General complications are similar to those associated with thyroidectomy. Specific complications include recurrent laryngeal nerve injury, hypomagnesemia, and hypocalcemia. The latter may arise due to suppressed function of the remaining glands after removal of an adenoma; injury to the parathyroid remnant; or bone hunger, which is the influx of calcium and phosphorus into metabolically active bones. Bone hunger can be predicted based on the severity of bone disease and the preoperative alkaline phosphatase level and is generally more severe in individuals with secondary hyperparathyroidism. Hypocalcemia can be treated with oral calcium and vitamin D supplementation (calcitriol, 0.25-0.5 μg twice daily). Intravenous calcium is seldom required but may be necessary in severely symptomatic patients.

THE ADRENAL (SUPRARENAL) GLAND

EMBRYOLOGY AND ANATOMY

The adrenals are paired structures located superior to the kidneys. The adrenal is divided into an outer cortex and an inner medulla. The cortex originates from mesodermal tissue near the gonads on the adrenogenital ridge at approximately the fifth week of gestation. Adrenocortical tissue can thus be found in the ovaries, splanchnic cord, and testes. The adrenal medulla originates from the neural crest, which is ectodermal in origin.

Each adrenal is supplied by three sets of arteries: the superior adrenal (from the inferior phrenic artery), the middle adrenal (from the aorta), and the inferior adrenal (from the renal artery). These vessels branch into as many as 50 arterioles. The left adrenal vein empties into the ipsilateral renal vein, whereas the right adrenal vein drains into the inferior vena cava (see Chapter 9).

Indications for Surgery

PRIMARY HYPERALDOSTERONISM

This disorder accounts for 1% of hypertensive patients and results from an adrenal adenoma (Conn syndrome, 75%), adrenal hyperplasia (24%), or adrenocortical cancer (1%). Glucocorticoid-suppressible hyperaldosteronism is another rare cause of hyperaldosteronism. Patients with primary hyperaldosteronism typically present with hypertension (long-standing and difficult to control despite multiple medications), muscle weakness, polydipsia, polyuria, headaches, and fatigue.

Diagnostic Tests

The diagnosis must be suspected in any hypertensive patient with spontaneous hypokalemia (<3.2 mmol/L) or hypokalemia while on diuretic therapy (despite potassium supplementation). Other abnormalities include hypernatremia, alkalosis, and hypochloremia. Elevated plasma and urine aldosterone levels with suppressed plasma renin activity levels confirm the diagnosis. Plasma aldosterone concentration to plasma renin activity ratios of >1:25 to 30 are highly suggestive of the diagnosis. The diagnosis can be confirmed by documenting failure to suppress plasma aldosterone with oral or intravenous salt loading. Once the biochemical diagnosis is confirmed, it is important to distinguish between patients with a unilateral adenoma from those with hyperplasia because unilateral adrenalectomy is virtually always curative for the former (see Chapter 9 for details). Tumors can be localized with CT scans, MRI, iodocholesterol scans, or selective venous catheterization for aldosterone and cortisol. A unilateral 0.5- to 2-cm adrenal tumor with a normal-appearing contralateral gland essentially confirms an aldosteronoma if the biochemical and clinical profiles are appropriate.

Surgical Management

Patients are prepared for surgery with potassium repletion, sodium restriction, and treatment with spironolactone or eplerenone (aldosterone antagonists). Amiloride or triamterene (potassium-sparing diuretics) as well as other effective antihypertensive medications, including calcium channel blockers and angiotensin-converting enzyme inhibitors, can also be used. Patients with a unilateral hyperfunctioning tumor are best managed with a laparoscopic adrenalectomy. Postoperatively, patients may require saline infusions, fludrocortisone (50-100 μg/d), or, rarely, glucocorticoids if they develop Addison disease. Adrenalectomy improves blood pressure in approximately 80% of patients and leads to resolution of hypokalemia in most. Only 20% to 30% of patients with bilateral hyperplasia benefit from adrenalectomy. Surgical candidates can be selected based on bilateral adrenal vein sampling for aldosterone and cortisol. A unilateral gradient suggests a potential benefit from surgical
intervention. The remaining patients are best managed by medical therapy with spironolactone, triamterene, or amiloride.

HYPERCORTISOLISM

Cushing syndrome refers to a complex of symptoms and physical signs resulting from cortisol hypersecretion, independent of etiology. Causes of Cushing syndrome include ACTH-secreting pituitary tumor leading to bilateral adrenal hyperplasia (Cushing disease 70%); primary adrenal adenoma, hyperplasia, or carcinoma (20%); ectopic ACTH-secreting tumors (small cell lung, pancreatic, thyroid, thymic, and other cancers—10%); or the exogenous administration of steroids. Patients present with weight gain, muscular weakness, polyuria, emotional lability, moon facies, acne, hirsutism, central obesity, hypertension, diabetes mellitus, and virilization.

Diagnostic Tests

Diagnostic tests in patients with Cushing syndrome are directed toward confirming the diagnosis and determining the etiology of the disorder. A low-dose (1-mg) overnight dexamethasone suppression test is usually performed. Patients with Cushing syndrome do not generally suppress cortisol levels to <3 µg/dL, although this threshold is controversial. In patients with a negative test but high clinical suspicion, the classic dexamethasone suppression test (2 mg over 48 hours) or a 24-hour urinary free cortisol measurement is performed. Salivary cortisol measurements are increasingly being used at some centers. Once hypercortisolism is confirmed, the plasma ACTH level, if suppressed, indicates a primary adrenal etiology for the disorder. High-dose (8-mg) dexamethasone suppression tests may be performed to delineate the source of increased cortisol secretion (see Chapter 9 for details). Adrenal tumors are localized using CT, MRI, or iodocholesterol scans and pituitary tumors by MRI scanning and selective venous catheterization of petrosal veins after corticotropin-releasing factor stimulation.

Surgical Management

Cushing disease is treated with trans-sphenoidal hypophysectomy and microsurgical excision of the pituitary adenoma. Irradiation may also be used, but the response is delayed, and the treatment often results in panhypopituitarism. Unilateral laparoscopic adrenalectomy is the treatment of choice in patients with adrenal adenomas, whereas open adrenalectomy is recommended for carcinomas. Bilateral laparoscopic adrenalectomy is used to treat patients with Cushing disease who fail to respond to radiation or hypophysectomy and selected patients with Cushing syndrome secondary to ectopic ACTH production. Symptoms of Cushing syndrome can be treated with medications that inhibit steroid production (ketoconazole, metyrapone, aminoglutethimide).

Preoperatively, electrolyte abnormalities are corrected, and all patients are given exogenous steroids (hydrocortisone, 100 mg intravenously every 8 hours). After unilateral adrenalectomy, steroids are tapered off over months. After bilateral surgery, lifelong treatment with hydrocortisone is necessary. Fludrocortisone is sometimes needed, and steroid supplementation must be increased in situations of stress. The prognosis after adrenalectomy for adenoma is excellent. After bilateral adrenalectomy, approximately 20% of patients develop Nelson syndrome (hyperpigmentation, headaches, exophthalmos, and blindness) from continuing growth of the pituitary tumor.

ADRENAL CORTICAL CARCINOMA

This rare neoplasm is slightly more common in women than in men and has a bimodal age distribution, occurring more frequently in children under 5 years of age and in adults in their forties and fifties. Approximately 50% of these tumors are nonfunctioning. The remaining secrete cortisol (30%), androgens (20%), estrogens (10%), aldosterone (2%), or multiple hormones (35%). Most adrenocortical cancers are sporadic, but they can also occur in the setting of the Li-Fraumeni syndrome (p53) and MEN 1 (MEN1). Adrenocortical cancers are often characterized by the rapid onset of Cushing syndrome with virilizing features. Nonfunctioning tumors usually present with an enlarging abdominal mass and abdominal pain or, less commonly, with weight loss, hematuria, varicocele, and dyspnea.

Diagnosis

The biochemical workup of a unilateral adrenal mass is outlined in the section on adrenal incidentaloma (see Chapter 9). CT or MRI scans are commonly employed to evaluate the size and invasiveness of the mass. The size of the mass remains the single most reliable indicator of malignancy. Carcinomas are more likely to be present in lesions over 6 cm in diameter. Studies based on SEER registry data show that the sensitivity, specificity, and likelihood ratio of tumor size in predicting malignancy as 96%, 51%, and 2, respectively, for tumors ≥4 cm; and 90%, 78%, and 41, respectively, for tumors ≥6 cm. Other features suggesting malignancy on CT include irregular shape and margins, heterogeneity, and hemorrhage. On MRI, carcinomas have a moderate signal intensity on T2-weighted image (adrenal tumor to liver ratio 1.2-2.8). FNAB is usually recommended for patients with an isolated adrenal mass and a history of carcinoma of the lung, breast, stomach, kidney, colon, melanoma, or lymphoma and in those with symptoms and signs of underlying malignancy. FNAB is generally not recommended when a primary adrenal carcinoma is suspected as the diagnosis cannot be reliably made via this test and has the potential to seed the biopsy tract. Care must be taken to exclude pheochromocytoma prior to biopsy to avoid precipitating a hypertensive crisis (see Chapters 9 and 11).

Surgical Treatment

Complete surgical excision offers the only chance of prolonged survival or cure. Transabdominal adrenalectomy with en bloc excision of contiguous involved structures (liver, kidney, spleen, or pancreas) is usually recommended. A thoracoabdominal approach may also be used for large (>10 cm) right-sided tumors.
Laparoscopic adrenalectomy is not usually recommended for suspected adrenal cancers. The adrenolytic agent mitotane and other antitumor drugs such as etoposide, cisplatin, and doxorubicin have also been used with partial success for metastatic tumors. Five-year actuarial survival rates of 32% to 48% have been reported in patients who underwent complete resection. Features predicting poor survival include tumor size over 12 cm, six or more mitoses per high-power field, intratumoral hemorrhage, local invasion, and distant metastases.

**SEX STEROID EXCESS**

Virilization and feminization can be caused by many disorders, including congenital adrenal hyperplasia, adrenal adenomas or carcinomas, ovarian or testicular tumors, hypothalamic or pituitary disease, placental disorders, and exogenous sex steroid administration. Several different variants of congenital adrenal hyperplasia occur, each caused by a specific enzyme defect. Adrenal virilization occurring postnatally usually results from an adenoma or carcinoma. Virilization presents in females with hirsutism, clitoromegaly, alopecia, breast atrophy, and oligomenorrhea. In males, feminizing tumors lead to gynecomastia and testicular atrophy.

**Diagnostic Tests**

Karyotype analysis to rule out sex chromosome anomalies such as Klinefelter syndrome and determinations of either plasma and or urinary steroid metabolites are needed to establish the diagnosis of a particular enzyme deficiency as discussed in Chapters 9 and 14. The dexamethasone suppression test (2-4 mg/d in divided doses 4 times daily for 7 days) can be used to distinguish congenital adrenal hyperplasia from neoplasia. CT, MRI, and iodocorticosteroid scans are used to localize the tumors.

**Surgical Management**

Congenital adrenal hyperplasia is managed medically not surgically. Adrenalectomy is reserved for treatment of adrenal steroid excess caused by an adenoma or carcinoma. The peroperative management is similar to that for patients with Cushing syndrome. Patients with adrenal carcinomas have a poor prognosis.

**PHEOCHROMOCYTOMA**

This catecholamine-secreting tumor of the adrenal medulla and extra-adrenal chromaffin tissue accounts for 0.1% to 0.2% of all patients with hypertension. It is often called the 10% tumor because 10% are bilateral, 10% are malignant, 10% occur in children, 10% are extra-adrenal, and 10% are familial (occurring in association with MEN 2A, MEN 2B, von Hippel-Lindau syndrome, neurofibromatosis, other neurocutaneous syndromes, and the familial paraganglioma and pheochromocytoma syndromes caused by mutations in the succinyl dehydrogenase family of genes [SDHB, SDHC, and SDHD]) (see Chapter 11).

Headache, palpitations, and diaphoresis constitute the classic triad of pheochromocytoma. Nonspecific symptoms include anxiety, tremulousness, severe headaches, paresthesias, flushing, chest pain, shortness of breath, abdominal pain, nausea, and vomiting as well as others. The most common clinical sign is hypertension, which may be sustained or episodic.

**Diagnostic Tests**

These are performed in a nonstressed patient. Twenty-four-hour urine collections are tested for catecholamines (epinephrine, norepinephrine, dopamine) and their metabolites (metanephrines and normetanephrines). Plasma metanephrines, catecholamines, and chromogranin A levels are also used to make the diagnosis. Provocative tests such as glucagon infusion and clonidine suppression are rarely necessary. Radiologic investigations such as CT or MRI scans, and metaiodobenzylguanidine scans are used to localize the tumors and assess for possible extra-adrenal tumors (see Chapter 11 for details). Of note, extra-adrenal sites lack phenylethanolamine-N-methyltransferase, and hence, secrete primarily norepinephrine rather than epinephrine.

**Surgical Treatment**

Adrenalectomy is the treatment of choice and can safely be performed laparoscopically. Preoperative preparation typically consists of treatment with an alpha-adrenergic blocker such as phenoxybenzamine (10-40 mg 4 times daily; maximum: 300 mg/d) for at least 7 days preoperatively. Beta blockers such as propranolol (5-40 mg 4 times daily) are added in patients who have persistent tachycardia and arrhythmias but only after adequate alpha blockade has been established in order to avoid the effects of unopposed alpha stimulation (ie, hypertensive crisis and congestive heart failure). Patients should also be volume repleted to avoid postoperative hypotension, which ensues with the loss of vasoconstriction after tumor removal. Nitroprusside is the drug of choice for intraoperative hypertension. After surgery, 95% of patients with paroxysmal hypertension and 65% with sustained hypertension become normotensive. Patients with malignant pheochromocytoma, defined by invasion into surrounding structures or presence of distant metastases, have a poor prognosis. Although risk of malignancy increases with size for all pheochromocytomas, size does not seem to reliably predict malignancy in pheochromocytomas. The risk of malignant tumors is also increased in patients with germline SDHB mutations.

**ADRENAL INCIDENTALOMA**

The term incidentaloma is used to denote an adrenal mass discovered during imaging done for other reasons. Adrenal masses have been identified in up to 8% of individuals in autopsy series and in 4.4% of those undergoing abdominal CT scans. The widespread use of ultrasound, CT, and MRI scans over the past two decades has led to an appreciable increase in the number of these lesions identified. Most of these lesions are benign nonfunctioning adenomas. The differential diagnosis of these lesions is summarized in Table 26–7.
TABLE 26–7 Differential diagnosis of an adrenal incidentaloma.

Diagnosis

The workup is used to discern which lesions are functional or malignant and thus, warrant adrenalectomy. Asymptomatic patients with obvious cysts, hemorrhage, myelolipomas, or diffuse metastatic disease do not mandate further testing. All other patients should undergo biochemical testing for hormonally active tumors. At a minimum, this includes serum electrolytes; low-dose (1-mg) dexamethasone suppression testing; and a 24-hour urine collection for catecholamines, metanephrines, and 17-ketosteroids; however, the issue of which tests to order is controversial. Confirmatory tests can be performed based on the results of these screening tests. It is extremely important to identify patients with subclinical Cushing syndrome. Functional tumors and nonfunctional masses over 4 cm in patients who have an acceptable operative risk are treated by laparoscopic adrenalectomy, whereas heterogeneous, irregular, or enlarging tumors are treated by open or laparoscopic adrenalectomy. FNAB should be performed only in patients with a history of carcinoma and a suspected isolated adrenal metastasis, or if there is a question as to whether the tumor is of adrenal origin (see Chapter 9 for details). Care must be taken to exclude pheochromocytoma prior to biopsy to avoid precipitating a hypertensive crisis.

Treatment

Laparoscopic adrenalectomy has become the procedure of choice for most of the lesions described above except when malignancy is likely or suspected. Patients with nonfunctioning homogeneous lesions <4 cm in diameter should be followed with serial examinations and CT or MRI scans at 3 to 12 months. Adrenalectomy is indicated for any lesion that grows during the observation period.

TECHNIQUE OF ADRENALECTOMY

There are no randomized controlled trials comparing laparoscopic and open adrenalectomies. However, several retrospective studies have shown that the laparoscopic technique is safe and associated with less postoperative pain, shorter mean hospital stay, lower morbidity, and more rapid complete recovery. Laparoscopic adrenalectomy has become the procedure of choice for most adrenal lesions, and the indications are similar to those for open procedures.

Laparoscopic adrenalectomy is contraindicated in patients with a known adrenocortical cancer or coagulo pathy. Two approaches have been described: transperitoneal (lateral and anterior) and posterior retroperitoneal. The former provides a conventional view of the anatomy, and the anterior approach allows for bilateral procedures without repositioning the patient. The posterior approach may be preferable in reoperative cases and obese patients but provides a limited working space. The lateral transperitoneal approach is described in the next paragraph.

The patient is placed in the lateral decubitus position, with the table flexed to open the space between the lower rib cage and the iliac crest. Pneumoperitoneum is created by insufflating carbon dioxide gas and four 10-mm trocars are placed between the midclavicular line medially and the anterior axillary line laterally (Figure 26–6A), approximately two finger-breadths below the costal margin. A 30-degree laparoscope inserted via the midclavicular port is used to aid the dissection, which is carried out viaatraumatic instruments inserted via the two most lateral ports. In general, the dissection of the adrenal usually begins superomedially and then proceeds inferiorly in a clockwise fashion (Figure 26–6B and Figure 26–6C). The adrenal gland is dissected from surrounding tissue using an electrocautery or an ultrasonic scalpel (Harmonic Ultrasonic Scalpel). These methods are also useful for control of the small adrenal arteries, but the larger adrenal arteries and adrenal veins need to be clipped or stapled. The adrenal is placed in a specimen (EndoCatch) bag and can be morcellated prior to extraction.

Open adrenalectomy may be performed by the anterior, posterior, retroperitoneal, or thoraco-abdominal approaches. The latter is very useful, particularly for large adrenal cancers.

Complications of Laparoscopic Adrenalectomy

Specific procedure-related complications include trocar site-associated hematoma and subcutaneous emphysema, injury to surrounding organs such as the spleen, pancreas, liver and colon, and bleeding from venous injuries.

THE ENDOCRINE PANCREAS

EMBRYOLOGY AND ANATOMY

The pancreas is a retroperitoneal organ located at the level of L2. It weighs 75 to 100 g, is approximately 15 to 20 cm in length, and is divided into the head and uncinate process, the neck, the body, and the tail. The uncinate process forms part of the head and surrounds the superior mesenteric vessels. The main pancreatic duct (duct of Wirsung) is 2 to 3.5 mm wide, runs in the center of the pancreas, and drains the body, tail, and uncinate process. The lesser duct (duct of Santorini) usually drains the head, communicates
with the duct of Wirsung, and drains separately via a minor papilla located 2 cm proximal to the ampulla of Vater. The common bile duct is found posteriorly in the pancreatic head and joins the main pancreatic duct before draining into the ampulla.

The pancreas originates as dorsal and ventral pancreatic buds from the primitive endoderm at about the fifth week of gestation. The former gives rise to the superior head, neck, body, and tail, whereas the later forms the inferior head and the uncinate process. The ventral duct fuses with the dorsal bud to form the duct of Wirsung, and the proximal portion of the dorsal duct forms the duct of Santorini. In 10% of individuals, the ducts fail to communicate, resulting in pancreas divisum, where the entire pancreas is drained by the lesser duct.

**Indications for Surgery**

Endocrine pancreatic tumors arise from the islet cells, which are derived from the neural crest. Common functioning tumors are described next.

**INSULINOMA**

This β-cell–derived neoplasm is the most common pancreatic endocrine tumor. Insulinomas are evenly distributed throughout the pancreas (one-third each in the head, body, and tail). Most patients (90%) have a benign, solitary lesion. Approximately 10% of patients have malignant insulinomas with metastatic disease to the liver and peripancreatic lymph nodes. The insulinoma syndrome is characterized by the Whipple triad, which includes symptoms of hypoglycemia during fasting, serum glucose <50 mg/dL, and relief of hypoglycemic symptoms by exogenous glucose administration. Hypoglycemic symptoms may result from neuroglycopenia (confusion, seizures, personality change, coma) or due to a catecholamine surge (tachycardia, diaphoresis, trembling). Other causes of hypoglycemia such as reactive hypoglycemia, adrenal insufficiency, end-stage liver disease, nonpancreatic tumors (mesothelioma, sarcoma, adrenal carcinoma, carcinoid), and surreptitious administration of oral hypoglycemics or insulin should be excluded.

**Diagnostic Tests**

The diagnosis is made during a 72-hour monitored fast if glucose levels fall to <50 mg/dL while insulin levels are more than 20 μU/mL and the insulin to glucose ratio is >0.4 (normal: <0.3). This is considered the gold-standard test. Increased levels of C peptide and proinsulin are also diagnostic, whereas low levels suggest factitious hyperinsulinemia.

Once the diagnosis is confirmed biochemically, noninvasive tests such as double-contrast, fine-cut (5 mm) CT or MRI scans can identify large tumors or liver metastases. Transgastric endoscopic ultrasound is the most successful preoperative localization test (sensitivity 83%-93%). Some pancreatic neuroendocrine tumors also express somatostatin receptors and can be imaged using radiolabeled octreotide. Unfortunately, this is only effective in about 30% of patients with insulinomas (see Chapter 18 for details). Selective arteriography with calcium stimulation of insulin secretion, monitored through a catheter positioned in the right hepatic vein (Imamura-Doppmann test, sensitivity 88%) is an invasive test that is used selectively when other localization studies fail to identify the tumor or in patients following unsuccessful prior surgery.
**Treatment**

A. **Surgical treatment**  Operation is the only curative treatment. Prior to surgery, patients are instructed to take several small frequent meals, and diazoxide administration can be helpful in avoiding hypoglycemic attacks. Other medications commonly used include verapamil, diphenylhydantoin, and glucocorticoids. Somatostatin analogues can also be used if the tumors are positive for somatostatin receptors. Glucose levels are monitored perioperatively. The combination of inspection, palpation, and intraoperative ultrasound allows detection of nearly all tumors and their relationship to the pancreatic duct. Small (<2 cm) benign tumors in any part of the pancreas that are not intimately associated with the main pancreatic duct are best treated by enucleation. Larger tumors (up to 5 cm) can be enucleated if located in the pancreatic head but are removed by spleen-preserving distal pancreatectomy if located in the tail. Large tumors in the head that appear malignant are usually resected by a Whipple procedure. When a tumor cannot be identified, blind distal resections should generally not be performed. However, a small distal pancreatic resection may be sufficient to rule out nesidioblastosis (β-cell hyperplasia). Resection of peripancreatic and periduodenal nodes is advised in patients with probable malignant tumors. Hepatic resection should be considered for cure or palliation in patients with metastatic tumors. In cases of nonresectable disease, debulking may be reasonable to achieve symptomatic control and may also prolong survival. Other modalities such as RFA, cryotherapy, and TACE may also be considered in this setting. Patients with insulinomas in the setting of MEN 1, in contrast to those with sporadic tumors, require distal pancreatectomy and enucleation of tumors from the head of the pancreas. Surgical resection is curative in about 95% of cases.

B. **Medical treatment**  Diazoxide and verapamil are often used to decrease insulin secretion from insulinoma. Combination chemotherapy (streptozocin, 5-FU, and doxorubicin) has also been used for unresectable insulinomas.

**GASTRINOMA (ZOLLINGER-ELLISON SYNDROME)**

This neoplasm leads to abdominal pain, peptic ulceration of the proximal gastrointestinal tract (90%) and diarrhea (50%). The diagnosis should be suspected in patients with recurrent postoperative and postbulbar ulcers, ulcers associated with diarrhea, a family history of ulcer diathesis or MEN 1, and failure to respond to adequate medical therapy. Up to 75% of gastrinomas occur sporadically. In contrast to insulinomas, 60% of gastrinomas are malignant and present with local invasion and metastases. Also, virtually all insulinomas are situated within the pancreas, but up to 70% of gastrinomas are found within the duodenum.

**Diagnostic Tests**

Fasting serum gastrin levels are generally over 200 pg/mL, and values over 1000 pg/mL are diagnostic of gastrinomas except in hypochlorhydric patients. Elevated gastrin levels may also be found in several other disease states (Table 26–8), and other tests are therefore necessary. Basal gastric acid output over 15 mEq/h (>5 mEq/h in patients with previous vagotomy) or a ratio of basal to maximal acid output >0.6 suggests a gastrinoma. An increase of gastrin over 200 pg/mL above the basal level on stimulation with 2 U/kg secretin confirms the diagnosis. In patients with ZES, serum PTH, calcium, and prolactin levels should be measured to rule out MEN 1.

Imaging studies used to localize gastrinomas are similar to those used for investigation of insulinomas. However, endoscopic ultrasound and visceral angiograms are less sensitive for gastrinomas, because many are small and not within the pancreas. Most pancreatic gastrinomas are situated to the right of the superior mesenteric vessels. Octreotide scans or positron emission tomography (PET) with Ga-DOTATOC may be useful. Selective pancreatic angiograms utilizing secretin stimulation and hepatic venous sampling for gastrin levels may also be used.

</tbody>
</table>

**Treatment**

A. **Surgical treatment**  Patients are treated with proton pump inhibitors preoperatively. Most gastrinomas are located in the gastrinoma triangle, which is surrounded by the cystic duct superiorly, the second and third portions of the duodenum inferiorly, and the junction of the neck and body of the pancreas medially. The Whipple procedure is recommended for large (>6 cm) or clinically malignant tumors in the head of the pancreas. Intraoperative ultrasound, endoscopy with duodenal transillumination, and a longitudinal duodenotomy are necessary to identify many tumors. All peripancreatic and peri-duodenal lymph nodes should be removed, as primary lymph node gastrinomas have been reported. Single hepatic metastases may be resected. Total gastrectomy is rarely indicated today except in noncompliant patients or those refractory to medical therapy when the gastrinoma cannot be identified or completely removed. Patients with MEN 1 often have multiple gastrinomas. The extent and role of surgery in patients with MEN 1/ZES remains controversial. Some groups
advise early and aggressive surgeries to prevent liver disease, whereas others advise resection of MEN 1 gastrinomas >2 cm as small tumors are characterized by a good prognosis. In advanced, surgically incurable tumors, cytoreductive measures including resection or RFA/TACE are reasonable if >90% of the tumor mass can be removed, although this does not appear to prolong survival. Liver transplantation may be a consideration in young patients with diffuse, unresectable pancreatic metastases. In contrast to patients with MEN 1 who have nearly 100% recurrence rates, about 34% of patients with sporadic gastrinomas remain disease-free at 10 years after surgical treatment. Overall survival rates after surgical treatment are reported to be 94% at 10 years.

B. Medical treatment Octreotide may be used to decrease gastrin secretion. The combination of doxorubicin, streptozotocin, and 5-FU can be used as systemic chemotherapy. Somatostatin analogues and interferons have not shown much efficacy.

VIPOMA (VERNER-MORRISON) SYNDROME

This disorder is also known as the WDHA (watery diarrhea, hypokalemia, achlorhydria) or pancreatic cholera syndrome. Patients typically present with high-volume diarrhea (>5 L/d), muscular weakness (due to hypokalemia) and lethargy, hyperglycemia, hypercalcemia, and, rarely, cutaneous flushing.

Diagnostic Tests

Because secretion of VIP can be episodic, multiple fasting levels should be measured. Localizing studies are performed as described earlier for insulinomas and gastrinomas.

Treatment

A. Surgical treatment Fluid and electrolytes should be aggressively repleted prior to surgery. The diarrhea often responds to octreotide. Most of these tumors are located in the body and tail and hence are best managed by a distal pancreatectomy. Small tumors may be enucleated. If the tumor is not localized, the autonomic chain and adrenals should be examined for extrapancreatic tumors. If no tumor is identified, distal pancreatectomy may be considered. Palliative debulking may be performed for metastatic disease to control symptoms if >90% of the tumor mass can be resected. Other ablative therapies such as RFA/TACE or cryo-therapy may also be used as cytoreductive measures and liver transplantation may be an option in selected cases.

B. Medical treatment Somatostatin analogues may provide palliation of symptoms particularly if the tumors are octreotide scan positive. They may also have an effect on tumor growth. Interferon-α may be indicated in tumors not responding to somatostatin analogues. Systemic therapy as described for other tumors may also be used.

GLUCAGONOMA

Patients with this tumor have mild diabetes, stomatitis, anemia, malnutrition, hypoproteinemia, and a characteristic severe dermatitis (necrotic migratory erythema). The latter is thought to be secondary to the hypoaminoacidemia.

Diagnostic Tests

The clinical presentation and biopsy of the rash are sufficient for the diagnosis. Hyperglycemia, hypoproteinemia, and an elevated fasting glucagon level (>150 pg/mL) confirm the diagnosis. Localizing and staging tests are performed, as described above for the more common tumors. Most of these tumors are malignant.

Treatment

A. Surgical treatment Patients need preoperative octreotide, hyperalimentation, and routine deep venous thrombosis prophylaxis. Up to 70% of these tumors present with metastases, and surgery is the only potentially curable treatment. Most tumors are solitary and located in the tail, where they are amenable to distal pancreatectomy. Palliative debulking with distal pancreatectomy and splenectomy (if needed) in the setting of metastatic disease may help refractory symptoms. If splenectomy is planned, appropriate vaccination to reduce the risk of overwhelming postsplenectomy sepsis is recommended preoperatively.

B. Medical treatment As with other neuroendocrine tumors, octreotide and embolization of hepatic metastases may help control symptoms.

SOMATOSTATINOMA

The somatostatinoma syndrome is characterized by steatorrhea, diabetes, hypochlorhydria, and gallstone disease. Most somatostatinomas are malignant (75% have metastases at presentation) and are located in the pancreatic head. The diagnosis is established by fasting somatostatin levels of 100 pg/mL or more. Somatostatinomas are usually treated with the Whipple procedure (ie, pancreaticoduodenectomy). Fluid and electrolyte abnormalities should be corrected preoperatively.

NONFUNCTIONING PANCREATIC TUMORS

Approximately 33% of patients with pancreatic endocrine neoplasms have no evidence of a defined clinical syndrome and are deemed to have nonfunctioning tumors. However, some of these tumors produce pancreatic polypeptide and chromogranin A, particularly in the setting of MEN 1. These patients usually present with abdominal pain, weight loss, and jaundice—similar to ductal adenocarcinoma of the pancreas. The tumors are most commonly present in the head, neck, and uncinate process. The tumors are localized and staged similar to functional tumors.
Octreotide scans are recommended to assess receptor expression status and assess extent of disease. Endoscopic retrograde cholangiopancreatography and percutaneous transhepatic cholangiography are used for the evaluation of jaundice.

**Surgical Treatment**

Approximately 75% of these tumors are malignant. Surgical resection (pancreatocoduodenectomy or distal pancreatectomy) is the treatment of choice for sporadic tumors, because these tumors are not amenable to enucleation. In the presence of MEN 1, the indications for surgery are controversial. More aggressive groups recommend tumor enucleation in the head and prophylactic subtotal pancreatectomy, whereas more conservative groups recommend close follow-up and enucleation of lesions >2 cm. Biliary and gastric bypasses may be necessary for palliation. These tumors often grow slowly. Five-year survival rates after resection are 50%. Resectable liver disease should be treated with surgery and or RFA. In patients with unresectable disease, combination chemotherapy (streptozocin and doxorubicin) with RFA/TACE may provide palliation. Poorly differentiated tumors are characterized by aggressive tumor biology, absence of somatostatin receptors, and poor prognosis. Surgical resection is recommended only for resectable primary tumors. Cytoreductive procedures are generally not recommended in these patients.

**Technique of Pancreatic Exploration for Neuroendocrine Tumors**

Patients are explored through a midline or bilateral subcostal incision. A detailed description of the Whipple procedure and a distal pancreatectomy is beyond the scope of this chapter, and the reader is referred to surgical atlases. A general description of the necessary maneuvers is presented here. The gastrocolic ligament and the inferior retroperitoneal attachments of the pancreas are divided to allow limited parathyroidectomy, improve success rate, and predict outcome. Supplementary ultrasound may facilitate identification of tumors. Early experience suggests that a laparoscopic approach is also feasible in these tumors, particularly sporadic insulinomas, when the lesion is identified with localization studies.

**Complications of Pancreatic Surgery**

The most important complications of pancreatic surgery (tumor enucleation, distal pancreatectomy, or Whipple resection) are pancreatic fistula, pseudocyst, or abscess formation, which may lead to necrotizing retroperitoneal infection, and hemorrhage. Other complications include upper gastrointestinal tract bleeding, marginal ulceration, and biliary fistula formation. The mortality of a Whipple procedure is <5% and that of other pancreatic surgical procedures is <1%.

### Adrenocorticotropic hormone (ACTH) stimulation test (cosyntropin test)

A dose of 0.25 mg of synthetic ACTH,24 (cosyntropin) is administered IV or IM, and serum cortisol is measured at 0, 30, and 60 min. Normal response: peak cortisol >20 μg/dl (>540 nmol/L). A dose of 1 μg of ACTH will give a similar response in the normal individual (see Chapter 9).

**Calcitonin stimulation test utilizing calcium infusion:** 2 mg/kg of calcium in the form of calcium gluconate is administered IV over 1 min. Blood samples for calcitonin are obtained at 1, 2, 5, and 10 min after the infusion. Normal peak values for calcitonin 2 min after calcium infusion: female: <70 ng/L (<20.5 pmol/L); male: <491 ng/L (<144 pmol/L).

Adapted from the Clinical Laboratories Manual of the University of California Hospital and Clinics, San Francisco, California, July 4, 2010; and, with permission, from Quest Diagnostics Nichols Institute normal values for endocrine tests. The Quest Diagnosis Manual. Endocrinology Test Selection and Interpretation. 4th ed. Fisher D, ed. 2007. The factors used in converting conventional units to SI units were derived in part from the CRC Handbook of Chemistry and Physics and conversion tables from other online resources. It is important to emphasize that normal ranges vary among different laboratories, and the clinician must know the normal range for the test of interest in the laboratory performing the test.

Semen analysis is discussed in Chapter 12.

BCE, bone collagen equivalent.

endocrine system changes with, 456-457, 457t

ovarian, 455, 456f

population, 737

reproductive function changes in men related to, 760-761, 760f, 761f

thyroid function changes related to, 182

Agnadism, XY, 516

AHO (Albright hereditary osteodystrophy), 454

AIDS

See Acquired immunodeficiency syndrome

AIDS wasting syndrome, 794-795

AIS (androgen insensitivity syndrome), 454

Albright hereditary osteodystrophy (AHO), 255

Albumin

androgens binding to, 292

cortisol binding to, 292

in thyroid hormone transport, 170-171

Alcohol ingestion, lipoprotein disorders associated with, 693

secondary hypertriglyceridemia associated with, 685-686

Aldosterone

adenoma due to, 324

surgical treatment of, 339

normal ranges for, 825t

in renin-angiotensin-aldosterone system, 331-332, 331f

Aldosteronism, primary, 332-340

clinical presentation of, 333

described, 332-333, 332t

diagnosis of, 333-338, 334f, 336f-338f

adrenal CT in, 335-336, 336f-338f

adrenal venous sampling (AVS) in, 336-337, 338f

case-detection tests in, 333-334, 334f

confirmatory tests in, 335

familial hyperaldosteronism type II assessment in, 338

glucoctoricoid-remelable aldosteronism-familial hyperaldosteronism type I assessment in, 337-338

intravenous saline infusion test in, 335

oral sodium loading test in, 335

subtype studies in, 335-338, 336f-338f

prevalence of, 333

treatment of, 339-340

Alimentary (reactive) hypoglycemia, 668-670, 669f

Alkaline phosphatase, normal ranges for, 825t

Allergy(ies), insulin, 625-626

Alpha-adrenergic blockers, in pheochromocytoma/paraganglioma management, 382-383

Alpha-adrenergic receptors, 352-354, 354f, 355f

Androgen(s)

and, 299-303. See also Androgen(s)

aging effects on, 457-458, 457t

disorders of, 514-516

hypothalamic-pituitary dysfunction, 99

in men, hypothalamic-pituitary dysfunction, 99

in women, hypothalamic-pituitary dysfunction, 99

dysgenetic, 46,XX due to, 501-504, 502f, 503t

excess of, in adrenal androgen evaluation, 303

formation of, 426f, 432

maternal source of, 509-516

in osteoporosis management, 269

relative androgenic activity of, 427, 427t

resistance to, in men with normal male genitalia, 516

secretion of, autonomous, in boys, 547

synthesis of, in steroidogenesis, 289

testicular, biosynthesis of, pathways for, 397, 398f

Androgen binding, 292

Androgen insensitivity syndrome (AIS), 454

Androgen-secreting tumor, hyperandrogenism and, 452

3α-Androstenediol glucuronide, normal ranges for, 826f

Androstenedione

in female reproductive system, 432

normal ranges for, 826f

Anemia, hypothyroidism and, 194-195

Androgen insensitivity syndrome (AIS), 454

Angiotensin- converting enzyme (ACE)

Angiotensin, in renin-angiotensin-aldosterone system, 330, 331f

Angiotsensin II

Ankylosis, hyperparathyroidism and, 578, 579f

Anomalies, in osteoporosis management, 460

Angiotsensin, in renin-angiotensin-aldosterone system, 329-330, 331f

Angiotsensin-converting enzyme (ACE) inhibitors, in pheochromocytoma/paraganglioma management, 383

Angiotsensinotypes, production of, renin-angiotensin system in, 330, 331f

Angiotsensin II

normal ranges for, 826f

in renin-angiotensin-aldosterone system, 330
Anorchia
bilateral, 407-408
causes of, 407
clinical features of, 407-408
differential diagnosis of, 408
imaging studies in, 408
laboratory findings in, 408
pathophysiology of, 407
symptoms and signs of, 407-408
testicular pathology of, 407
treatment of, 408
congenital, 516
hypergonadotropic hypogonadism and, 540-541
Anorexia nervosa
amenorrhea and, 440
delayed puberty and, 539
secondary hypercholesterolemia associated with, 688-689
Anovulation, 445-452.
Anti-oxidant(s), in lipoprotein disorders
Antidiuretic hormone (ADH), normal ranges
Antigen-presernting cells (APCs), 29-31, 30f, 31f
Antilbody(ies)
inslet cell, normal ranges for, 836t
to sperm or seminal plasma, male infertility-related, treatment of, 415
thyroid, normal ranges for, 841t
tyrotopin-blocking, normal ranges for, 842t
Antidiuretic hormne (ADH), normal ranges for, 826t
Antigen(s), 27, 28t
Antigen-presenting cells (APCs), 29-31, 30f, 31f
Anti-hyperglycemic agents, in type 2 diabetes management, 625
Antimllerian hormone, defects in synthesis, secretion, or response to, 516
Antioxidant(s), in lipoprotein disorders management, 693-694
Antiresorptive agents, in osteoporosis management, 267-269, 267t
Antiretroviral therapy, HIV infections and, 800-801
APCs, See Antigen-presenting cells
Aphalla, 518

Diabetes mellitus, 587-652
adult-onset. See type 2 below
in AIDS patients, 796-799, 797t, 798t
classification of, 587, 587t
clinical features of, 599-609, 600t
clinical trials in, 606-609
Diabetes Control and Complications Trial (DCCT), 606
Diabetes Prevention Trial-1, 607
immune intervention trials in new-onset type 1 diabetes, 607
complications of acute, 626-634, 626t-628t, 631t. See also specific types, e.g., Hypoglycemia coma, 628-634, 628t, 631t
hypoglycemia, 626-27, 626t, 627t
chronic, 634-642, 634t
effects on bone and joint, 634t, 641-642
effects on cardiovascular, 634t, 640-641
dermatologic, 634t, 641
genetic factors in, 635-636
infections, 634t, 642
mucous membrane-related, 634t, 641
neurologic, 634t, 638-640
ophthalmologic, 634t, 636-637
prevalence of, 635
renal, 634t, 637-638
vascular diseases, 634-635
described, 587
in the elderly, 743-750
cardiovascular disease related to, 745
Diabetes mellitus, in the elderly (Cont.):
- complications of, 745
- screening for, 749-750
- diagnostic criteria for, 744, 744t
- glycemic control for, 745-749, 746t-748t, 748f
- goals of, 744-745
- treatment strategies for achieving, 745-749, 746t-748t, 748f
- drugs, 746-749, 746t-748t, 748f
- insulin, 747-749, 748f, 748t
- lifestyle interventions, 746
- oral hypoglycemic agents, 746t
- in hospitalized patients, management of, 642-644, 643t-645t, 750
- prevalence of, 743
- in hospitalized patients, management of, 642-644, 643t-645t
- glucose control in, 643-644
- hypotalamic-pituitary axis evaluation- related problems and, 89
- insulin-treated, during surgery, management of, 642, 643t, 644t
- laboratory testing in, 601-606, 602t, 604t
- blood glucose, 602-603, 602t
- glycated HBs, 604-605, 604t
- insulin levels, 605
- interstitial fluid glucose samples, 603
- IVGTT, 605-606
- lipoproteins, 606
- microalbuminuria, 601-602
- oral glucose tolerance test, 602t, 605
- proteinuria, 601-602
- serum fructosamine, 605
- serum ketone determinations, 603
- urine glucose, 601
- urine ketone determinations, 603
- non-insulin-dependent. See Diabetes mellitus, type 2

Diabetes mellitus, treatment of, hyperglycemic agents in (Cont.):
- drug combinations, 617
- drugs acting on insulin target tissues, 611t, 613-615
- drugs acting on sulfonylurea receptor complex, 611t, 612-613
- drugs affecting glucose absorption, 611t, 615-616
- GLP-1 receptor agonists, 611t, 616-617
- incretins, 611t, 616-617
- meglitinides analogs, 611t, 613
- metformin, 611t, 613-614
- peroxisome proliferator-activated receptor agonists, 611t, 614-615
- pramlintide, 611t, 617
- sulfonylureas, 611t, 612-613
- insulin in, factors reducing response to, 590, 591-592
- metabolic syndrome and, 592-593
- obesity effects on, 590, 591, 704-705
- symptoms and signs of, 600-601, 600t
- treatment of
- antihyperglycemic agents in, 625
- bariatric surgery in, 625
- drugs in, 610-617, 611t
- specific therapy in, 624-625
- weight reduction in, 624-625
- types of, diseases of exocrine pancreas, 598-599
- vascular disease associated with, classifications of, 634-635
- Diabetes Prevention Program, 608
- Diabetes Prevention Trial-1, 607
- Diabetic cheiroarthropathy, 634t, 641
- Diabetic gastroenteropathy, during pregnancy, 647
- Diabetic ketoacidosis (DKA), 628-631, 628t, 631t, 769-773, 770f, 771t
- causes of, 628
- clinical features of, 629
- clinical setting of, 769-770
- complications of, 631, 773
- diagnosis of, 770-771, 770f
- disposition to, 631, 631t
- laboratory abnormalities in, 628t
- laboratory findings in, 628
- management of, 629-631, 771-773, 771t
- pathogenesis of, 628-629
- prognosis of, 631
- symptoms and signs of, 629
- Diabetic nephropathy, 634t, 637
- during pregnancy, 647-648
- Diabetic neuropathy, 634t, 638-640
- autonomic, 634t, 639-640
- described, 638
- painful, 634t, 638-639
- peripheral, 634t, 638-639
- Diabetic retinopathy, 634t, 636
- during pregnancy, 647
- Diagnostic accuracy
- in clinical epidemiology, 51 defined, 49
- Diaphoresis, pheochromocytomas and, 371
- Diazoxide
- for congenital hyperinsulinism, 672-673
- for insulinomas, 667
- Diet
- in diabetes management, 609-610
- in obesity management, 706
- universal, in lipoprotein disorders management, 694
- Dietary factors, in lipoprotein disorders management, 693-694
diabetic ketoacidosis (DKA), 769-773, 770f, 771t
hypercalcemic crisis, 775-777, 776t
hypotension, 779-782, 780r, 781t

during surgery, management of, 642, 643t, 644t
for type 1 diabetes, 39
for type 2 diabetes, 747-749, 748f, 748t
factors reducing response to, 590, 590t
types of, duration of action of, 618, 618f
Insulin allergy, 625-626
Insulin analogs, rapidly acting, 619
Insulin aspart, 619
Insulin detemir, 620
Insulin glargine, 619-620
Insulin glulisine, 619
Insulin hypoglycemia test, in hypohalamic-pituitary function evaluation, 85, 86t
Insulin-induced hypoglycemia testing, in adrenal androgen evaluation, 302-303
Insulin-like growth factor(s) (IGFs) deficiency of, IGF-I, primary, GH insensitivity and, 144t, 149-150
described, 130-131
hypersecretion of, causes of, 108
IGF-I metabolic effects of, 78, 78t
normal ranges for, 834t-835t
IGF-II, normal ranges for, 835t
measurement of, in acromegaly diagnosis, 108 in postnatal growth, 132, 137-138, 138f
IGF-I, 137-138
IGF-II, 137-138
Insulin-like growth factor-binding protein(s) (IGFBPs) described, 130-131
IGF-III, normal ranges for, 835t
Insulin-like growth factor (IGF) receptors, described, 130-131
Insulin pumps, in insulin administration, 620
Insulin receptor(s), 579-580, 580f, 581f
Insulin release, regulation of, 578-579, 579t
Insulin resistance in AIDS patients, 796-799, 797t, 798t
immune, 626
measurements of, 450, 450t
obesity effects on, 704-705
in type 2 diabetes, 590t, 591-592
causes of, 590t, 591-592
clinical causes of, 592
tissue heterogeneity in, 592
Insulin secretagogues, short-acting, for type 2 diabetes, 746t
Insulin signaling deactivation of, 580
downstream, 579, 580f
outline of, 579, 580f
Insulin-signaling pathway, in transcriptional regulation, 579-580, 581f
Insulin target tissues, drugs acting on, in type 2 diabetes management, 611t, 613-615
Insulinoma(s), 663-667, 665t, 666f, 819-820
clinical findings in, 664
described, 663-664, 819
diagnosis of, 664-667, 665t, 665f, 819
home blood glucose monitor in, 664
insulin in, 665
patient history in, 664
72-hour fast in, 664-665, 665t
stimulation tests in, 665
tumor localization studies in, 666-667, 666f
hyperinsulinism associated with, 665-666
in multiple endocrine neoplasia (MEN) 1, 724
treatment of, 667, 820
Insulinoma syndrome, 820
Interleukin-2, 590
Intermodal communication, chemical mediators in, 66, 66f
International Conference on Management of Insipidus, 149
International Diabetes Federation (IDF), 705
International Obesity Task Force, 699
Intestinal calcium transport, vitamin D in, 239
Intestinal peristalsis, hypothyroidism and, 194
Intravenous fluids, in adrenocortical hypofunction, 311
Intravenous glucose tolerance test (IVGTT), 590
Intravenous saline infusion test, in primary hyperaldosteronism diagnosis, 335
Kallmann syndrome delayed puberty and, 537-538, 538f
X-linked, 537
Ketoacidosis, diabetic, 628-631, 628t, 631t, 769-773, 770f, 771t. See also Diabetic ketoacidosis (DKA)
Ketoconazole, in ACTH-secreting pituitary adenoma management, 111
Ketone(s) serum, determination of, in diabetes mellitus evaluation, 603
in type 1 diabetes mellitus, treatment of, 631, 631t
urine, determination of, in diabetes mellitus evaluation, 603
Ketosis-prone diabetes, 596-597
17-Ketosteroid(s), normal ranges for, 836t
Kidney(s) in euglycemia maintenance in postabsorptive state, 660
glucocorticoid effects on, 295t, 296t, 298-299

  Neuropeptide Y (NPY), secretion of, 388, 397
Neuropathies
  diabetic, 634r, 638-640. See also Diabetic neuropathy
  peripheral, isolated, 634r, 638
Neuropeptide Y (NPY), secretion of, 388, 397
Neuropharmacologic agents, GH secretion effects of, 80, 80t
Neuropsychiatric disease, thyroid function in, 197
Neurotransmitter(s)
  actions of, 2, 3f
  cholinergic, in counter-regulatory response to hypoglycemia, 660
Neurotransmitter receptors, 6-7, 7f, 7r
Neutral Protamine Hagedorn (NPH), 619
Neurontin, glucose and lipid metabolism effects of, 797, 798t
Newborn(s)
  hypothyroidism in, 193
  transient hypoglycemia in, 670
NF-1. See von Recklinghausen neurofibromatosis
NF-1 gene mutation, 364, 364r
Niacin, in hyperlipoproteinemia management, 695
Nicotinic acid, in hyperlipoproteinemia management, 695
NICTH. See Nonislet cell tumor–induced hypoglycemia
Nieman-Pick disease, 692
Nifedipine, in pheochromocytoma/paraganglioma management, 385
Nitric oxide (NO), guanylyl cyclase–linked receptors activated by, 16-17, 17f, 18f
Nitroglycerin, in pheochromocytoma/paraganglioma management, 385
Nitric oxide (NO), guanylyl cyclase–linked receptors activated by, 16-17, 17f, 18f
Nitrogenic acid, in hyperlipoproteinemia management, 695
Nitroprusside, in pheochromocytoma/paraganglioma management, 385
Nodule, thyroid, 209, 209r, 215-217, 215r, 216f, 217f. See also Thyroid nodules
Nonalcoholic fatty liver disease (NAFLD) obesity and, 705-706
Secondary hypertriglyceridemia associated with, 686
Nonalcoholic steatohepatitis (NASH), secondary hypertriglyceridemia associated with, 686
Nonchromaffin parasympathetic paragangliomas, 365
Nonislet cell rumor-induced hypoglycemia and, 542
Nonalcohol diabetes, 543-545, 699-709
adverse health events related to, 452
causes of, syndromes in, 703t
complications of adipose tissue as endocrine organ, 703-704
cancer, 706
cardiovascular, 705
dyslipidemia, 705
gastrointestinal, 705-706
gynecologic, 706
insulin resistance, 704-705
mechanisms underlying, 703-704
metabolic syndrome, 704
Nontoxic goiter, 209-211, 209r, 210f, 211r
incidence of, 705-706
screening and prevention of, 706
Type 2 diabetes, 704-705
in Cushing syndrome, 317, 317t
defined, 699, 700
described, 452
epidemiology of, 699-700
genetics of, 702-703, 703t, 704t
health consequences of, 703-706
hypothalamic-pituitary axis evaluation–related problems and, 89
increased rates of, possible explanations for, 700
leptin resistance in, 702
management of, 452-453, 706-708, 707t, 708f
evergence in, 707
weight loss in, 706-708, 707t, 708f
bariatric surgery in, 707-708
in children, 708
oral glucose tolerance resr, in diabetes
Osmolality, normal ranges for, 838r
Ophthalmopathy.
Oocyte(s), depletion of, during menopause,
onycholysis, 201, 205f, 207r
Oncogene(s), in feral growth, 130
OMI (oocyte maturation inhibitor), 434
Oocytre(s), 259f, 260
Osreocalcin, normal ranges for, 838r
Osreoblast(s), 260, 260f
Osreiris deformans, 277-280, 278f, 279, 279r.
with pituitary disorders, 794
with thyroid disorders, 788
Oral glucose tolerance test, in diabetes
mellitus evaluation, 602, 605
Oral hypoglycemic agents, for type 2 diabetes,
oral sodium loading resr, in primary
Ovarian dysfunction, in AIDS patients
Osteopenia, 266
in AIDS patients, 791
Osteoporosis, 262-271
in patients, 791
bone mineral density (BMD) in, 266
bone gain in, 263-264, 264f, 264r
bone loss in, 263-265, 264f, 264r
estrogen deficiency and, 264f, 265
bone maintenance in, 263-264,
264f, 264r
bone physiology in, factors affecting,
751-752, 752f, 753f
in Cushing syndrome, 317t, 318
defined, 750
described, 262-263
diagnosis of, 265-266, 265f
in the elderly, 750-757
architectural changes and, 752, 753f
bone loss and, 752, 753f
evaluation of, 733-755, 754f, 755f
treatment of, 755-757
bisphosphonates in, 755-756
calcitonin in, 756
calcium in, 755
adenosine in, 270
bone-forming agents in, 269
bone-forming agents in, 269
calcitonin in, 268
calcitriol in, 267
calcium in, 267, 267f
denosumab in, 268-269
Oxytocin, 126
Painful diabetic neuropathy, 634t, 638-639
Pituitary hormones
adenohypophysial, 71t
anterior, 75-78, 76f, 77f
fetal, 5672
in puerperium, 566
Pituitary hypersecretion, pituitary disorders and, 92
Pituitary insufficiency, pituitary disorders and, 92
Pituitary stimulation, in ACTH evaluation, 85, 87-88
Placenta, in growth, 130
Placental bed, microanatomy of, 554f
Plasma renin activity, in pheochromocytoma testing, 373-374, 376t
Plasma ACTH levels, in adrenocortical insufficiency diagnosis, 309, 310f
Plasma-binding proteins
Plasma-fractionated free metanephrines, in pheochromocytoma testing, 373-374, 376t
Plasma free cortisol, in adrenal androgen evaluation, 300-301
Plasma free metanephrine, levels of, 374
Plasma lipoproteins
abnormal patterns of, clinical differentiation of, 680-681
in lipid transport, 676, 676f, 677f
Plasma renin activity, in pheochromocytoma testing, 375
Plasma steroids, in women, production-,
endoctrine chang es associated with, 553
endocrine function tests effects of, 567-569
endocrine disorders during, 567-569
endocrine functions of, 553-571
endocrine dystocradia and, 570-571
hypothyroidism in, 567
hyperparathyroidism in, 567
sex hormone transport, 170

Polydipsia, primary, ingestion of excess fluid and normal urine excretion and, 118
Polyglandular failure syndrome, 195
Polycystic ovarian syndrome (PCOS), 445-451, 445v, 447f-449f, 450t
biochemical abnormalities associated with, 450
characteristics of, 447
diagnosis of, 445-446, 445t
hyperandrogenism and, 446-447, 447fi, 448f
hyperinsulinemia and, 449-450, 449f, 450t
management of, 450-451
obesity-related infertility associated with, 706
pathogenesis of adrenal gland in, 448-449
intraovarian modulators in, 448, 449f
prevalence of, 445
risks associated with, 450
clinical features of, 570
described, 569
pathophysiology of, 569-570
risk factors for, 569
symptoms and signs of, 569
Premalignant nerves
parasympathetic, 345
sympathetic, 345-346
Pregnancy
conception in, 553-555, 554f
in diabetic patients, 644, 646-652, 646f, 649f-651f. See also Diabetes mellitus, pregnancy in patients with eclampsia in, 569-570
diabetes mellitus in, 567-569
diabetes mellitus in, 567-569
diabetes insipidus due to, 119-120
unplanned, prevalence of, 464, 464f
vasopressin increase during, diabetes insipidus due to, 119-120
Pregnane-3, normal ranges for, 838t
Pregnanolone, normal ranges for, 838t
Premature adrenarche, 549
Premature menarche, 549
Index

Puberty (Continued):
- metabolic changes during, 535
- ovulation in, 534
- physical changes associated with, 527-531, 528f-531f
- age at onset of, 529-530
- body composition-related, 528, 530f
- in females, 528, 528f, 529f
- growth spurt, 530-531
- in males, 528, 530f
- physiology of, 527-535
- precocious, 545t, 546f, 550f, 554-551
- adrenal rest tissue and, 548
- central, 545-547, 546f
- constitutional or familial, 546-547
- idiopathic, 546, 546f
- treatment of, 549-551
- virilizing syndrome, 547
- classification of, 545, 545t
- described, 545
- differential diagnosis of, 549, 550t
- follicular cysts and, 547
- McCune-Albright syndrome and, 548
- incomplete, 545
- treatment of, 551
- incomplete in boys, 547
- in girls, 547-548
- incomplete in boys, 547
- McCune-Albright syndrome and, 548
- pubic hair, development of, stages of
  - in females, 528, 529f
  - in males, 528, 530f
- Pubertal changes
  - endocrine changes in, 566
  - endocrinology of, 566
  - physiologic and anatomic changes of, 566
  - uterine changes in, 566
- Pulmonary system
  - hypothyroidism effects on, 194
  - obesity effects on, 705
  - pheochromocytoma effects on, 371
  - thyroid hormone effects on, 180-181
- Pyogenic infections of skin, chronic, in diabetic patients, 641

syndrome of inappropriate antidiuretic hormone (SIADH), 122-126, 122t, 123f, 125t
causes of, 124, 125t
clinical syndromes of, 124-125, 125t
described, 122-123, 122t
hyponatremia in pathophysiology of, 123-124, 123f
treatment of, 125-126
pathophysiology of, vs. diabetes insipidus, 127f
Syndrome of inappropriate antidiuretic hormone (SIADH) secretion, 717-718, 718t
causes of, 718, 718t
clinical features of, 718
described, 717
laboratory features of, 718
pathogenesis of, 718
Symptomatic adiposity, 483-484, 483f
Subclinical hypothyroidism, 399-400, 399f
Subclinical hyperthyroidism, 472-473
Subfertility, 461
Succinate dehydrogenase gene mutations, 364-366, 366t
Sulfonylurea(s), in type 2 diabetes management, 611t, 612-613, 625, 746r
Sulfonylurea receptor complex, drugs acting on, in type 2 diabetes management, 611t, 612-613
Sunitinib, in pheochromocytoma/paraganglioma management, 389
Suppression, active, 32f, 33, 35
Supradiaphragmatic liver. See Adrenal gland
SWAN (Study of Women's Health Across the Nation), 458
Sweetener(s), in insulin administration, 620
T
T cell(s), activation of, 29-31, 30f, 31f
antigen recognition by, 30, 30f
pre-, 28-29
tolerance of, 31-35, 32f, 34f
T3. See Triiodothyronine (T3)
T4. See Thyroxine (T4)
Tall stature, 160-161
cerebral gigantism, 160-161
constitutional, 160
endocrine disorders and, 161
familial, 160
nonendocrine causes of, 160
syndromes of, 160-161
Tangier disease, 689
TBG. See Thyroxine-binding globulin
TB-II. See Thyrotropin-binding inhibitory immunoglobulin
T-cell receptor (TCR) genes, 28-29, 29f
T-cell receptor (TCR) genes. See T-cell receptor (TCR) genes
10% tumor. See Pheochromocytoma(s)
Tenofevir, glucose and lipid metabolism effects of, 797, 798r
Teriparatide, in osteoporosis management, 756
Teriparatide, in osteoporosis management, 756
Testicular biopsy, in testicular function evaluation, 403
Testicular determination, genes involved in, 483-484, 483f
Testicular differentiation, 487f-491f
Testicular diabetes syndrome, 516
Testicular failure, primary, hypergonadotropic hypogonadism and, 540
Testicular function control of, 399-400, 399f
disorders of, in AIDS patients, 792-793
evaluation of, laboratory tests in, 401-403, 401f
in male reproductive system, control of, 399-400, 399f
Testicular function, 514-515
Testicular germ cell tumors, 397-399f, 398f, 399f, 399t
measurement of, in testicular function evaluation, 402, 402t
plasma, in women, production-, secretion-, and metabolic clearance rates of, 427, 428t
in puerperium, 566
sex. See Sex steroids
Steroid hormone(s), nongenomic effects of, 25
during pregnancy, 558-559
Steroid hormone receptor resistance syndromes, 25-26
Steroid receptor complex, signaling through, 19, 19f
Steroid receptor family, 18-21, 19f, 20f, 20r
Steroid receptor molecule, structural schematic of, 19f
Steroidogenesis, 287-289, 287f, 290t
adenocorticotropic hormone (ACTH) and, 291, 291f
adenocorticotropic hormone (ACTH) secretion in, 289-290
androgen synthesis in, 289
cholesterol in metabolism of, 289
uptake and synthesis of, 288
interaction synthesis in, 288f, 289-290
corticotropic-releasing hormone (CRH) secretion in, 289-290
intravascular factors in, 432
ovarian, 426-427, 426f, 427r, 428t
progestin effects on, 466, 467f
zones and, 288, 288f
Steroidogenic acute regulatory protein (StAR), 426
Steroidogenic acute regulatory protein (StAR) deficiency, 509-510
Steroidogenic factor-1 (SF-1) gene, in organogenesis of bipotential gonad, 482f, 483
Steroidogenic pathway, components of, 290t
Stiff person syndrome, autoimmune diabetes and, 588-589
Stimulation tests, in hypopituitarism diagnosis, 97
Stimulus-secretion coupling, 229
Stress ACTH and cortisol secretion and, 291 in the elderly abnormal response to, 759 glucocorticoids and, 758, 759f, 760f fetal, during PTB, 564, 564f maternal, during PTB, 564, 564f Struma ovarii, 207 Study of Women's Health Across the Nation (SWAN), 458 Subacute thyroiditis, 207, 211-212, 212f. See also Thyroiditis, subacute Subclinical hyperthyroidism, 201 Subclinical hypothyroidism, 195 Subdermal implants, in contraception, 472-473 Subfertility, 461 Succinate dehydrogenase gene mutations, 364-366, 366t Sulfonylurea(s), in type 2 diabetes management, 611t, 612-613, 625, 746r Sulfonylurea receptor complex, drugs acting on, in type 2 diabetes management, 611t, 612-613 Sunitinib, in pheochromocytoma/paraganglioma management, 389 Suppression, active, 32f, 33, 35 Supradiaphragmatic liver. See Adrenal gland SWAN (Study of Women's Health Across the Nation), 458 Sweetener(s), in diabetes management, 610 Sympathetic nervous system, thyroid hormone effects on, 180 Sympathetic preganglionic nerves, 345-346 Sympathoadrenal activity, regulation of, catecholamine receptors in, 356 Syndrome of complete androgen resistance, 514-515 Syndrome of gonadal dysgenesis. See Gonadal dysgenesis
Syndrome of complete androgen resistance, 514-515 Syndrome of inappropriate antidiuretic hormone (SIADH), 122-126, 122t, 123f, 125t causes of, 124, 125t
clinical syndromes of, 124-125, 125t
described, 122-123, 122t
hyponatremia in pathophysiology of, 123-124, 123f
treatment of, 125-126
pathophysiology of, vs. diabetes insipidus, 127f
Thyroid cancer, 217-224, 217f, 219f-221f, 222r, 223f-224f, 806-808, 806r, 807f, 807t differentiated, 219 course of, 221-224, 222r, 223f-224f management of, 221-224, 222r, 223f-224f prognosis of, 221-224, 222r, 223f-224f surgery for, 806-807, 806r, 807t in the elderly, 743 lymph nodes in, management of, 808, 809f management of, 219-224, 221f, 222r, 223f-224f surgical, 806-808, 806r, 807f medullary, surgery for, 807-808 metastatic, surgery for, 808 molecular biology of, 218-219, 219f, 220f pathology of, 217-219, 217f, 219f, 220f recurrent, surgery for, 808 undifferentiated, surgery for, 808 Thyroid carcinoma, 207-208 Thyroid cell function of, TSH effects on, 176-177 Thyroid dermopathy, pathogenesis of, 199-200, 199f, 200f Thyroid diseases/disorders, 190-214. See also specific disorders in AIDS patients, 787-789, 788t, 789t described, 787-788 medication effects, 788-789, 789t neoplasms, 788 opportunistic infections, 788 prevalence of, 787 thyroid function tests in alterations in, 788, 788t anovulation and, 453-454 autoimmune aspects of, 37-38, 38f in animal models, 38, 38f autoimmune response, 37-38 genes and environment, 37 in the elderly, 738-743, 739f, 740f Graves disease, 198-206 history of, 190-191 hyperthyroidism, 198-209 hypothyroidism, 191-198, 192t, 194f-196f, 197t nontoxic goiter, 209-211 physical examination of, 191, 192f thyroid cancer, 217-224, 217f, 219f-221f, 222r, 223f-224f thyroid hormone resistance syndromes, 208-209 thyroid nodules, 209f, 215-217 thyroiditis, 211-214 thyrotoxicosis, 198-209 Thyroid function tests in AIDS patients with thyroid disorders, alterations in, 788, 788s; 217, 217f, 219f-221f, 222r, 223f-224f in HIV-infected patients, 788, 788t

Thyroid gland, 163-226 abnormalities of, developmental, surgery for, 804 anatomy of, 163, 164f, 165f, 803-804 autoantibodies of, measurement of, 190 autoimmune disease of, spectrum of, 213, 213f autoimmunity of, 183-184 biopsy of, 189-190 biosynthesis of, iodine excess effects on, 169 biosynthetic activity of, 187-188, 187f cancer metastatic to, pathology of, 218 disorders of, 190-214. See also Thyroid disorders: specific disorders dysfunction of, hypertension and, 342 embryology of, 165, 803-804 examination of, 191, 192f tests in biopsy, 189-190 imaging tests, 188-189, 188f, 189f in measurement of thyroid autoantibodies, 190 of peripheral thyroid hormone actions, 190 fetal, 562 functions of acute and chronic illness effects on, 182-183, 182f, 182t aging effects on, 182 control of, 173-181 in fetus, 181 glucocorticoid effects on, 295t, 299 physiologic changes in, 181-183, 182f, 182t pituitary and peripheral deiodination, 177 in pregnancy, 181-182 serum TSH in, 177 tests of, 184-190 serum T4 and T3 measurements, 185-187, 187t serum TSH measurements, 184-185, 185f-186f, 186f in thyroid hormone metabolism assessment, 187-188, 187f thyroid-releasing hormone (TRH) in, 172, 173-175, 174f thyroid-stimulating hormone (TSH) in, 175-176, 175f, 176f thyroid stimulators, 177 thyrotropin in, 175-176, 175f, 176f histology of, 163, 166f imaging of, 188-189, 188f, 189f iodine metabolism in, 164-169, 166f-170f. See also Iodine, metabolism of ionizing radiation effects on, 214-215 maternal, during pregnancy, 559, 560f-561f medullary carcinoma of, 241-242, 241f, 242e. The renowned one-stop guide to the entire field of clinical endocrinology and its scientific underpinnings—now in full color

Features

Greenspan's Basic & Clinical Endocrinology, 9th edition, delivers a succinct, leading-edge overview of the underlying molecular biology of the endocrine system and the latest perspectives on the diagnosis and treatment of specific diseases and disorders. Featuring an enhanced design that includes hundreds of full-color illustrations and clinical photographs, Greenspan's is a true must-have during traditional or integrated courses in endocrinology, endocrinology rotation, or for exam prep in internal medicine and endocrinology.

Greenspan's provides clinically relevant coverage of metabolic bone disease, pancreatic hormones and diabetes mellitus, hypoglycemia, obesity, geriatric endocrinology, and many other diseases and disorders. Supporting this essential material is a handy appendix of normal hormone reference ranges.

Concise, balanced coverage of both scientific and clinical principles

The best source for current concepts in endocrine pathophysiology to aid clinical decision making

Important new approaches to the medical management of endocrine disorders, including therapeutic recommendations

The most practical, current insights into diagnostic testing

More than 270 full-color illustrations and clinical photographs
